When an unlabeled sample comes, it will also be transformed into a vector or said embedding and compute the Euclidean distance among all embedded samples in the vector store. After sorting based on distance, the most similar records will be considered as the target and the label will be assigned to the new data for classification result. For a common RAG implementation, in each retravel, the first five similar, or said the top-5 similar records will be extracted to promise a high hitting rate. In this agent system, top-5 retrieval is applied.

In the next step, the top-5 similar retrieval results will be fed to the LLM with a prompt to warp the prediction with contextual information including background introduction, technical details, and the system configuration to form a fault diagnosis statement in the following format:

Retrieval results: ['fault type1', 'fault type2', ..., 'fault type5']

Diagnosis results: ['fault type']

Inference evidence: [fault type1 with <score1>, ...]

Description of the Fault: This state indicates that…

In this compact diagnosis report, retrieval results will be shown, and the classification is presented as 'fault type'. In addition, inference evidence is the list of scores of the retrieval. In this case, the Euclidean distance is used for an interpretable purpose so that people can understand how the system gets the result. The more similarity between the unlabeled one and the records, the smaller the Euclidean distance will be. The description of the fault is summarized in the given document to explain to human operators clearly what is happening in the system with plain natural language.

In the next step, the brief statement is fed back to the LLM later and the fault type will be recognized for parsing the query for searching the database. For example, if the detected fault is 'spalling' on a ball-screw actuator given in the statement, the LLM can generate highly related several searching strings:

- How to recover spalling damage in ball-screw actuators?
- What are replacement options for ball-screw actuators with spalling damage?
- Replacement options for ball-screw actuators with spalling damage.
- Diagnosing spalling in linear actuators for effective maintenance.

These questions are then used for matching contents in a database, for instance, a general knowledge base e.g. Wikipedia, or a specific expert system with the tool usage capability of the LLM. All the obtained information will be summarized to direct maintenance suggestions and action recommendations in the final step.

4. USE CASE ON LINEAR ACTUATOR FAULT DIAGNOSIS

4.1. Experimental Setup

The time series data[1] is collected on a linear actuator system reported in the paper (Ruiz-Carcel & Starr, 2018). The detailed description including the mechanical components, structure, and parameters of configuration are all illustrated clearly in the article. This paper will not fully reintroduce the actuator system. The dataset acquired during the testing is the starting point of the introduction to the agent system application use case.

At first, the rig was operated under typical working conditions without any malfunctions to gather a substantial volume of data that represents the system's behavior under varying loads and motion patterns. Two distinct motion profiles were examined:

- Trapezoidal profile with a constant speed set point
- Sinusoidal profile with a smooth transition speed

In this paper, only data under the trapezoidal profile is considered for simplicity, the utilization of multiple profiles can be taken into account in future upgrades. The trapezoidal profile is tested for normal and faulty conditions under three distinct load scenarios: 20kgf, 40kgf, and -40kgf. The full motion sequence was repeated 5 times in one working situation under a load as one test. Each test will be conducted 10 times repetitively to generate a dataset with an adequate amount of observation in each case studied. a total of 50 samples, in every scenario analyzed. Furthermore, three distinct mechanical flaws in different degradation levels were intentionally introduced into various portions of the system to simulate modes typically experienced by these types of machines. The faults of the system in this dataset include:

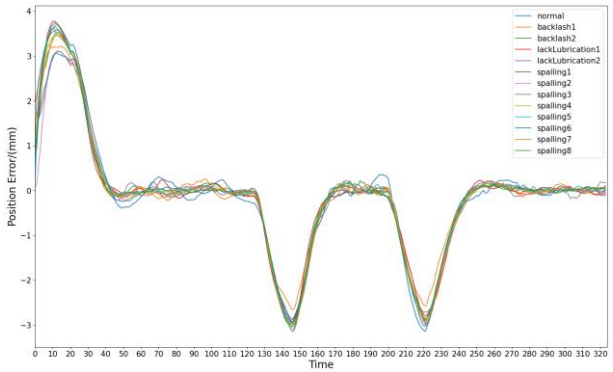
- Spalling from level 1 to level 8 (8 states)
- Lack of lubrication from level 1 to level 2 (2 states)
- Backlash from level 1 to level 2 (2 states)

In short, including the normal and all other flaw states, there are 13 different types and 650 samples in each load circumstance leading to a total of 1950 samples. For evaluation, 20% of all samples will be randomly selected to form a testing dataset, and the remaining samples will be used for constructing the vector store as introduced in section 3.2.

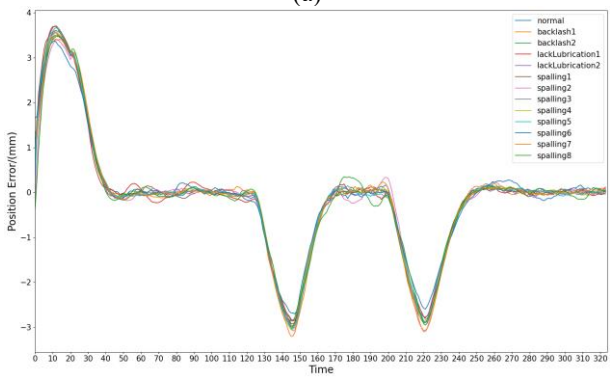
4.2. Implementation

For analysis, samples under all 13 flaws in each load can be visualized in Figure 3 and Figure 4 after using the moving average smoothing with the window size 20 and 15 respectively reported in the paper (Ruiz-Carcel & Starr,

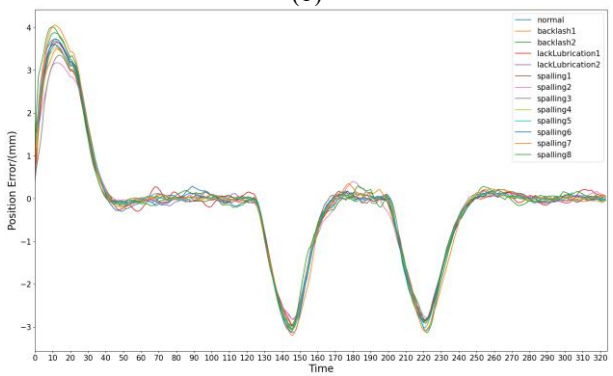
1.The dataset can be found on the link: https://cord.cranfield.ac.uk/articles/dataset/Data_set_for_Data-based_Detection_and_Diagnosis_of_Faults_in_Linear_Actuators_/5097649



(a)

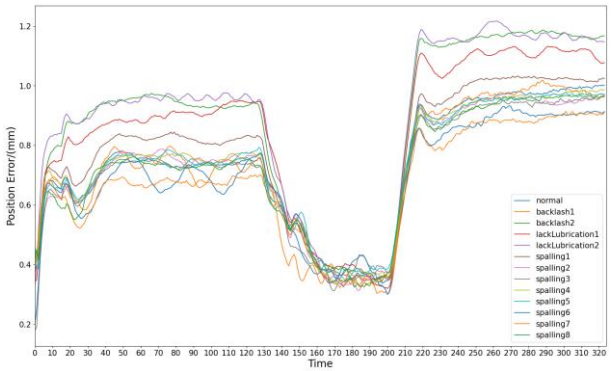


(b)

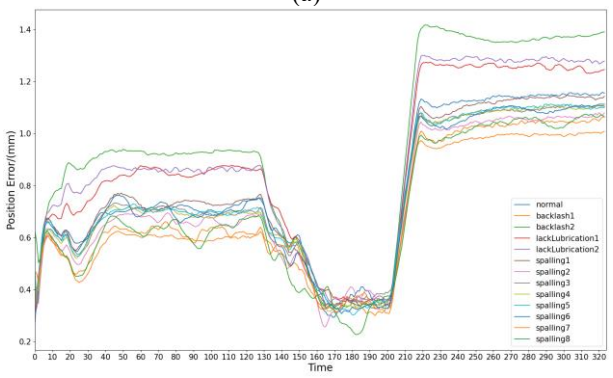


(c)

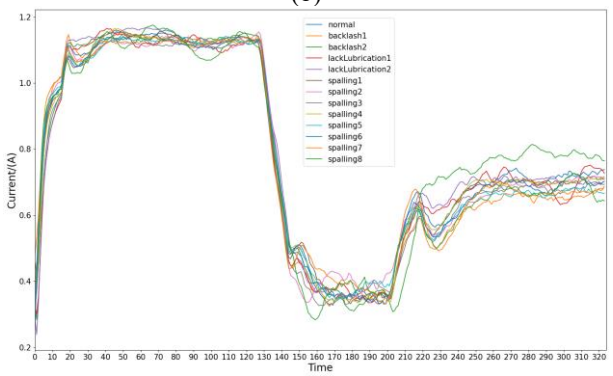
Figure 3. Position error (mm) signals in different fault states under three load conditions after smoothing. (a) 20kgf (b) 40kgf (c) -40kgf



(a)



(b)



(c)

Figure 4. Current (A) signals in different fault states under three load conditions after smoothing. (a) 20kgf (b) 40kgf (c) -40kgf

2018). As shown in Figure 3, no matter in which situation, the position error signals in each fault are distributed too close to be separated from others, while the pattern of current signals is more distinguishable. Therefore, the current signal is the univariant for time series processing in this use case.

Then the univariant time series will be transformed into a vector representation using the ROCKET. To further improve the computational efficiency, a trick from the variant of the ROCKET, namely MiniROCKET (Dempster et al., 2020), is applied. The main difference is that the kernel length usage is fixed to 9, instead of randomly selected from choices {7, 9, 11} in the original ROCKET. By doing this, it can make the result more deterministic. In this use case, the ROCKET is implemented with the Python package called Pyts (Faouzi & Janati, 2020).

Then the vector consisting of features computed from each kernel (20000 dimensions) will be stored together as a vector database for retrieval.

During the validation, prediction accuracy will be tested in three different loading conditions individually and the average value will also be computed. For the diagnosis report

Table 1. Fault classification accuracy under 20kgf, 40kgf, and -40kgf loading situations with different methods.

Method	20kg	40kg	-40kg	Average
InceptionTime (with 100 epochs)	83.8462%	86.0465%	79.2308%	83.0412%
ROCKET + top-1 retriever	63.0769%	75.1938%	46.1538%	61.4748%
ROCKET + ridge classifier	80.7692%	82.1705%	83.0769%	82.0055%
ROCKET + top-5 retriever	83.0769%	91.4729%	81.5385%	85.3628%

generation, given a loading, randomly select a sample from the testing dataset to review the fault statement and the relativity between the generated recommendations and the fault type.

4.3. Results

To summarize the results of the experiment, different methods for the classification based on the ROCKET features with Euclidean distance metric are listed in Table 1. The comparison between the proposed fault detection method is compared with the performance of the strong deep learning baseline method, the InceptionTime. There is an obvious gap between the top-1 precision based on the ROCKET vectorization and the baseline algorithm, only around 60% on average versus the InceptionTime, which is more than 80% over three loading circumstances. However, the computational time can be cut down dramatically by the ROCKET method. For the same historical dataset, for instance, using all 520 samples under 20kg, the result can be obtained with CPU (i7-12700H @3.30Hz) for about 25 seconds, while using the InceptionTime with 100 training epochs, the prediction drawn from scratch requires more than 60 seconds on GPU (Nvidia GeForce RTX 3060 Laptop GPU). Even though the deep learning model can quickly conclude after training, the parameters are fixed once the training is done. When out-of-distribution samples come, the model requires to be updated without forgetting previously obtained knowledge. Retraining or fine-tuning the model in this way is still an ongoing research topic. In contrast, using the ROCKET with the distance-based metric retriever, new samples can be encoded in nearly real-time to query existing vector databases to get the results. Thus, it shows the potential of on-the-fly data processing capability in industrial applications.

One way to further improve the classification accuracy is the incorporation of the ridge or logistic classifiers which can reach a better prediction outcome. As shown in Table 1, the ROCKET feature with the ridge classifier can even surpass InceptionTime in terms of prediction accuracy under the load of 40kg. In addition, an alternative approach is to use a top-5 retriever. By doing this, when one of the retrieved samples indicates the correct label, the prediction can be treated as correct. It can obviously boost the prediction accuracy (up to 85%) compared to any other top-1 classifiers, while with the cost of bringing the noise and uncertainty by considering more historical samples. Some types of faults may have highly similar patterns in the time series data, resulting in their simultaneous extraction as targets in the retrieval process. For instance, the ‘spalling2’ sequence can potentially retrieve ‘spalling1’ or ‘normal’ records from the vector database because their shapelets share great similarities. More importantly, this kind of uncertainty is usually unknown when deploying the system into the real production environment and delivering imprecise information to the users.

This problem can be addressed by refining the fault in a prompt in the brief fault diagnosis statement generation using the LLM. This is meaningful, as in real-life scenarios, system degradation occurs gradually and may not have a clear boundary or change in different malfunctions from a macro perspective. Therefore, two similar types of faults such as ‘spalling1’ and ‘spalling2’ may have nearly identical effects to the system and appear to have the same level of degradation. Thus, they can be regarded as the same fault type when proposing maintenance suggestions in practice. By reassigning these faults with a shared label in the prompt for the LLM, we can shrink the noise introduced by the top-5 retriever and take practical considerations into account while generating maintenance suggestions, which will make them more useful and accurate in real-life situations. This is the first step towards integrating realistic contextual information into the fault diagnosis process, making it more reliable and practical.

After getting the refined fault labels, the LLM (in this case, the GPT-4) can be instructed for multiple query generation, database retrieval, and the final summarization with handcrafting prompts step-by-step as illustrated in Figure 2 (The completed prompt can be found in the project repository listed in the Appendix). This can compile the final diagnostic report for converting the classification result to an actionable plan. Also, the Google Chrome web browser is selected as a general knowledge base used for query searching in this proof-of-concept verification. As a result, Figure 5 shows a part of the generated document indicating that the GPT-4 can give context-aware suggestions to a detected fault.

5. Discussions and Future Work

The use case successfully demonstrates the feasibility of applying the LLM to convert the single prediction to the

Retrieval results: ['spalling7_40_1_5', 'spalling7_40_9_3', 'spalling7_40_10_4', 'spalling7_40_7_3', 'spalling7_40_10_2']
Diagnosis results: Refined fault type1: Obvious fault in spalling
Inference evidence: [spalling7_40_1_5 with 3.1987850822921007, spalling7_40_9_3 with 3.772884271423856, spalling7_40_10_4 with 3.989529120390713, spalling7_40_7_3 with 4.239072661571159, spalling7_40_10_2 with 4.822921558144848]
Description of the Fault: This state indicates that the ball-screw mechanism within the actuator has significant surface damage. This level of spalling affects the actuator's smoothness and efficiency severely. The presence of such a fault suggests that the actuator's performance and longevity are compromised, necessitating immediate attention and likely repair or replacement to restore normal operation.

Searching for:
how to repair spalling damage in ball-screw actuators
best practices for preventing spalling in linear actuators.
replacement options for ball-screw actuators with spalling damage
diagnosing spalling in linear actuators for effective maintenance
cost-effective solutions for spalling damage in actuator mechanisms

Searching results:
Reconditioning the Actuator's Ball Screw: This involves repairing and/or replacing worn or damaged internal components of the actuator.
Replacing Cover Bands: When necessary, the cover bands should be replaced to ensure the proper functioning of the actuator.
Addressing Premature Flaking or Abnormal Damage: This may include looking for the cause of the problem, such as careless handling, excessive misalignment, or insufficient lubrication, and taking measures to prevent machine failure.
Checking for Damage: It is crucial to check for metal fragments that can indicate broken parts and could cause further damage. Also, inspect ball nut threads for damage and replace them if necessary.
Troubleshooting and Countermeasures: Check for specific damage conditions like the raceways of the screw shaft and ball nut and/or the surface of the ball peeling off like scales. Implement countermeasures based on identified causes, such as misalignment or lack of lubrication.
Seeking Professional Help: For severe damage or complex repairs, consulting with or hiring a professional service that specializes in actuator repair might be beneficial. Emergency repair teams can restore damaged ball screws and actuators when time is critical.
Observing Safety and Proper Procedures: Always follow safe handling practices and the manufacturer's instructions to minimize the risk of further damage during the repair process.
…

Repair and Reconditioning Strategies
To address immediate damage and restore functionality, the following steps are vital:
Ball Screw Reconditioning: Essential for repairing or replacing the internal parts of the actuator to improve functionality.
Cover Bands Replacement: Required when these components are damaged to maintain efficiency.
Addressing Underlying Causes: Investigating and rectifying root causes like misalignment or insufficient lubrication to prevent recurrence.
Damage Inspection: Identifying broken parts through inspection is crucial for preventing further damage.
Implementing Countermeasures: Specific damage conditions should be examined and addressed accordingly, emphasizing the correction of misalignment and proper lubrication.
Professional Consultation: Seeking expert advice is recommended for complex or severe damages.
Safe Handling and Procedure Adherence: Following manufacturer guidelines and safe practices is imperative throughout the repair process.
…

In summary, the effective management of spalling in balls crew actuators involves a balanced approach of timely and appropriate repairs, adherence to best practices for prevention, and the consideration of replacement when necessary. The combination of condition-based maintenance and leveraging cost-effective technological solutions plays a crucial role in enhancing the longevity and reliability of these actuators, ultimately ensuring their optimal performance in various applications.

Figure 5. A partial piece of an example document for the randomly selected ‘spalling7’ fault.

prescription of repairing and reconditioning strategies for maintenance decision support. Without any extra training or fine-tuning, and no requirement on manual feature engineering, dataset construction, and rule-based system definition, the LLM can automatically link different (public or private) knowledge sources to compile a reasonable solution after the fault diagnosis based on humans’ intention. Therefore, it improves the functionality of current machine learning as a more proactive and user-friendly production for industrial applications. In addition to the work presented in this paper, there are a few interesting directions that can be explored in the future.

From Univariant to Multivariant: In this study, only univariant time series (the current signal) is considered for the ROCKET feature construction, while the data related to position error has been ignored due to the similar shape patterns in the time domain. This raises the question of how to incorporate multiple time series patterns into the vector store section for fault diagnosis. The ROCKET can be extended to process multivariant time series, and it is a candidate update to the proposed agent system with this capability. In addition, all the introduced methods are in the time domain, how to integrate information from the frequency domain into the proposed framework is another question. By doing this, the time series can be analyzed from different points of view and construct more distinguishable features for retrieval with less amount of data.

From Suggestion to Automation: The report generated after the workflow is expected to offer assistance to people in maintenance planning. A further idea is to explore how to

connect the decision with the action to automate the entire maintenance process from fault detection and identification to system recovery and reconfiguration. A quick idea is to extend the sequentialization of prompts till to execution stage by incorporating external application programming interfaces (APIs) to directly link to actuators for the system maintenance. Recent relevant research is conducted for this purpose such as code-as-policy (Liang et al., 2023). In this way, it is exciting to develop an automated agent that can be self-awareness, self-decision, and self-action to the system health management without too much human intervention. However, it is also important to note that the verification and evaluation from the human side are critical to ensure the final action satisfies all practical and aesthetic requirements in production environment. How the agent can learn from human feedback to further align their performance with our expectations and values is a critical consideration for this direction.

From Ad-hoc Prompting to Long-Term Memory: The prompts used in this paper are yet fully automatically generated. Handcrafting is still needed during the prompting process. For every generation, the GPT-4 should reload all information from scratch and provide suggestions merely limited to the information written in the prompt. Hence, the agent cannot view and refer to any of previous diagnostic reports to improve its performance and keep accumulating experience for future analysis. Some studies show that if an agent can learn from the contents generated by itself, after self-learning on these contents, the performance may improve and even exceed the human level. AlphaGo, for instance, can self-play with enormous virtual games by itself and eventually defeat top-ranked human players (Silver et al., 2017). A further question is whether this similar idea can be applied to the agent. If the prompting and previous diagnosis reports can be stored in long-term memory and retrieved for new situations by the agent itself. It is possible to let the agent itself to prompt itself automatically with lower human supervision. This can cut down the requirement of human knowledge and computation time. Also, it can increase the likelihood of producing more optimal solutions that people have yet to conceive.

From the Given Knowledge Base to Self-Exploration: It is noticeable that automation is built upon a human-defined logic written in prompts. Thus, the basis of automation still relies much on human labor and insight. More importantly, the knowledge base for agent retrieval is also created and mainly maintained by human beings, thus, heavily restricting the potential of machine knowledge discovery. It is then followed by a question of how to allow the machine to acquire knowledge with the self-exploring capability to discover new methods to alleviate human bias and errors in maintenance tasks. Furthermore, it is fascinating to investigate how to enable the agent to contribute to the existing knowledge with human beings together for knowledge acquisition in the system health management domain.

6. CONCLUSION

This paper presents an LLMs agent-based method for elaborating predictions from machine learning to actionable strategy descriptions for maintenance decision support. A use case of linear actuator fault diagnosis is studied with an agent built upon ROCKET time series representation, the concept of RAG, and the prompts chaining technique. By prompting engineering, the LLM agent can recognize the fault and parse highly relevant queries to the database using a search tool, (in this case, the Google Chrome web browser), and summarize the retrieval results to report to human operators. The study demonstrates the possibility of constructing autonomous agents for proactive decision assistance without much human supervision and training and shows how current LLMs can be integrated into the industrial workflow.

ABSTRACT

Due to their location and related complexities, the offshore wind farms (OWF) have higher downtimes and operation and maintenance (O&M) costs compared to their onshore counterparts. Condition monitoring could help in bringing down the O&M costs of OWFs. The pitch system is one of the components most prone to failure. This paper details an approach for enhanced diagnosis of the electric pitch systems especially focusing on the induction motor drives (IMD) in wind turbines. The proposed method uses an extended Park vector approach (EPVA) in conjunction with a convolutional neural network (CNN) to accurately classify the condition of an IMD and localize the faults. The method is validated on data collected from a laboratory setup. The advantage of the proposed approach is that the condition of the IMD can accurately be classified, and faults localized in operating conditions with varying load and frequency without any additional information on the instantaneous operating speed, frequency, or load on the motor drives. This results in a non-invasive diagnostic approach incurring least additional expenses to implement.

1. INTRODUCTION

Offshore wind farms (OWF) have significant potential to contribute towards global energy sustainability. However, they face unique operational challenges, mainly because of their remote locations and harsh marine environments in which they operate. To put this in perspective, while onshore wind farms are attaining a 95% to 97% availability for modern systems Pfaffel, Faulstich and Rohrig (2017), the availability of OWFs is relatively lower and highly variable. The data from earlier offshore wind farms suggest an availability of 67% to 85% (Feng, Tavner, & Long, 2010) with more latest estimates of 80% to 84% (Cevasco, Koukoura, & Kolios, 2021). The limited weather windows for performing necessary maintenance leads to longer downtimes, which explains the gap in operational availability between onshore and offshore wind farms. Furthermore, the operational and maintenance (O&M) costs constitute a significant proportion of the lifetime costs associated with OWFs with estimates ranging from roughly 23% on the lower end (Ren, Verma, Li, Teuwen, & Jiang, 2021) to 30% at the higher end of the spectrum (Hammond, & Cooperman, 2022). This represents a stark contrast to onshore wind farms, where the lifetime O&M costs typically account for approximately 5% (Ren et al., 2021). Thus, implementing condition-based maintenance (CBM) strategies, and hence condition monitoring (CM) become vital in reducing the costs associated with O&M and helps in reducing the downtimes in maintenance activities.

The pitch system of wind turbines is among the components most prone to failures and one that contributes significantly to a non-trivial amount of downtime. The results from ReliaWind project (Wilkinson et al., 2010) indicate the pitch system was responsible for nearly 15% of failures per turbine per year and close to 20% of total downtime hours per year across different manufacturers in their database. A more recent study (Walgern, Fischer, Hentschel, & Kolios, 2023) suggests a pitch system failure rate of 0.54 (hydraulic) and 0.56 (electrical) per turbine per year. Pitch systems are also found to be the most critical subcomponent in the premature failure period (Santelo, De Oliveira, Maciel, & De A. Monteiro, 2022). This makes the pitch system an ideal candidate for enabling CM systems, particularly in OWFs because of the additional costs and downtimes associated with their reactive maintenance.

Although there have been some efforts to develop CM solutions for wind turbine pitch systems, the extent of these attempts has not been commensurate with their critical impact on downtime and failure rates. Cho, Gao and Moan (2016) developed a Kalman filter based method for diagnosing pitch sensor and actuator faults in floating wind turbines based on the NREL 5MW wind turbine model. However, the focus here was not on the incipient fault detection. Several machine learning-based techniques for fault diagnostics in pitch systems are also found in the literature. supervisory control and data acquisition (SCADA) data has been used to detect anomalies in the pitch system in tandem with Isolation Forest based anomaly detection models (Mckinnon, Carroll, Mcdonald, Koukoura, & Plumley, 2021). In this work, the authors developed different models of varying amounts of training data to detect anomalous patterns. Further, they experimented with varying lengths of post-processing window to see how it affects their model. Their results show that their method could notice signs of turbine failure 12 to 18 months ahead. Park, Kim, Dinh and Park (2022) used neural networks to find abnormal operations in the pitch system of a wind turbine. The authors define the abnormal operation for the pitch system using the deviation in the blade pitch angle, where a deviation of more than 4.95° in blade pitch angle was considered abnormal. Wei, Qian and Zareipour (2019) developed a condition monitoring and fault detection system for the wind turbine pitch system using optimized relevance vector machine regression. Their work leverages the SCADA data to detect faults in the pitch system particularly focusing on encoder failures, pitch controller failures, electric motor failures, and slip ring failures. Similarly Chen, Matthews and Tavner (2013) used SCADA data to develop an a-priori knowledge-based ANFIS (APK-ANFIS) model to detect faults in the wind turbine pitch system. The authors identified four critical characteristics features (CF) of pitch faults after analyzing data in the developmental stage of a fault and that immediately after the maintenance has been carried out. These CFs have been used to develop the corresponding APK-ANFIS models, the results from which where aggregated to detect the fault in the pitch systems. Most of the studies in the literature reviewed are effective in detecting faults in the pitch systems, however, they fall short of delineating the fault diagnosis to a subcomponent level.

A subcomponent level diagnosis of faults is essential as it contributes to efficient planning and implementation of maintenance activities, especially in OWFs, where precise planning is paramount. While SCADA data can be effectively used for preliminary fault diagnosis, it is less effective in the subcomponent level fault diagnosis. In this paper, we focus on fault diagnostics for the induction motor drive (IMD) of an electrical pitch system. Subcomponent level fault diagnosis for pitch motor drives using current signature analysis have been previously addressed by the authors (Kandukuri, Karimi, & Robbersmyr, 2016; Kandukuri, Senanayaka, Huynh, Karimi, & Robbersmyr, 2017) , and also proposed a two-stage fault classification scheme based on support vector machine (SVM), for large-scale deployment in OWFs (Kandukuri, Senanyaka, & Robbersmyr, 2019).

The issue with classical current signature-based methods in fault detection is that there is an assumption of steady state operations in terms of speed and load. The wind turbine pitch systems on the other hand are operated intermittently and are exposed to varying speed and load profiles. This means that, either regions of steady state operations must be carefully detected for data acquisition or advanced signal processing techniques are to be employed (Benbouzid, M El Hachemi, 2000; Bhole, & Ghodke, 2021; Liu, & Bazzi, 2017).

Thus, in this paper, a novel solution is proposed by calculating the extended Park vector (EPV) current from the three-phase motor line currents and then extracting the time-frequency representation using Short-Term Fourier Transform (STFT). The three-phase motor line currents for this purpose are observed at varying operating conditions: speed, and load. For detecting the condition of the IMD, these representations are subsequently converted into spectrograms, which are then used to train a convolutional neural network (CNN) for classification of the IMD's condition. CNNs have earlier been reported focusing on diagnostics of gearboxes (Amin, Bibo, Panyam, & Tallapragada, 2023; Gecgel, Ekwaro-Osire, Gulbulak, & Morais, 2021; Jiang, Han, & Xu, 2020), bearings (Choudhary, Mian, & Fatima, 2021; Lu et al., 2023; Ruan, Wang, Yan, & Gühmann, 2023; Wang, Mao, & Li, 2021; Yuan, Lian, Kang, Chen, & Zhai, 2020), and IMDs (Junior et al., 2022; Khanjani, & Ezoji, 2021; Kumar, & Hati, 2022; Lee, Pack, & Lee, 2019; Skowron, Orlowska-Kowalska, Wolkiewicz, & Kowalski, 2020). However, most of these works depend on vibration sensors, or are specific to one type of fault. Further, most of them assume constant supply frequency and load. Skowron et al. (2020) warrants a special mention as they use motor line currents to detect faults in an IMD. They normalize these currents to create a vector that is then reshaped to form an RGB matrix corresponding to each of the three phases. While they were able to detect and differentiate between various kinds of stator faults including insipient faults, their work still deals with one kind of fault within the induction motor.

Thus, what differentiates this work from other works are as follows:

1. Fault diagnostics of IMDs operating under varying speed, frequency, and load conditions without needing any additional data on these parameters.
2. Beyond identifying a single type of fault, the proposed approach is capable of fault localization using extended Park vector approach (EPVA) in conjunction with a CNN classifier.

3. The proposed approach, through EPVA, negates the need for additional sensors to be deployed. This makes it an economically viable option for wind turbines without vibration sensors, especially those that are nearing their end of designed life. Because while vibration sensor-based diagnostics are more widely applicable, they are expensive (Trajin, Regnier, & Faucher, 2010) compared to motor current signature analysis (MCSA).
4. Since continuous monitoring of the WT pitch system is not required in this method, intermittent snapshots of the three-phase currents are sufficient for reliable diagnosis. Thus, reducing the data transmission load from each turbine.
5. The proposed algorithm need not be implemented at each turbine, the proposed approach can contribute towards farm-level health management.

While EPVA and similar MCSA methods have earlier been used for IM diagnosis and prognosis (Erik Leandro, Levy Ely De Lacerda De, Jonas Guedes Borges Da, Germano, & Luiz Eduardo Borges Da, 2012), to the best of authors' knowledge this is the first time the diagnostics of the induction motor has been fully automated while using spectrogram of the EPVA in conjunction with a deep learning based classifier. The rest of the paper is organized as follows. In section 2, the induction motor faults under consideration and the reason for selecting these are discussed. This is followed by a brief explanation of theories of EPVA and CNNs in section 3. Section 4 details the laboratory setup used to collect the necessary data and Section 5 discusses the methodology of research and details about the CNN based classifier. Results from the classification scheme are discussed in section 6. The paper is concluded, and possible future directions are briefly highlighted in section 7.

2. IMD FAULTS CONSIDERED

Despite being robust, induction motors are not immune to failures. Stator faults and bearing faults are among the most reported components contributing to the total failures in an IMD (Benbouzid, M., 1999; Benbouzid, M. E. H., & Kliman, 2003; Singh, & Ahmed Saleh Al Kazzaz, 2003; Thorsen, & Dalva, 1995) as shown in Figure 1. Nearly half of the total failures are the result of stator faults, making it one of the most important types of faults to be detected. This is followed by bearing faults which account for almost one-third of the total failures. Compared to those, a menial 10% of the failures are accounted for by rotor faults. These faults occur generally because of drive-generated harmonics, poor ventilation at low-speed operation, and abrupt load variations.

Thus, in this study, we have considered the two components contributing the most to the total IMD failures: stator fault and bearing fault. A future study may be done including rotor bar faults such as different severities of broken rotor bar (BRB) faults.

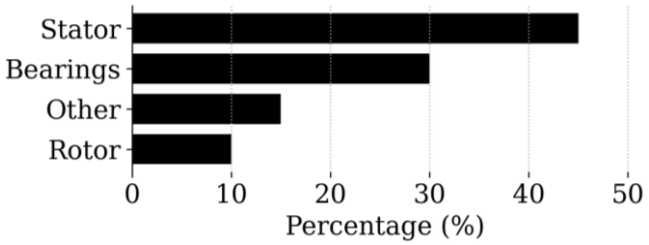

Figure 1. Distribution of IMD faults

3. THEORY

3.1. Extended Park Vector (EPV) Analysis

The theory behind using MCSA for IMDs revolves around the concept that an induction motor, while operating in healthy state, is symmetrical across the three phases. A fault in the motor disrupts this symmetry causing a periodically recurring asymmetry in the motor's operational characteristics. This periodic recurrence manifests as a particular frequency in the current known as "fault frequencies" or "signature frequencies."

These fault frequencies arise due to the interaction between the motor's electrical and mechanical components influenced by the fault. For example, a stator fault, such as insulation failure, due to short circuits between the stator windings, or phase imbalance, causes an asymmetric distribution of electromagnetic fields (EMF) within the motor. This asymmetry causes variations in the magnetic effect on the rotor resulting in irregular rotor motion. The interaction between the EMF and the rotor's motion produces specific frequency components in the motor's currents called "stator fault frequencies". These stator fault frequencies are then reflected in the MCSA as harmonics of the fundamental frequency, or appearance of specific sidebands around the fundamental frequency and its sidebands. In the case of a bearing fault, which can occur because of physical damage, wear and tear, inadequate lubrication, or external factors, leads to mechanical vibrations which modulate the EMF within the motor affecting the air gap flux density. This introduces specific frequencies in the motor's current signature called "bearing fault frequencies". The specific frequency of the bearing fault depends on several factors like bearing design, motor speed, and the nature of the fault. These signature frequencies are then used to diagnose the faults in MCSA.

EPV analysis builds upon the foundational principles of MCSA and has been used for a while now in diagnosing motor electrical faults (Cardoso, Cruz, & Fonseca, 1997). The direct (i_d) and quadrature (i_q) axis currents are initially calculated as a function of three phase motor currents (i_a, i_b, i_c) as follows:

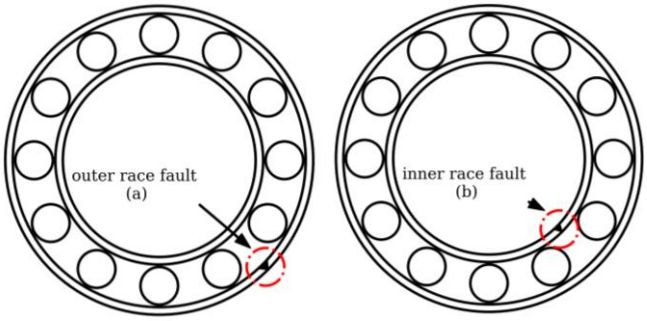

Figure 2. Schematic diagram of (a) an outer race fault, and (b) an inner race fault in a rolling element bearing.

$$i_d = \left(\sqrt{2}/\sqrt{3}\right) i_a - \left(1/\sqrt{6}\right) i_b - \left(1/\sqrt{6}\right) i_c \quad (1)$$

$$i_q = \left(1/\sqrt{2}\right) i_b - \left(1/\sqrt{2}\right) i_c \quad (2)$$

The extended Park vector (i_p) is then calculated as follows:

$$i_p = \left|(i_d + j i_q)\right| \quad (3)$$

Where, j is the imaginary unit defined as $j^2 = -1$.

When a stator turn fault (STF) occurs due to shorting between the phase windings, the three phase currents become imbalanced and the ideal values for direct and quadrature axis currents mentioned in Cardoso et al. (1997) doesn't hold anymore. The result is that the stator turn fault can be identified only using the spectral component at twice the supply frequency, f_s (Sahraoui, Zouzou, Ghoggal, & Guedidi, 2010) in the spectrum of i_p:

$$f_{STF} = 2f_s \quad (4)$$

Figure 2 shows the schematics of an outer race fault (a), and an inner race fault (b) in a rolling element bearing. A bearing fault, as discussed earlier, causes spectral components at different frequencies as determined by bearing design, motor speed, and the nature of the fault (e.g., faults on the inner race, outer race, ball spin, or cage defects). This results in three additional spectral components in the spectrum of i_p along with the fundamental component of the power supply (Zarei, & Poshtan, 2009) as:

$$f_{BRG} \in \{f_v, 2f_v, |2f_v - f_s|\} \quad (5)$$

For an outer race fault, as shown in Figure 2 (a), the characteristic vibration frequency, f_v, can be estimated using the following equation (Zarei, & Poshtan, 2009):

$$f_v \approx 0.4 N_b f_r \quad (6)$$

where N_b is the number of rolling elements in the bearing, and f_r is the shaft rotational frequency.

Even though these frequencies (f_{STF}, *and* f_{BRG}) can reliably be used for fault diagnosis in short time windows of constant operation, this fails in the case of a variable load and frequency because of the changes in the shaft rotational frequency, f_r, and supply frequency, f_s.

Characterizing the time-frequency response of the extended Park vector, i_p is critical in EPVA. The short-term Fourier transformations (STFT) is used to decompose the Park vector into its time-frequency components, which offers an in-depth view of how these frequency components evolve over time. This level of detail is more suitable for diagnosing the faults within motors operating under non-stationary conditions.

STFT is a special case of Fourier transforms where the Fourier transform is applied in series to smaller slices of the signal. The assumption here is that for a shorter time window, the original non-stationary signal becomes stationary. The STFT of a non-stationary signal $y(t)$ can be estimated by discretizing the continuous-time signal to a discrete-time signal, $y(n)$, where n is the discrete time indices. Then the discrete STFT is calculated for the discrete-time signal as:

$$Y(\omega, b) = \sum y(n) w(n - b) e^{-j\omega n} \quad (7)$$

where $w(.)$ is the windowing function and b is the window-shifting time constant. The calculation of STFT is done using a fixed-size window, which means that if the window is longer, frequency resolution is better at the expense of time resolution and vice versa for shorter windows. Thus, deciding a window length for the STFT operation is crucial in accurately extracting the desired time-frequency information (Oppenheim, 1999) and thereby diagnosing the motor condition.

3.2. Convolutional Neural Networks (CNN)

Though there has been some precedents in computer vision research inspired by natural vision, CNNs developed by Lecun et al. (1989) were instrumental in the development of computer vision at scale. CNNs are similar to artificial neural networks or "vanilla neural networks" in that they are made up of neurons. However, CNNs generally consists of three types of layers, namely convolutional layer, pooling layer, fully connected layers, and an output layer.

The convolutional layers are used to learn a feature representation from the inputs provided to create feature maps. In this layer, a learned kernel convolves with the input producing a feature map, the result of which is then passed on to an elementwise non-linear activation function to get the activation maps. Each element of the feature map is connected to a local subset of neurons in the previous layer or the input. The feature map element at (i, j) in the k^{th} feature map of the l^{th} layer can be calculated as:

$$z^l_{i,j,k} = \boldsymbol{w}^l_k \boldsymbol{x}^l_{i,j} + b^l_k \quad (8)$$

where $\boldsymbol{w}^l_k$ and b^l_k are the weight vector and bias term of the k^{th} filter of the l^{th} layer, respectively. $\boldsymbol{x}^l_{i,j}$ is the local subset of

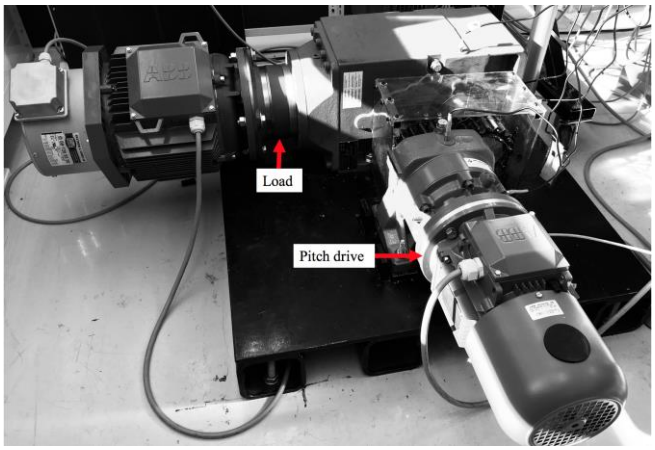

Figure 3. Laboratory setup for motor diagnostics

input to the convolutional layer centered at (i, j). An activation function such as rectified linear unit (ReLU) later introduces non-linearities helping the network to learn non-linear features.

The pooling layer, often placed between two convolutional layers, introduces shift-invariance to the feature maps. This is achieved by reducing the resolution of the feature maps. Usually, average pooling and max pooling layers are used depending on the task at hand. Higher-level feature representations are extracted eventually by stacking several convolutional and pooling layers.

One or more fully-connected layers usually succeed in CNNs aiming to achieve high level reasoning (Simonyan, & Zisserman, 2014). The last layer of CNNs is an output layer, which uses a task appropriate activation function such as sigmoid function for classification or ReLU for regression problems.

4. Laboratory Setup

Figure 3 shows the laboratory setup built to study the common faults in the pitch motor drives and planetary gear boxes of a wind turbine. A 1.1 kW, three-phase induction motor served as the test motor. Another 2.2 kW three-phase induction motor was used to supply the loads in the setup through a bevel-planetary-helical gearbox. Both the motors were driven by commercial field-oriented control (FOC) drives. Further details of the setup can be found in Table 1. The selection of the current sensor for this setup has been influenced by the desire for a common industrial sensor which is economical for installation on multiple units. Further, the overall frequency content of the signal has been tested over ideal power source and showed excellent signal-to-noise ratio. The speed and torque references for both test and load motors are provided to their respective FOC drives through a PC.

Table 1. Details of the test setup

Test Motor	
IM Rated Power	1.1 kW
IM Rated Speed	1420 rpm
IM Rated Torque	7.2 Nm
Current Sensor	
Model	LEM LTS-6NP
Primary nominal RMS current, I_{PN}	6 A
Accuracy @ I_{PN}, 25° C	±0.2
Data Acquisition	NI USB DAQ
Acquisition rate	15 kHz

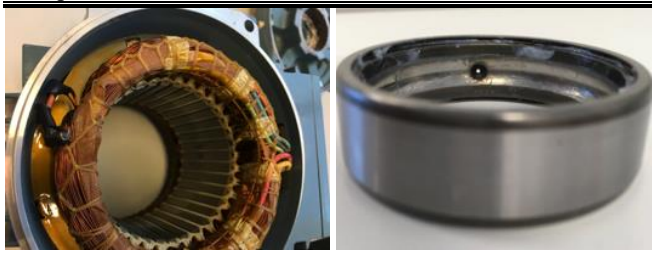

Figure 4. Seeded motor faults: stator turns fault (left), bearing fault (right).

The STF, and BRG faults were artificially seeded as shown in Figure 4. The STF was seeded by shorting 10% of a phase winding, while BRG was seeded as an outer race fault with a diameter of a ≈ 2mm through hole.

5. Methodology

Initially, the test motor was run in healthy condition, across a range of speeds varying between 850 rpm and 1420 rpm. At the same time, the loads were varied between no-load and full-load conditions at random to simulate the random loading on the wind turbine's pitch system. The speed interval was used after consulting the motor loadability curves to ensure that the motor reaches neither an overload condition nor stall condition because of the random loading. The randomness of operational conditions was ensured using different random number generators with seeds refreshed every thirty second interval. The three-phase currents were recorded as snapshots of 30 seconds each. Similarly, records were made for the motor operating in faulty conditions as mentioned in Section 4. A total of nearly a thousand minutes of data was collected from the test setup for this purpose.

Further, the Park vector, i_p and its STFT has been calculated for each of the recorded snapshots using equations (1), (2), (3), and (7). Examples of the STFT results from each of the three conditions: healthy, STF, and BRG is shown in Figure 5–7. Classical signal processing methods to detect faults from the STFT of the Park vector may fail here, however, from the figure, it can be noted that there is an increase in frequency content around 100 Hz in the STF condition, which is around $2f_s$ (Figure 6). A similar increase in frequency content can

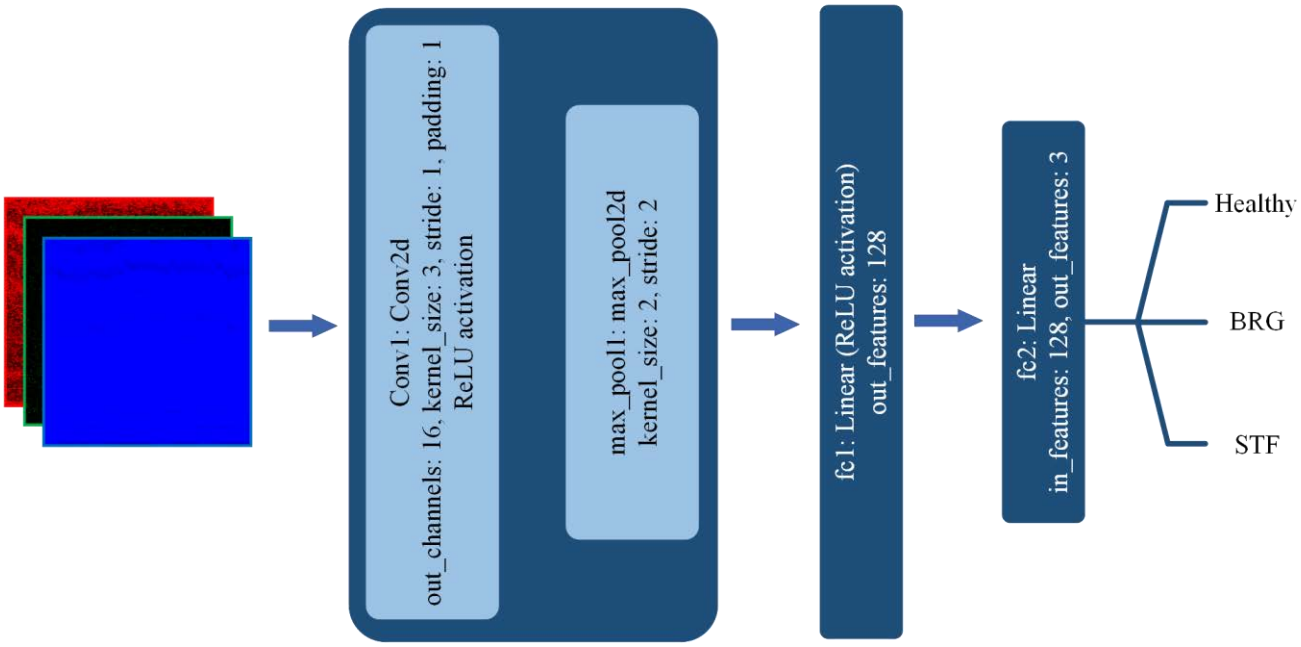

Figure 8. CNN architecture

also be observed in the case of BRG faults at around 500 – 600 Hz (Figure 7), which is distinct from the healthy case (Figure 5).

Around 2100 STFT images containing the time-frequency information associated with the operation of the motor in the three different states mentioned in the previous paragraph were then used to develop a CNN model. The entire dataset of images was split at random and 70% of the data was used in training while 15% each was used for validation and testing purposes. The STFT spectrum of the current, i_p, is obtained as an RGB image, which was then resized to 360 x 360. The architecture of the CNN that was developed for fault classification is shown in the Figure 8. The architecture consists of a convolutional layer followed by a max pooling layer, the output from which is flattened and forwarded to a fully connected layer. This fully connected layer learns high-level features from the flattened inputs. The final layer serves as the classifier, which takes the output from the fully connected layer to classify the image into one of the three conditions previously mentioned.

The CNN was trained on a system equipped with an Intel Xeon processor, NVIDIA Tesla V100-SXM3-32GB GPU on Python 3.10 using PyTorch 2.2. The model was trained over hundred epochs with a batch size of 256 and a learning rate of 10^{-3}. The learning rate was arrived at after narrowing down the value by using a learning decay scheduler. Early stopping and L2 regularization were employed to mitigate the possibility of model overfitting to the training dataset. The early stopping algorithm checks for any improvements in the validation loss and stops training if no improvement is

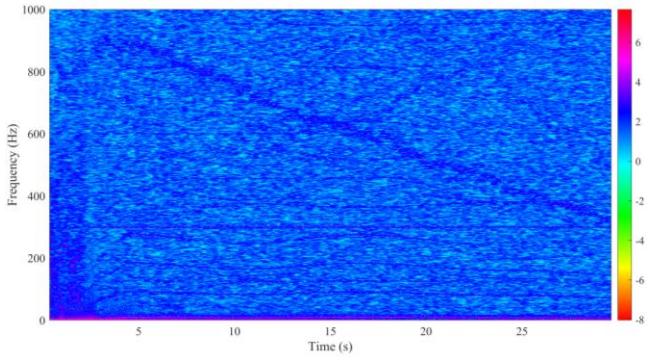

Figure 5. STFT of a Park vector, i_p, of motor working in healthy condition.

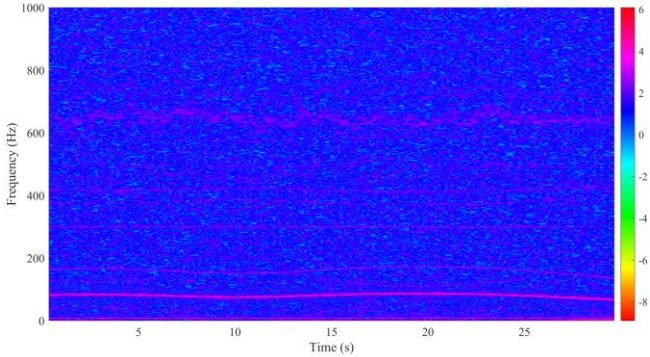

Figure 6. STFT of a Park vector, i_p, of motor with STF fault.

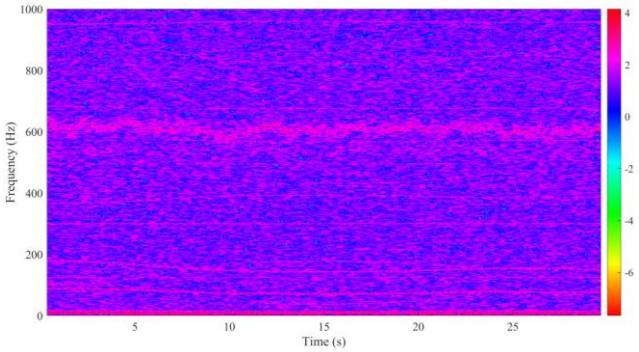

Figure 7. STFT of a Park vector, i_p, of motor with BRG fault.

observed for 25 epochs. Since this is a multi-class classification problem, the cross entropy loss was used as the loss function and the Adam optimizer (Kingma, & Ba, 2014) was selected for optimizing the loss function. At the end of each epoch the model was validated with the validation dataset and results recorded, which is detailed in the following section.

6. Results and Discussions

Figure 9 and Figure 10 illustrates the feature maps generated after the convolutional layer and max pooling layers of the trained CNN model in BRG and STF fault conditions, respectively. It is clear from the figures that the convolutional layer followed by the max pooling layer effectively identifies the specific locations within the spectrum associated with each fault condition.

After training, the model was tested on a previously unseen test dataset. Inference on GPU takes slightly higher than 17 seconds and that on CPU takes approximately 36 seconds to classify the 320 snapshots. Table 2 shows the confusion matrix of the model's performance on this dataset. The STF fault was the most accurately classified among the three

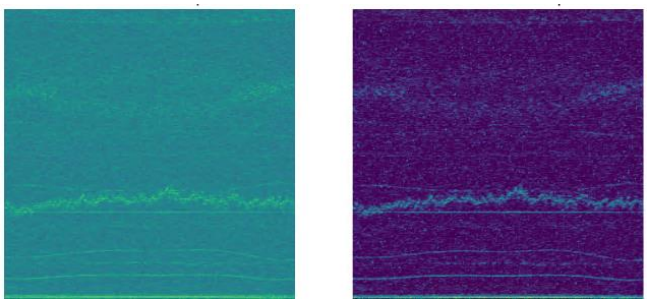

Figure 9. One of the feature maps after convolutional layer (left) and max pool layer (right) in BRG fault condition.

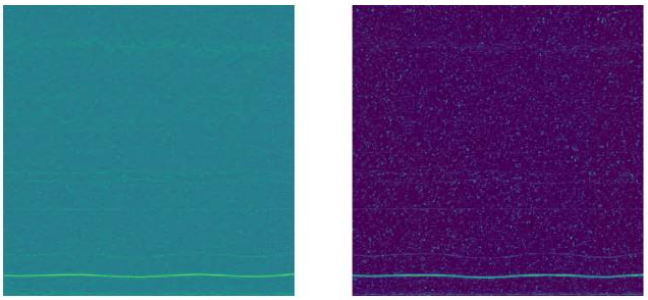

Figure 10. One of the feature maps after convolutional layer (left) and max pool layer (right) in STF fault condition.

Table 2. Confusion matrix of the model performance on test data.

	Healthy	STF	BRG	Percentage
Healthy	94	0	3	96.9%
STF	0	109	0	100%
BRG	4	0	110	96.5%

conditions with 100% of the cases being correctly identified as such. On the other hand, the model makes some mistakes while classifying the healthy and BRG fault conditions.

Table 3 shows the performance of the developed model in classifying the three motor conditions. The model has an overall accuracy of 97.8%. Similarly high values of precision, recall, and F1-score are observed when the model encounters the test dataset. Such high numbers might raise the suspicion of overfitting or data leakage, which is the case where the test dataset was inadvertently used in training the model. Early stopping and L2 Regularization help in preventing overfitting of the model on the training dataset while the entire data pipeline has been verified manually to ensure that there is no data leakage. Thus, the performance as shown in Table 3 highlights that the model has effectively learned the underlying pattern and can classify the three motor conditions effectively. Further, these high values in performance also indicate that the model is sufficiently complex to match the problem's complexity.

Table 3. Performance of the CNN model on test dataset.

Metric	Healthy	STF	BRG	Overall
Accuracy	-	-	-	97.8%
Precision	95.9%	100%	97.3%	97.7%
Recall	96.9%	100%	96.5%	97.8%
F1-Score	96.4%	100%	96.9%	97.78%

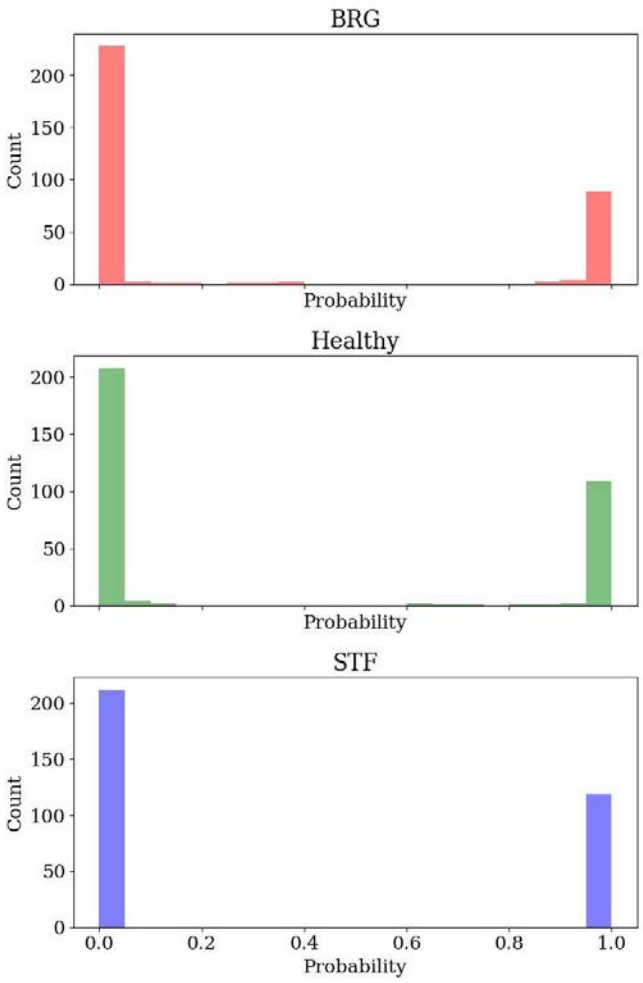

Figure 11. Histogram of predicted probabilities for each motor condition in test dataset.

To further explore the inference pattern, a histogram of the predicted probabilities was drawn across different classes as shown in Figure 11. Histogram of predicted probabilities illustrates the confidence of the model in classification to different classes. The pronounced skewness towards the extremities of the probabilities indicates a high level of certainty in classification. This is especially true for the STF fault where the model has a hundred percent confidence if a given snapshot is indicative of an STF fault (probability = 1.0) or not (probability = 0.0). On the other hand, the model is slightly less confident in identifying the healthy condition or the bearing fault as evidenced by relatively higher variance in the model's predicted probabilities.

7. Conclusion

In this paper, we have successfully developed and demonstrated a method for enhanced diagnostics for IMDs used in wind turbine pitch system. In addition to detecting the operational state of the motor (healthy/faulty), this approach also helps in localizing the fault to the stator or the bearing of the IMD. The presented approach uses the extended Park vector approach (EPVA) and short-term Fourier transforms (STFT) to extract the time-frequency information from the three-phase induction motor currents taken as 30-second snapshots. These snapshots are then classified using a convolutional neural network. The high accuracy in classification of the conditions indicates that the model can accurately diagnose the state of the IMD in question.

The advantage of the proposed method is that CNN requires only snapshots of 30 seconds each to determine the state of operation. Other than the sampling frequency, no additional information is required about the loading conditions or the frequency of operation, making it a suitable candidate for farm-level implementation. Further, as continuous monitoring is not required in this approach, it is ideal for WT pitch systems that operate intermittently. Since only 30-second snapshots of motor currents are the requirement, the data transferred from the WTs will be minimal.

The results presented here are tested on different motors of the same type, further validation of the methodology over different test motors could help strengthen the study in future. Additionally, at present two different fault conditions have been studied, more faults like broken rotor bar (BRB) faults or different stages of the STF could also be included in future works.

While the CNN classifier can be used to determine the motor condition accurately, the bottleneck in this methodology is the STFT calculations, which are computationally intensive. Thus, as a next step, the authors intend to test different ML paradigms to bypass the STFT calculations and directly detect these conditions from the Park vector current, i_p.

BIOGRAPHIES

Manuel S. Mathew is a PhD Research Fellow at the Information and Communication Technology department at the University of Agder, Norway. His interest is in the application of artificial intelligence in renewable energy systems particularly focusing on prognostics for wind farms. He completed his master's degree in Renewable Energy in 2021 from the University of Agder. In addition, he also holds a master's degree in systems engineering by research from the University of Brunei Darussalam. He did his bachelor's degree in electrical and electronics engineering from the Mahatma Gandhi University, India.

Surya Teja Kandukuri is a Senior Scientist at NORCE. He holds a part-time position as a researcher at University of Agder, Grimstad, Norway. He obtained his PhD in condition monitoring from the University of Agder in 2018. He has over 12 years of experience in industrial research within aerospace, energy, marine and oil & gas sectors, developing condition monitoring solutions for high-value assets. He received his master's degree in systems and control engineering from TU Delft, The Netherlands, in 2006 and bachelor's in electrical engineering from Nagarjuna University in India in 2003.

Christian W. Omlin has been a professor of Artificial Intelligence at the University of Agder since 2018. He has previously taught at the University of South Africa, University of the Witwatersrand, Middle East Technical University, University of the South Pacific, University of the Western Cape, and Stellenbosch University. His expertise is in deep learning with a focus on applications ranging from safety to security, industrial monitoring, renewable energy, banking, sign language translation, healthcare, bio conservation, and astronomy. He is particularly interested in the balance between the desire for autonomy using AI technologies and the necessity for accountability through AI imperatives such as explainability, privacy, security, ethics, and artificial morality for society's ultimate trust in and acceptance of AI. He received his Ph.D. from Rensselaer Polytechnic Institute and his MEng from the Swiss Federal Institute of Technology, Zurich, in 1995 and 1987, respectively.

Graph Neural Networks for Electric and Hydraulic Data Fusion to Enhance Short-term Forecasting of Pumped-storage Hydroelectricity

ABSTRACT

Pumped-storage hydropower plants (PSH) actively participate in grid power-frequency control and therefore often operate under dynamic conditions, which results in rapidly varying system states. Predicting these dynamically changing states is essential for comprehending the underlying sensor and machine conditions. This understanding aids in detecting anomalies and faults, ensuring the reliable operation of the connected power grid, and in identifying faulty and miscalibrated sensors. PSH are complex, highly interconnected systems encompassing electrical and hydraulic subsystems, each characterized by their respective underlying networks that can individually be represented as graph. To take advantage of this relational inductive bias, *graph neural networks* (GNNs) have been separately applied to state forecasting tasks in the individual subsystems, but without considering their interdependencies. In PSH, however, these subsystems depend on the same control input, making their operations highly interdependent and interconnected. Consequently, hydraulic and electrical sensor data should be fused across PSH subsystems to improve state forecasting accuracy. This approach has not been explored in GNN literature yet because many available PSH graphs are limited to their respective subsystem boundaries, which makes the method unsuitable to be applied directly. In this work, we introduce the application of *spectral-temporal graph neural networks*, which leverage self-attention mechanisms to concurrently capture and learn meaningful subsystem interdependencies and the dynamic patterns observed in electric and hydraulic sensors. Our method effectively fuses data from the PSH's subsystems by operating on a unified, system-wide graph, learned directly from the data, This approach leads to demonstrably improved state forecasting performance and enhanced generalizability.

1. INTRODUCTION

In power grids, pumped-storage hydropower plants (PSH) are well-established for large-scale energy storage due to their efficiency, scalablilty and flexibility. In this role, these plants dynamically respond to potentially large fluctuations in grid demand. In the transition towards smart grids, PSH sensor data is collected via *wide area measurement systems (WAMS)* (Pagnier & Chertkov, 2021a) and is stored in centralized *energy management systems (EMS)*. By processing the aggregated WAMS data, modern EMS provide crucial functionalities for PSH operators such as load forecasting, real-time monitoring, distribution and demand-side management, and various decision support tools aimed at increasing efficiency and sustainability. To enhance system reliability, EMS implement anomaly and sensor fault detection based on short-term forecasting and state estimation, playing a pivotal role in preventing failures that could lead to widespread power grid outages and significant economic losses. However, the dynamic operation of the PSH and the vast amounts of data transmitted by the WAMS significantly complicate the task. In the PSH environment, conventional state estimation is often ineffective because the computation can take several minutes (Li, Pandey, Hooi, Faloutsos, & Pileggi, 2022). This delay leads to a rapid divergence between the most recent and the previously used system state for the estimation, resulting in numerous false-positives when applied to anomaly detection. Consequently, it becomes challenging to maintain a comprehensive overview of the system's health and performance. As a solution, deep-learning-based short-term state forecasting has recently been applied, which offers significantly faster processing times and holds the potential to benefit from the additional data increasingly collected at a high sampling rate (Kundacina, Cosovic, & Vukobratovic, 2022).

Developing deep-learning-based state forecasting for PSH is particularly challenging. These challenges stem from the necessity to accurately represent two distinct physical domains within the PSH: the hydraulic and electrical systems. Al-

though these domains are mechanically interconnected by electromagnetic generators, they are traditionally modeled independently in mechanical engineering. This division mainly stems from the distinct dynamics governing each subsystem. It is, therefore, challenging to model hydraulic and electrical domains simultaneously. Nonetheless, considering the direct causal relationship between the systems – wherein kinetic energy is transformed to electric energy – we hypothesize that fusing data from both subsystems, which operate under a unified control input, can significantly enhance state forecasting.

To address the challenge of fusing electric and hydraulic data, we posit that both subsystems of the PSH consist of extensive networks, which are coarsely monitored with sensors that can be represented in the non-Euclidean graph domain. By operating on this more effective graph representation, which can capture biases given by the PSH system architecture and homophily biases, addressing the phenomenon that sensor measurements tend to be connected with "similar" or "alike" others (Ma, Liu, Shah, & Tang, 2023), *graph neural networks* (GNNs) have recently gained significant attention. When a graph is available, GNNs have been effectively applied in key applications to (hydro) power plants (Liao, Bak-Jensen, Radhakrishna Pillai, Wang, & Wang, 2022) and in the broader power grid environment. However, these methods depend on the availability of apriori graphs, derived from PSH's electrical and hydraulic network diagrams. Therefore, their applicability is limited by the fact that, although the underlying network structure of both electric and hydraulic subsystems of a PSH can be modeled as a graph, network diagrams for PSH exist typically only separately for each subsystem. Consequently, most graph-based methods are confined within the boundaries of their respective systems. To overcome this limitation, we propose learning a PSH sensor graph from latent dependencies in the data. While it has previously been demonstrated that graph structures can be efficiently learned from data, this approach remains unexplored in the context of hydropower plants. In light of this, inspired by (Cao, Li, Ma, & Tomizuka, 2021), we propose using *spectral-temporal graph neural networks* (STGNN) to learn a latent correlation graph structure across the entire PSH asset for the fusion of electric and hydraulic data, leveraging the self-attention mechanism.

Compared to numerical simulation, our data-driven GNN-based methodology is computationally inexpensive and does not require expert knowledge while maintaining interpretability, due to the accessibility of the learned graph. Our proposed approach can be easily transferred to different PSH assets without any calibration. To the best of our knowledge, there is no other work on data-driven electric and hydraulic data fusion for PSH using graph neural networks.

To summarize, in this work, we introduce the application of attention-based graph neural networks to effectively learn intra- and interdependencies between the subsystems' sensors to enhance the short-term state forecast in the pumped storage power plant (PSH) environment. We tackle several challenges when applying state forecasting to PSH:

- In line with the dynamic operation of the PSH, the dynamic behavior of sensors adds complexity to the forecasting. We propose a *spectral-temporal graph neural network* (STGNN) that effectively captures these patterns by incorporating the PSH' underlying structural and homophily biases, such as load patterns that are reflected across sensor measurement sites.
- State forecasting in the PSH environment depends strongly on environmental parameters, such as temperature, daily load profiles, and power grid customer-related factors, which cannot be modeled in numerical simulations (Lin, Wu, & Boulet, 2021). In contrast, our STGNN is able to learn these factors from data.
- The PSH is a spatially distributed complex system that spans across the hydraulic and electric domains. We propose a graph learning module that learns a unified graph representation across the hydraulic and electrical subsystems from latent dependencies in the data.
- We assess the performance of our method on a multivariate PSH dataset containing 58 signals, showcasing the dynamic operation of the asset.

The reminder of this paper is organized as follows: Sec. 2 reviews relevant literature that focuses on graph-based deep learning and data fusion. Sec. 3 introduces our STGNN approach. In Sec. 4, we discuss the case study conducted on a Swiss PSH plant, including the experimental and training setups. In Sec. 5, we present our results. Finally, Sec. 6 concludes this work and outlines future steps.

2. Background and Related Work

Conventional machine learning applied to power systems have primarily focussed on linear regression models and recurrent neural networks (Zheng, Xu, Zhang, & Li, 2017). These methodologies continue to be effective and provide competitive results, particularly in areas like short-term load forecasting (Guo, Che, Shahidehpour, & Wan, 2021) and daily peak-energy demand forecasting (Kim, Jeong, & Kim, 2022). Since their introduction, GNNs (Bronstein, Bruna, LeCun, Szlam, & Vandergheynst, 2017) have been applied to many tasks in power systems. By now, graph-based deep learning has become a well-established method for analyzing power system data, thanks to its ability to include structural and homophily biases that cannot be modeled conventionally. Message-passing GNNs have been successfully applied to state estimation (Kundacina et al., 2022), and power flow estimations (Ringsquandl et al., 2021). The same tasks have also been addressed using *graph convolutional neural networks*

(GCN) (Fatah, Claessens, & Schoukens, 2021). In the broader power-grid environment, GNNs are also used for wind speed forecasting in renewable energy (Liao, Yang, Wang, & Ren, 2021). Additionally, GNN-based state forecasting was used in a range of downstream tasks in several previous research studies, including graph-based early fault detection for IIoT systems (Zhao & Fink, 2024), anomaly detection in the electrical grid (Li et al., 2022), fault diagnosis for three-phase flow facility (Chen, Liu, Hu, & Ding, 2021), predicting dynamical grid stability (Nauck et al., 2022), and physics-informed parameter and state estimations (Pagnier & Chertkov, 2021b, 2021a).

Other works have used spatial-temporal extensions of GNNs in the electrical domain for residential load-forecasting (Lin et al., 2021), fault diagnostics in power distribution systems (Nguyen, Vu, Nguyen, Panwar, & Hovsapian, 2022), and with complex-value extensions (T. Wu, Scaglione, & Arnold, 2022) for state forecasting. In another lie of research, (Wang et al., 2022) propose spatial-temporal graph learning for power flow analysis, where the graph is dynamically created from thresholded normalized mutual information. At the component feature level, attention-based graph learning (GAT) has been applied to power flow analysis (Jeddi & Shafieezadeh, 2021) and in a different work for probabilistic power flow to quantify uncertainties of distribution power systems (H. Wu, Wang, Xu, & Jia, 2022). To the best of our knowledge, the approach of employing a self-attention mechanism at the graph level to learn a graph structure that integrates electrical and hydraulic data using *graph neural networks* has not yet been addressed in previous research.

In the context of power systems, data fusion represents a crucial technique for enhancing the accuracy and reliability of forecasting algorithms by integrating diverse data sources. In the electrical domain, the fusion of diverse electrical system information was utilized to estimate the voltage in distribution networks (Y. Zhu, Gu, & Li, 2020), using cross-correlations between individual transformers. Another research study achieved state-of-the-art multi-site photovoltaic (PV) power forecasting (Simeunović, Schubnel, Alet, & Carrillo, 2022), fusing spatially distributed PV data by exploiting the intuition that PV systems provide a dense network of virtual weather stations. Integrating weather station data was also explored for anomaly detection for the industrial internet of things (Y. Wu, Dai, & Tang, 2022). Given its importance, modeling the interaction between the PSH subsystems has previously been explored using higher-order numerical simulation (SIMSEN) (Simond, Allenbach, Nicolet, & Avellan, 2006). However, operating numerical simulators in practice requires precise calibration and, consequently, extensive documentation of the components, which is typically not readily available. This calibration step is indispensable due to the components exhibiting highly non-linear characteristics (Nicolet et al., 2007). Given the significant variations in designs across different PSH assets, and the necessity for expert knowledge (which is often unavailable), applying this simulator-based methodology is often infeasible in real-world applications. For PSH, these limitations shift the focus to data-driven interaction modelling with GNNs, which is computationally affordable and does not necessitate expert knowledge, yet remains unexplored.

3. METHODOLOGY

This section introduces the Spectral-Temporal Graph Neural Network (STGNN) that we propose for the fusion of electric and hydraulic data in PSH state forecasting. In Section 3.1, we define the forecasting problem. From Section 3.3 onwards, we decompose the forecasting problem into learning the underlying latent graph structure from time series data (Sec. 3.4). Subsequently, on the learned graph, we introduce graph-spectral and time-spectral filtering (Sec. 3.6). An overview of the methodology is provided in Figure 1.

Notation: In this work, we use slicing notation denoted by the colon (:) symbol. Given a matrix $A \in \mathbb{R}^{m \times n}$, where m and n represent the number of rows and columns respectively, slicing is expressed as $A[i:j, k:l]$ or $A^{i:j,k:l}$. This notation represents the selection of rows i through $j-1$ and columns k through $l-1$ of matrix A. If i or k is omitted, it implies starting from the first row or column, respectively. Similarly, if j or l is omitted, it implies selection until the last row or column, respectively. We use $\otimes$ to denote element wise multiplication and $\oplus$ for concatenation. The Frobenius norm is denoted as $\| \bullet \|_{\mathrm{F}}$.

3.1. Problem Formulation

The specific objective of this work is to provide accurate state forecasting for the electrical subsystem of the PSH. Our approach utilizes learnable graph-spectral and time-spectral filtering to compute state predictions (the forecast). Let $\bar{\mathbf{X}} \in \mathbb{R}^{T \times H+E}$ represent the smoothed time series data $\bar{\mathbf{X}} = S(\mathbf{X})$ computed from unsmoothed time series $\mathbf{X}$ using the smoothing function S for E sensors in the electric and H sensors in the hydraulic subsystem, respectively, over a time period T. We define our forecasting model as a function $M : \mathbb{R}^{w \times H+E} \rightarrow \mathbb{R}^{h \times E}$ for a specific point in time $w < t < T$, that operates on input windows of the data of length w sliced as $\bar{\mathbf{X}}[t-w : t]$. The goal is to forecast the subset of electrical sensors $\bar{\mathbf{X}}[t : t+h, : E]$ for a horizon of size h. Model M operates on a graph $\mathcal{G}$ that is either inferred from the input data by a parameterized function $\mathcal{G}_\phi(\bar{\mathbf{X}}[t-w : t])$, which is trained alongside M, or may be provided apriori. We introduce two sets of learnable parameters: θ for the filtering M_θ and ϕ for the graph learning $\mathcal{G}_\phi$. Thus, state forecasting and state reconstruction estimates denoted by $\widetilde{\bullet}$ at a selected timepoint t, are computed by the model M as follows:

$$\widetilde{\mathbf{X}}_{\text{elec}}^{t:t+h}, \widetilde{\mathbf{X}}_{\text{elec}}^{t-w:t} = M_\theta(\bar{\mathbf{X}}^{t-w:t} \mid \mathcal{G}_\phi) \tag{1}$$

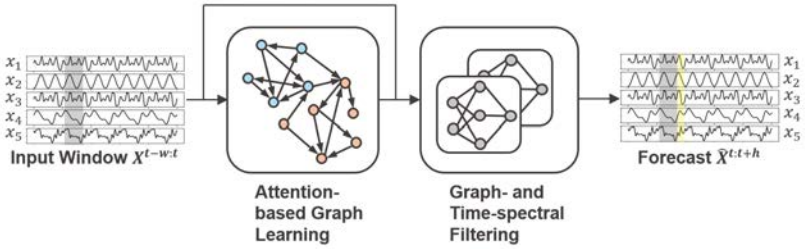

Figure 1. An overview of the two processing steps of our *spectral-temporal graph neural network* to fuse data from the electrical and hydraulic subsystems of a PSH. Utilizing *attention-based graph learning*, our method dynamically constructs a graph based on an input window $\bar{\mathbf{X}}^{t-w:t}$. Subsequently, by operating on this graph, the *graph- and time-spectral filtering* module efficiently extracts information from the hydraulic and electrical sensor data to forecast the subset of electrical sensors $\widetilde{\mathbf{X}}_{\text{elec}}^{t:t+h}$.

3.2. Training Objective

By employing a sliding window approach, we construct a training dataset $\mathcal{X}^{\text{Train}}$ of length N_{train}, where N_{train} depends on the training data split. We also construct analogous validation and test datasets $\mathcal{X}^{\text{Val}}$ and $\mathcal{X}^{\text{Test}}$, respectively:

$$\mathcal{X}^{\text{Train}} = \{\bar{\mathbf{X}}_{\text{elec}}^{t:t+h}, \bar{\mathbf{X}}_{\text{elec}}^{t-w:t}, \bar{\mathbf{X}}^{t-w:t}\}_{t=w}^{N_{\text{train}}}$$

We optimize the parameters of the model by minimizing the forecasting error $\mathbf{E}_{\text{f}}^t = \widetilde{\mathbf{X}}_{\text{elec}}^{t:t+h} - \bar{\mathbf{X}}_{\text{elec}}^{t:t+h}$. To learn meaningful and compact representations, we introduce an optional reconstruction error $\mathbf{E}_{\text{r}}^t = \widetilde{\mathbf{X}}_{\text{elec}}^{t-w:t} - \bar{\mathbf{X}}_{\text{elec}}^{t-w:t}$ for regularization. The final training objective is expressed as:

$$\mathcal{L}(\widetilde{\mathbf{X}}, \bar{\mathbf{X}}) = \sum_{t=w}^{N_{\text{train}}} \left(\lambda_{\text{f}} \|\mathbf{E}_{\text{f}}^t\|_F^2 + \lambda_{\text{r}} \|\mathbf{E}_{\text{r}}^t\|_F^2\right)$$

During the model's training process, we identify the optimal parameters:

$$\theta^*, \phi^* = \arg\min_{\theta,\phi} \mathcal{L}(\widetilde{\mathbf{X}}, \bar{\mathbf{X}}; \phi, \theta) \tag{2}$$

3.3. Node Features and Graph Representation

For the forecasting problem, we consider spatially distributed sensor sites modeled as nodes (vertices) $v \in V$ of a graph that spans the pumped storage hydropower plant. Due to differences in raw sensor sampling rates, we use resampled time series based on simple moving averages, taking into account the true sensor sampling rate of the j-th sensor S_j. This step smooths the time series:

$$\bar{\mathbf{X}}[i,j] = S(\mathbf{X}[i,j]) = \frac{1}{S_j} \sum_{\tau=1}^{S_j} s_\tau^j \tag{3}$$

We model each measurement site, containing one or more sensors as an individual node. Each node is associated with a feature vector $\mathbf{x}_v^{t-w:t} \in \mathbb{R}^{w \times d}, \quad \forall v \in V$, containing a window w of the smoothed sensor data and additional $d-1$ covariate dimensions such as a temporal encoding. This strategy is uniformly applied to both the electrical and hydraulic components within the pumped-storage power plant environment. Nodes are exclusively assigned to one of the sets: $\mathbb{1}_{\text{el}}(v) = 1$ for electrical components or $\mathbb{1}_{\text{hyd}}(v) = 1$ for hydraulic components, ensuring $\mathbb{1}_{\text{hyd}}(v) + \mathbb{1}_{\text{el}}(v) = 1$. As input for the subsequent model M, we consider the joint graph:

$$\mathcal{G}_\phi = \left(V_{\text{el}} \cup V_{\text{hyd}}, E_\phi(\bar{\mathbf{X}}[t-w:t])\right)$$

where the edges may be learned by a parameterized function E_ϕ.

3.4. Attention-based Graph Learning

We define a trainable function that implements self-attention among the sensor nodes to infer the edges $E_\phi(\mathbf{X})$ of the graph $\mathcal{G}$. To compute the self-attention, we first map the time series to an embedding space $\mathbf{E} = \text{GRU}(\bar{\mathbf{X}})$ using a gated recurrent unit (GRU). We then proceed by computing the self-attention of the embedded time series. For this purpose, we define a query sequence Q and a key sequence K to compute the attention scores W:

$$Q = EW^Q, K = EW^K, W = \text{Softmax}\left(\frac{QK^T}{\sqrt{d}}\right) \tag{4}$$

by linear projection with the trainable matrices $\phi = (W^Q, W^K)$. Unlike in *graph attention networks* (GAT) (H. Wu et al., 2022), which define attention over features of a pre-existing graph, we directly compute the symmetrically normalized graph Laplacian L from the attention scores W , which we convert into a symmetrical adjacency matrix $A = \frac{1}{2}(W + W^T)$. We compute the Laplacian as $L = I - D^{-\frac{1}{2}} A D^{-\frac{1}{2}}$, where L is the Laplacian matrix, I is the identity matrix, D is the diagonal degree matrix of A, the adjacency matrix. L is then used for the graph spectral filtering in Section 3.6.

3.5. Spectral-temporal Graph Neural Network

To predict the sensor dynamics, the model processes the input data $\bar{\mathbf{X}}^{t-w:t}$ on the learned graph $\mathcal{G}$ (obtained as introduced in Section 3.4) by mapping the input data from the spatial-temporal vertex domain of the sensor signals to a spectral latent representation. This mapping is achieved through the sequential application of graph-spectral and time-spectral transformations, as introduced in Sec. 3.6. The corresponding inverse transformations are utilized to reconstruct the sensor signal in the spatial-temporal domain. To address the problem of vanishing gradients and performance degradation with increasing network depth, we introduce skip connections to compute the final forecast. We denote the output of the residual blocks as s_k. Thus, model M can be expressed with spectral filtering (F), and a bypass layer f_b as follows in the recursive equation:

$$(s_k^f, s_k^b) = \begin{cases} F\left(\bar{\mathbf{X}}\right) \mid \mathcal{G}_\phi(\bar{\mathbf{X}})\big), s_0^b = \bar{\mathbf{X}} & k = 0 \\ F\left(\sigma(s_{k-1}^b - f_s(s_{k-1}^b)) \mid \mathcal{G}_\phi(\bar{\mathbf{X}})\right), & k > 0 \end{cases} \tag{5}$$

where the final forecast is computed as $\widetilde{\mathbf{X}}_{\text{elec}}^{t:t+h} = \Omega_f\left(\sum_{i=1}^k s_i^f\right)$ with an application-specific feedforward head function (Ω), and the backcast as $\widetilde{\mathbf{X}}_{\text{elec}}^{t-w:t} = \sum_{i=1}^k s_i^b$.

3.6. Graph- and Time-spectral Filtering

For the spectral filtering module F, we use graph convolutional filtering and the trainable *Spe-Seq Cell* S_θ introduced in (Cao, Wang, et al., 2021). We denote the graph Fourier transform as $\mathcal{GF}$, and its inverse as $\mathcal{IGF}$. The j-th channel y_j in the graph-spectral domain is therefore computed as follows:

$$y_j = \mathcal{IGF}\left(\sum_i g_{\theta_{ij}}(\Lambda_i) S_\theta(\mathcal{GF}(\mathbf{X}_i))\right). \tag{6}$$

In the graph-spectral domain, we implement the parameterized filtering $g_\theta(\Lambda_i)$ on the eigenvalues Λ. Instead of computing y_j directly, we compute the Chebyshev polynomials of L to efficiently approximate the graph Fourier transform without performing the costly eigenvalue decomposition of the Laplacian matrix $L = U\Lambda U^T$, where U is the graph's eigenvector matrix. We obtain the i-th Chebyshev polynomial $T_i(\bullet)$ with the recurrence relation: $T_0(x) = 1, \quad T_1(x) = x, \quad T_{k+1}(x) = 2xT_k(x) - T_{k-1}(x)$. Thus, we implement graph-spectral filtering with the graph spectral operator $g(L)$ as follows:

$$g(\widetilde{L})\mathbf{X}_j \approx \sum_{n=0}^{N} c_n S_\theta(T_n(\widetilde{L})\mathbf{X}_j) \tag{7}$$

where c_n are the learnable parameters and $\widetilde{L} = 2L/\lambda_{\max} - I_N$ is the normalized Laplacian matrix. The *Spe-Seq Cell* enhances the output of $\mathcal{GF}$, treating it as a multivariate time-series in the graph-spectral domain. It then elevates this output into the time-spectral domain to learn feature representations. To achieve this, the *Spe-Seq Cell* uses the Discrete Fourier Transform (DFT) and gated linear units (GLU) for element-wise modulation of the signal in time-spectral domain as follows:

$$\text{GLU}(\mathbf{x}) = \mathbf{x} \otimes \sigma(\mathbf{W}^g\mathbf{x} + \mathbf{b}^g) \tag{8}$$

This approach effectively implements convolution on the multivariate time-series in the graph-spectral domain.

4. Case Study and Experimental Setup

The dataset in this case study was obtained in collaboration with the Swiss Federal Railways (SBB). SBB maintains a separate railway traction current network (RTN) that operates at a frequency of 16.66 Hz to power rolling stock across Switzerland. The power plant operators of SBB use *supervisory control and data acquisition (SCADA)* protocols to transmit sensor data to a centralized *energy management system* (EMS). This setup allows for real-time monitoring of assets, ensuring timeliness and synchronicity between sensor signals, making it a technically sound environment to evaluate the proposed methodology.

Objective: For this case study, our aim is to forecast the currents measured by the electrical sensor network of the PSH. From an operator's perspective, forecasting currents is particularly compelling when dealing with rolling stock, given their highly dynamic current profile that is vastly different to residential power grids. While the residential sub-grid of Zurich, the largest City of Switzerland, is subject to transient load changes within 15 minutes intervals of up to 35MW, the RTN of SBB experiences load changes up to 250 MW whithin the same time interval due to the orchestrated and periodic timetable of the Swiss railway network (Halder, 2018). The importance of accurate current forecasts is additionally heightened because electrical components in power systems, like transformers and conductors, have thermal limitations that depend on the amount of current flowing through them. Unlike voltage levels, current levels in the PSH dynamically react to transient loads changes. Anomalies such as sudden increases or decreases in power demand, or failures in equipment, are therefore more immediately reflected in current fluctuations. We therefore focus on phasor current forecasting in this study.

Dataset & Data Preparation: We collected data spanning four months from a PSH in Switzerland, consisting of readings from 58 sensors that monitor pressures, flow rates, and lake levels of the hydraulic subsystem, as well as electrical currents from seven generating units, including connected substations in the electrical subsystem. The time series are averaged to a 1-minute resolution and were collected from

January to March in 2021. We maintained the temporal ordering of training (70% of the data), validation (15%) and test (15%) datasets to ensure that the validation and test indices are sequentially higher than the training indices. We normalize the data using feature-wise min-max scaling. To provide a comprehensive understanding of the dataset, we show a detailed segment of the sensor data in Figure 2.

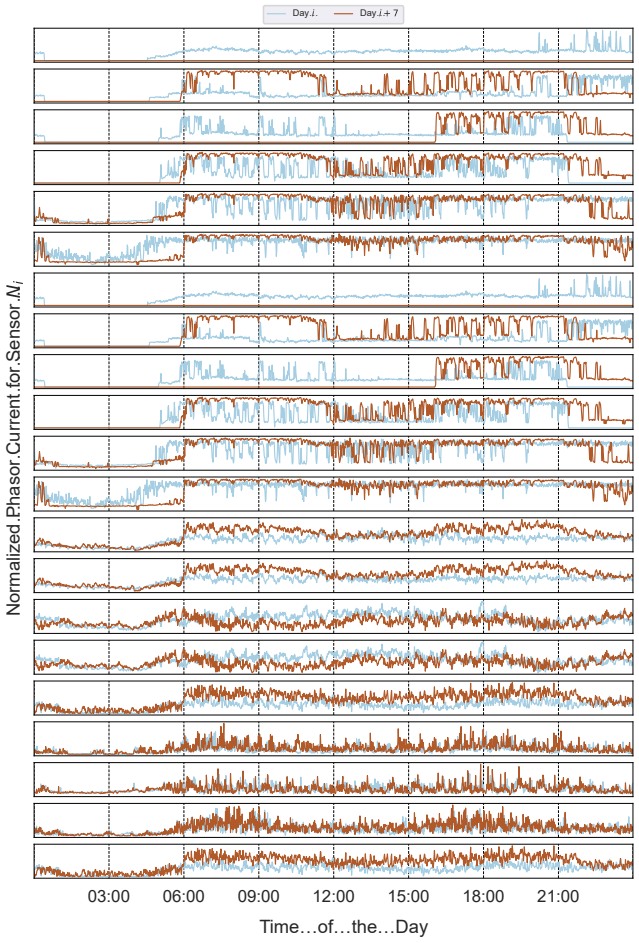

Figure 2. Segment of the dataset, displaying all 21 normalized phasor current sensors (the forecasting target of our case study), indicating the dynamic nature of the sensor measurements. We show the same day of the week (i and $i + 7$) for two consecutive weeks.

Model & Training: The experiments were conducted on an NVIDIA RTX3060 using PyTorch 2.0 and CUDA 11.8 for the development and training of the models. The proposed model utilizes a window size (w) of 24 and a horizon size of 1, meaning that it predicts the currents for the next minute. This configuration is tailored to the synchronized operation of the Swiss railway network, which organizes its periodic timetable in half-hourly intervals. Our selected model's input window takes this operational profile into account, thereby reducing the influence of the previous interval. During model fine-tuning, we truncate the Chebychev polynomial expansion to $k = 4$ for both the graph- and time-spectral filtering. We set the number of residual blocks to two and configure the *Spe-Seq Cells* to five layers. We adjust the negative slope of *LeakyReLU* α to 0.2, and dropout to 0.5 for regularization. We use Adam for optimization.

Table 1. Overview of trainable parameters in the neural network models.

Model	Parameter
MLP (4-layer, el+hy)	2.8 M
STF (el+hy)	366 K
Ours (el)	481k
Ours (el+hy)	481k

4.1. Baseline Approaches for Comparison

We compare our approach with relevant baselines for time series forecasting in the power grid domain, such as a linear model with trend decomposition, a fully connected neural network (FNN) and a *recurrent neural network*, specifically the LSTM. Given the recent increase in attention towards transformer-based energy forecasting, we also consider the *time series transformer* model (*Spacetimeformer*, (Grigsby, Wang, & Qi, 2022), denoted as STF) Additionally, we include an Attention-based GNN (A3-GCN, (J. Zhu, Song, Zhao, & Li, 2020)) that has been demonstrated to outperform the classical GCN on similar forecasting tasks. All baseline models were trained and validated on the same dataset and with the same input window size. Each model was trained to reach convergence on the validation dataset.

5. Results

In this section, we summarize the numerical results to evaluate the proposed method and compare it to the baselines. Additionally, we study the output from the graph learning and compare it to the connectivity of the PSH asset. Furthermore, we ablate the hydraulic information from the model input to assess its benefits. All results are based on the dataset introduced in Section 4.

In the initial step, we compare the performance of the adopted *spectral-temporal graph neural network* to the baseline models introduced in Section 4.1 based on normalized mean squared error (NMSE). We summarize model performances in Table 2. Our model surpasses all conventional baselines, including LSTM (by 28%) and the, in terms of parameters, much larger FNN (by 14%), as evaluated by the NMSE. A3-GCN is unable to integrate hydraulic information due to the lack of a graph. Spacetimeformer (STF) can learn from hydraulic signals but does not outperform our method.

For the evaluation of A3-GCN, we translate the PSH's electrical network diagram into a processable graph, as having apri-

Table 2. Average (normalized) model performance across nodes, comparing six different methods. We indicate whether the PSH network diagrams were translated into a processable graph for the computation (Network Diagram) and epmhasize if hydraulic (Hyd.) or electric (El.) information was used for training.

Method	El.	Hyd.	Network Diagram	Type	NMSE
Linear	✓	✓	✗	-	1.11e-1
A3-GCN	✓	✗	✓	GCN	8.74e-3
LSTM	✓	✓	✗	RNN	7.51e-3
MLP (3-layer)	✓	✓	✗	FNN	6.84e-3
MLP (4-layer)	✓	✓	✗	FNN	6.21e-3
STF	✓	✗	✗	Transformer	5.84e-3
STF	✓	✓	✗	Transformer	5.83e-3
Ours	✓	✗	✗	Att. GCN	<u>5.71e-3</u>
Ours	✓	✓	✗	Att. GCN	**5.34e-3**

ori graph is a computational requirement for the method. Surprisingly, we found that the A3-GCN is outperformed by the much simpler LSTM by 14% in terms of NMSE. This finding highlights that the intuitive approach of applying GNN directly to a graph derived from schematic diagrams, does not always yield acceptable results. In this context, since our proposed STGNN is also based on GCN, the 34.7% improvement in NMSE illustrates that, beyond choosing the right model, finding a suitable computational graph is crucial for processing PSH data. Our results provide further support for the observation in (Ringsquandl et al., 2021) that statistical properties of graphs derived from network diagrams of power grids may be unsuitable for direct graph processing. Graphs derived from such network diagrams significantly differ from those typically discussed in the graph-theoretical literature, with statistical properties like lower clustering-coefficients, lower node degrees, and higher graph diameters, which could explain the subpar performance of A3-GCN in the state forecasting task. From a message-passing perspective, the specific properties of these graphs hinder effective message propagation unless the GNN comprises many layers. Unfortunaltely, this model choice, in turn, significantly boosts oversmoothing, which is already a prevalent challenge in the power grid environment due to the high similarity of the electrical sensor data.

We assess the performance of time-series transformers (Spacetimeformer), which are structurally similar to our attention-based GNN approach, because they incorporate a self-attention layer across the one-dimensional timeseries. However, the experiment with Spacetimeformer displays a 9.2% reduction in performance in terms of NMSE compared to the STGNN. Additionally, we found it difficult to scale Spacetimeformer to the problem without overfitting. Altrough showcasting respectable performance, compared to the STGNN, STF did not benefit from the additional information from hydraulic systems (resulting in a 0.1% improvement).

An advantage of our STGNN, compared to conventional methodology suited for multivariate time series analysis such as LSTM, is that we have access to the learned graph topology. To derive insights from the inferred graph, we calculate the mean attention $a_{ij} = \frac{1}{N}\sum_{i=1}^{N} a_{ij}$ over the test data set. We expect our method to converge to the same graph for randomized training initialization when learning physical relationships between the sensors. To verify our expectation, we visually compare the average attention across random seeds in Figure 4. Additionally, our analysis reveals that the inferred attention graph's minimal parameterization yields temporally stable graphs, accurately reflecting the situation in the PSH, which usually has stable topology across time.

Interestingly, the attention graph recovers casual relations given by the functioning of the hydropower plant and therefore shows similarity to the underlying physical network of the hydropower plant. In Figure 6, we depict the relationships between the water inflow (flow-rates, pressures), the generator units (groups and transformers, indicated by TRF), and the PSH outlets (substations, denoted by SP), overall making the model's predictions more interpretable. Leveraging this interpretability, we compare Figures 5 and 6. Surprisingly, our model focuses on the PSH outlets to predict the power plant input's phasor currents in the absence of hydraulic information from the forecast, which could explain the more severe outliers in the forecast (Figure 3). When adding hydraulic information to the forecast, we observe that the model makes additional use of penstock flow-rate and pressure sensor data, thereby improving the prediction quality.

5.1. Ablation Study

In an ablation study, we exclude the hydraulic sensor data from the forecast to validate the effectiveness of fusing electric and hydraulic sensor data for improving the electrical state forecasting. We find that incorporating the hydraulic subsystem leads to an 6.5% reduction in NMSE. The NMSE absolute forecasting performance from the ablation experiment is included in Table 2. Figure 7 and 8 evaluate the relative improvement on a per-node basis, demonstrating that the benefits of our methodology are distributed across most sen-

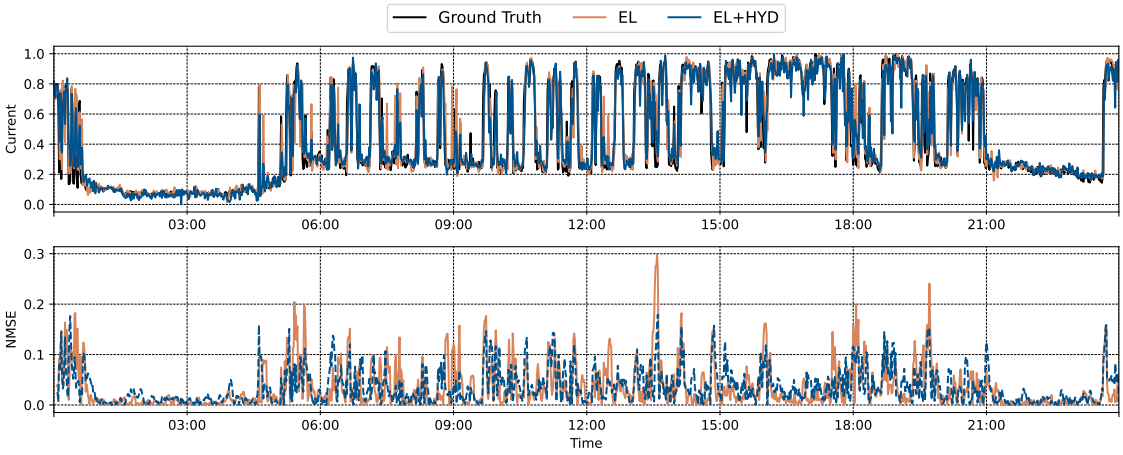

Figure 3. Comparison of normalized phasor current forecasts with (EL+HYD) and without the hydraulic information (EL) for our proposed STGNN model. We show the forecast for single node N_i ($i = 1$) across a randomly selected day including ground truth. In the upper Figure, we display the dynamic range of the forecast. In the lower Figure, we display the normalized MSE of both approaches with respect to the ground truth. Removing hydraulic information results in heightened discrepancies and more pronounced outliers in the predictions. First, we select the data based on the above criteria. Then, we normalize the selected data using min-max scaling.

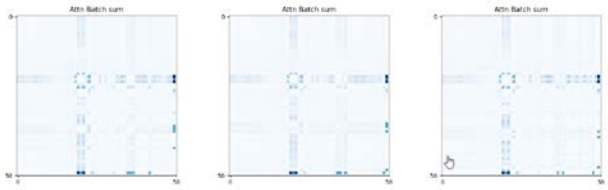

Figure 4. The averaged learned attention across the test set of the *attention-based graph learning* module over all 58 signals from the electrical and hydraulic subsystems. We show three random seeds. The learned attention is stable for different random initializations.

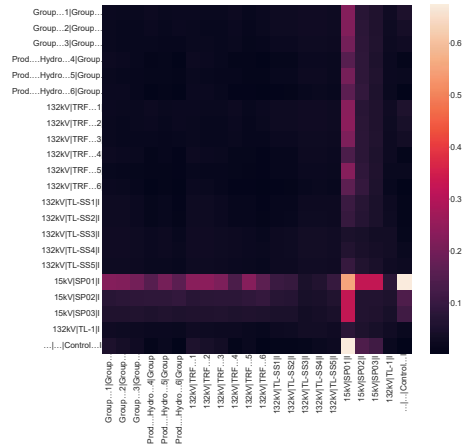

Figure 5. The heatmap represents the averaged learned attention by the *attention-based graph learning* module across the test set as for the model processing only electrial information (EL). Counterintuitively, the model focuses on the PSH output (SP) when forecasting the phasor currents of the electromagnetic generators, which represent the PSH input.

sor forecasts (nodes), thereby ensuring that no sensor forecast experiences a major decline in performance from including hydraulic sensor information.

6. Conclusions

In this paper, we demonstrate that integrating information across the electrical and hydraulic subsystems is beneficial for state forecasting in pumped-storage hydropower plants (PSH). Our proposed *spectral-temporal graph neural network* is the first approach to integrate information across the PSH's subsystems by applying *attention-based graph learning*, which effectively represents PSH states for short-term phasor current forecasting. Compared to numerical simulation, our method requires neither knowledge of the underlying network and sensor connectivity graph nor a tedious calibration step. Through a real world case study, we demonstrate that relying exclusively on graphs derived from network diagrams for state forecasting does not always yield the best performance. We highlight the advantages of learning a PSH-wide graph, complementing the critical perspective on network-diagram-derived graphs introduced in (Ringsquandl et al., 2021). Moreover, we show that our method remains interpretable, unlike other deep-learning methods that process electrical and hydraulic data simultaneously. Future work looks to reintegrate the underlying network diagram while maintaining the flexibility of attention-based graph learning, thereby harnessing the strengths of both approaches. This could also allow for the incorporation of physics-informed losses, such as electromagnetic generator efficiency or power flow, which may reduce the volume of training data required.

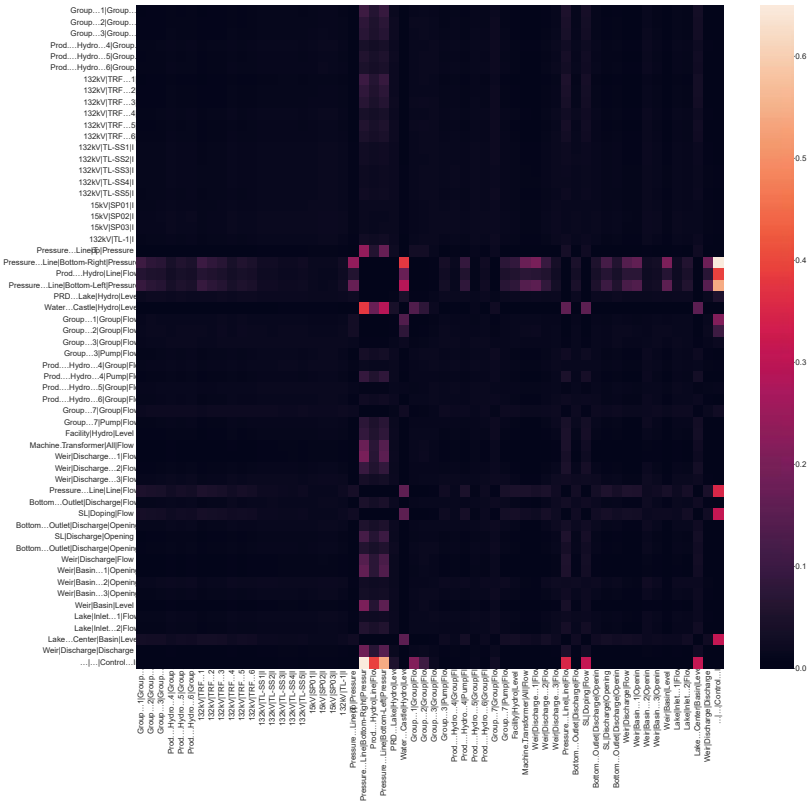

Figure 6. The heatmap visualizes the averaged learned attention of the *attention-based graph learning* module across the test set visualized for the model that processes both electrial and hydraulic information (EL+HYD). Notably, the model focuses on the hydraulic subsystem (the PSH input) when forecasting the phasor currents of the electromagnetic generators.

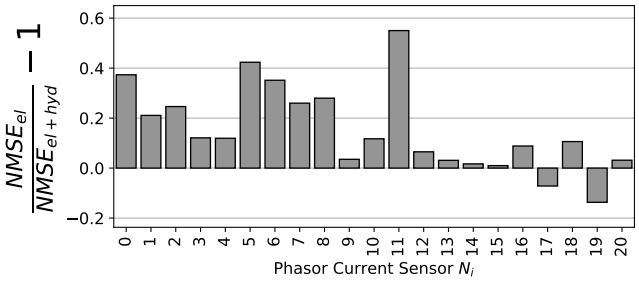

Figure 7. Relative improvements across the test set (normalized MSE, averaged) for our STGNN models with (EL+HYD) and without hydraulic information (EL). for each of the 21 phasor currents sensors of the electric subsystem. 19 out of 21 phasor current forecasts are improved by the additional hydraulic information.

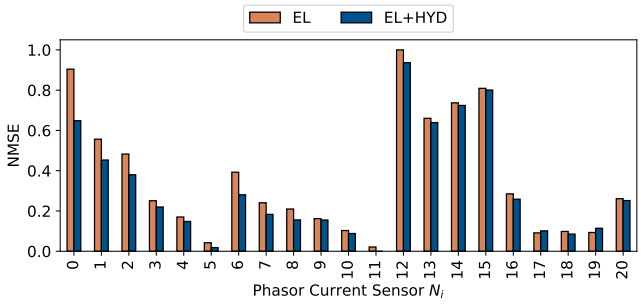

Figure 8. The normalized MSE averaged across the test set is displayed, comparing our STGNN models with (EL+HYD) and without hydraulic information (EL). The performance across the 21 phasor currents sensors of the electric subsystem is shown. The additional hydraulic information improves the phasor current forecasts in 19 out of the 21 cases.

ABSTRACT

In response to the urgent need to combat climate change and reduce greenhouse gas emissions, the transition towards renewable energy sources such as solar and wind power is indispensable. However, the intermittent nature of these sources poses significant challenges to the stability of power grids. Battery Energy Storage Systems (BESS) offer a viable solution, and there is potential for Electric Vehicles (EVs) to serve as energy reservoirs, thereby bolstering grid stability through Vehicle-to-Grid (V2G) technology. While V2G holds promise, concerns persist regarding the longevity of batteries, particularly with the additional demand from charging and discharging cycles. To address these concerns, this study introduces a health-aware control strategy for V2G service scenarios. By employing feedback control mechanisms to adjust degradation rates, the strategy aims to effectively manage battery aging. Simulation outcomes of a V2G scenario with random input sources illustrate the efficacy of this proposed approach, demonstrating its potential applicability in practical settings where battery health needs to be managed. In summary, this research contributes to the advancement of health-aware strategies for an interconnected grid where electric vehicles participate as energy sources, with a primary focus on optimizing battery health management while fulfilling grid demands. Future efforts will concentrate on refining optimization strategies and integrating control methodologies with state estimators to ensure the performance of the approach on embedded battery health management systems.

1. INTRODUCTION

In the face of climate change and the urgent need to reduce global greenhouse gas (GHG) emissions, the transition to non-fossil fuels and renewable energy sources is crucial. While photovoltaics and wind power energy are promising solutions, their intermittent nature poses a challenge to the stability of the power grid. In solving this problem, Battery Energy Storage Systems (BESS) are proving to be a crucial component in ensuring a consistent energy supply. In parallel, the proliferation of Electric Vehicles (EVs) offers the opportunity to use their batteries as energy storage units, which can act as an energy buffer during the day reinforcing the stability of the power grid.

The concept of using EV as energy storage known as Vehicle-to-Grid (V2G) offers advantages, but also pose some challenges. According to (Didier et al., 2021) a fleet of 15% electrified cars in France in 2030 would mean an energy stock of 25GWh throughout the day, equivalent to 20% of the daily average production of the French renewable energy grid in 2020. Another notable benefit is the potential for users to recoup their investment by participating in grid-level demand response programs. However, the use of batteries, particularly EV batteries, raises concerns about their longevity as these batteries are more often used in a ”two-shifts” operation. The impact on battery life has direct financial and environmental implications and therefore justify efforts to find V2G strategies that take battery health into account.

A well- known solution is to use the grid operator as an intelligent conductor, requesting energy from multiple energy sources to ensure the effectiveness of grid distribution while reducing the cost of multiple sources, including the cost of battery aging. An overview of such an approach that uses optimized scheduling methods to control the power grid including V2G application is discussed in (Collath, Tepe, Englberger, Jossen, & Hesse, 2022). However, it is important to

note some limitations of this solution, such as a generalized modeling of battery degradation and the non-consideration of aging-related changes in electrical behavior. An additional challenge lies in the prediction of degradation behavior, a task that remains difficult even with the improved accuracy of data-driven methods.

With recent advancements in online estimation methods for determining the state of health in individual battery packs, the feasibility of health management has expanded to the battery management system (BMS) level. The overall objective is to ensure optimal discharge using adaptive control algorithms to alleviate stress factors and manage the aging process throughout the operational lifespan of electric vehicles, accounting for varying conditions. Recent studies have shown the benefits of implementing a health management controller in wind turbines (Kipchirchir, Do, Njiri, & Söffker, 2023). Using a feedback controller framework can effectively mitigate the degradation process and regulate the end-of-life of these systems using control laws and dynamic models to adapt or reconfigure operational processes. It is expected that incorporating this approach into battery-powered applications can also bring benefits as the aging process in can be efficiently managed.

In this sense, this article presents a health-aware control (HAC) strategy to address battery aging by considering the dynamical interaction between operational and stress variables (e.g. state of charge and temperature). The approach is based on the modulation of the degradation-rate using a feedback controller, as proposed in (Félix, Martinez, & Bérenguer, 2023), in a V2G scenario. For this purpose, a novel dynamic model is first proposed that models the degradation-rate as a function of identified stress factors in response to operational demands. As presented in (Pelletier, Jabali, Laporte, & Veneroni, 2017), the stress factors and effects in battery aging are closely interrelated and an optimal control behavior is not obvious. In addition, the discharge process does not behave linearly and suffers from the fluctuations of aging mechanisms. Therefore, based on the proposed model, a control design is also presented that incorporates robust techniques to handle uncertainties inherent in the degradation modeling and randomness induced by the system operation.

The effectiveness of the approach is evaluated through simulations with a degraded battery model that simulates electrical and thermal dynamics, taking into account variations in critical factors such as increments on the internal resistance and reduction on the battery capacity induced by the ageing process and affecting battery autonomy. To demonstrate practical applicability, the article includes a case study of a simulation of in V2G scenario, integrating uncertainties and random elements to highlight the advantages of the approach in real-life. The results initiate a discussion on the benefits of the approach and its limitations of implementing HAC to V2G and further applications.

Accordingly, Section 2 presents the electrical circuit model of a battery subject to degradation and the proposed model of aging behavior. Section 3 describes the design of a feedback control approach to regulate the degradation-rate. Section 4 shows the results obtained by implementing such a health-aware controller at the BMS level of a V2G application. Conclusions and future perspectives are discussed in Section 5.

2. System model of a degraded battery

2.1. Equivalent circuit model

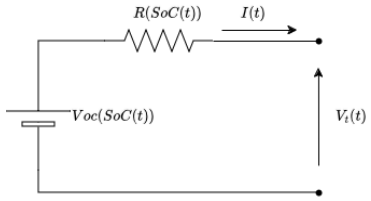

Figure 1. A simplified equivalent circuit model of the battery.

Figure 1 illustrates an equivalent circuit model of a lithium battery simplifies the complex electrochemical processes within the battery into a basic electrical behavior (Pelletier et al., 2017). It includes a voltage source $V_{oc}(k)$ representing the open-circuit voltage, internal resistance R to account for losses within the battery, both dependent of the State-of-Charge (SoC) usually expressed by a parameter $SoC(k)$ to track the available capacity of the battery. This model also incorporates a capacity element C modeling the battery's charge storage capability, and the flow of current $i(t)$ through the battery during charge-discharge cycles. Let us represent such equivalent circuit model as follows:

$$SoC(k+1) = SoC(k) - T_s \frac{I(k)}{(3600 \cdot C_n)} 100 \cdot \gamma(k) \ , \quad (1)$$

$$V_t(k+1) = aV_t(k) + (1-a)E(k) \ , \quad (2)$$

$$\text{with } E(k) = V_{oc}(SoC(k)) - R_n(SoC(k)) \cdot I(k) \cdot \gamma(k) \ . \quad (3)$$

In such model the dynamics of SoC is modeled using Coulomb counting of Eq.1, a function of the charge-discharge current rate $I(k)$ and counting sampling T_s, whereas the behavior of terminal voltage $V_t(k)$ follows Eq. 2 that is driven by a filter parameter a, and V_{oc} and R_n that are functions of the current $SoC(k)$.

2.2. Aging mechanism

In the equivalent circuit model, the state-of-charge and terminal voltage fluctuate in response to the current rate $I(k)$ ($I(k) < 0$ during discharging). Moreover, the charge-discharge behavior is intricately linked to the battery's aging process.

While aging stems from physical-chemical factors, its effects are reflected in electrical characteristics such as capacity fading and increasing internal resistance (Barré et al., 2013). This relationship suggests that these characteristics are influenced by an aging parameter, denoted here as γ. Specifically, the capacity $C(k)$ decrease and resistance $R(k)$ increase can be expressed as functions of γ:

$$C(k) = \frac{C_n}{\gamma(k)} \tag{4}$$

$$R(k) = R_n(SoC(k)) \cdot \gamma(k) \ , \tag{5}$$

where C_n and R_n are the nominal value for capacity and internal resistance.

For simplicity, let us consider γ to be equivalent in both effects, as they pertain to the same aging process. This framework sets the stage for developing a degraded battery model, just as introduced in (Martinez, Félix, Kulkarni, Orchard, & Bérenguer, 2024), where $\gamma = 1$ represents a new battery. During each discharging and charging mission, γ tends to increase until it reaches a maximum value of $\gamma = 2$, indicating that the battery can no longer operate.

2.3. Degradation extended model

As an electrochemical process, charge-discharge behavior incurs energy losses and generates thermal effects. This behavior is externally influenced by ambient temperature $T_{\text{amb}}(k)$ and the Joule effect, which produces heat ($T_{\text{Joule}}(k)$) when the current rate is non-zero. The thermal model can be described by Eq. 6, where c_0 is the inertial parameter of the thermal behavior, and $T_{\text{Joule}}(k)$ is defined by Eq. 7, incorporating factors such as c_1, $R_n(SoC(k))$, $I(k)$, and $\gamma(k)$.

$$T(k+1) = c_0 T(k) + (1 - c_0)\left(T_{Joule}(k) + T_{amb}(k)\right), \tag{6}$$

$$T_{Joule}(k) = c_1 R_n(SoC(k)) I(k)^2 \gamma(k) \tag{7}$$

How γ increases is an important research topic. In this matter, it is known that the increased current generates heat and accelerate degradation by promoting the dissolution of the electrode material and the breakdown of the electrolyte, thus we propose a model for the increase in γ based on the same influences as heating:

$$\gamma(k+1) = c_3 R_n(SoC(k)) I(k)^2 \gamma(k) \tag{8}$$

While this model remains an assumption and approximation, it is crucial for simulating the aging process responsible for increased resistance and decreased capacity. A similar approach to finding a degradation growth model is presented in (Brown et al., 2009) for electro-mechanical actuator applications. Also, this sheds light on which variables of the charging-discharging process could be considered as relevant factors for making decisions regarding aging acceleration.

Note that as the model is posed, an increase in γ increases the acceleration of the aging process itself, similar to how increased temperatures in degraded batteries increase the degradation of the batteries themselves. In addition, a significant increase in γ can lead to instability of T.

3. PROBLEM FORMULATION

This work focus on the application of health-aware discharging for power sale to the grid, known as V2G or V2Market. In this application, there are three main concerns:

1. Supplying the grid with enough energy stored in the battery in order to stabilize it.
2. Monetizing the time the car spends parked in the parking lot without charging.
3. Yet, taking into account the cost of battery degradation since discharging counts as a cycle in the battery's lifespan.

As explained in (Reniers, Mulder, Ober-Blöbaum, & Howey, 2018), when purchasing stored energy, the grid offers a value per kWh correlated with intermittent sources (e.g., solar and wind) availability. Energy prices fluctuate stochastically due to the stochastic behavior of these resources. A grid operator manages participation percentages and demand for each source to optimize production, considering costs, including batteries degradation. This optimization is reviewed in (Collath et al., 2022). While grid demand is generated, users aim to monetize their parked time without charging. Such profitability can be determined by:

$$R = \sum_{k=0}^{t_f} P(k) \times \text{Price}(k) \tag{9}$$

Here, $P(k)$ represents the power sold at discrete time step k, which can be measured by:

$$P(k) = V_t(k) \times I(k) \tag{10}$$

With power demand and price previously established, maximizing profitability becomes a matter of ensuring that $P(k)$ closely matches the power demand and maximizing the discharging interval t_f.

Despite the potential for monetizing a parked car, it is important to acknowledge that there is a cost associated with battery degradation when discharging. This degradation ultimately shortens the battery's lifespan, leading to decreased

performance and necessitating eventual battery replacement. Let us consider this cost as the accumulated degradation over the discharging mission:

$$D = \gamma(t_f) - \gamma(0) \tag{11}$$

To proceed with a solution, let us consider the following:

- The power demand profile (i.e., $P_{grid}(k)$) is pre-defined on an hourly basis, and the power sold never exceeds the power demand ($P(k) \leq P_{grid}(k)$).
- The battery experiences degradation during discharge, as described by Eq. 8. The initial degradation index γ is estimated online using algorithms such as the one proposed in (Didier et al., 2021) or (Martinez et al., 2024).
- The initial State of Charge (SoC) is known and may be lower than the maximum capacity, while a minimum battery SoC is specified and consistently lower than the initial SoC, as represented by:

$$SoC_{\text{min}} \leq SoC(k) < SoC(0) \leq 100\%$$

- The maximum duration for which the vehicle remains parked, selling energy, is predefined as follows:

$$k \leq t_{\text{max}} \sim U(t_1, t_2)$$

- The terminal voltage remains consistently above a safe minimum ($V_t(k) > V_{\text{min}}$).

Figure 2 illustrates the proposed V2G service scenario with battery health management control acting as a discharging auxiliary system. It is assumed that SoH and SoC estimations are available and provided by a BMS.

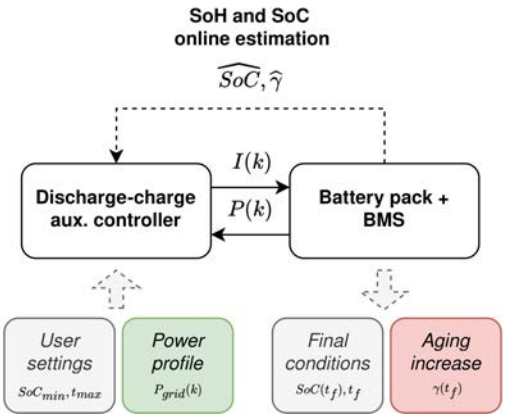

Figure 2. Illustration of Power-sale discharging mission.

3.1. Discharging strategies

The sale of vehicle energy can have numerous strategies. The first and simplest strategy is to manage the delivery of energy to exactly match the grid demand, only stopping the discharge when any of the restrictions (i.e. SoC_{min}, t_{max}, or V_{min}) are triggered. However, this strategy is not optimized, as it does not prioritize maximizing profitability or minimizing degradation costs. Therefore, we can assume other strategies that act on the current rate to maintain power close to demand, while at the same time, avoiding excessive degradation or deliberately degrading to manage battery lifespan. Here we are assuming that the grid is supplied by several other vehicles, and that its stability will not be affected if $P(k) < P_{grid}$.

In the scope of this study, we consider two control strategies:

1. Find the appropriate current $I(k)$ at time k that facilitates discharge in a manner that SoC achieves its minimum by time $tf = t_{max}$, i.e. $SoC(t_{max}) = SoC_{min}$. This strategy optimizes the utilization of parked time and the current, a key factor influencing degradation.
2. Find the optimal current $I(k)$ at time k that allows the degradation rate to follow a predefined reference $\Delta\gamma_{ref}$, ensuring a desired growth rate by time $t_f = t_{max}$, i.e. $\gamma(t_{max}) - \gamma(0) = \Delta\gamma_{ref}$.

The first strategy emphasizes managing the discharge duration. If the discharge time is shorter than the parking duration, the current is adjusted to meet the objective. This approach ultimately influences degradation growth through effective time management.

On the other hand, the second strategy prioritizes degradation effects. It involves tracking a desired γ growth rate either to meet a predefined lifespan or to meet a optimize a value γ^d derived from an optimization problem involving power sold and γ growth rate.

As discussed in (Collath et al., 2022), BESS technology that addresses only issues 1 and 2 of the previously formulated problem does not account for degradation costs over time, reducing the profitability of V2G usage. The two strategies proposed here aim to address the third issue. The first strategy involves mitigating the impact of current on aging increase during discharge, while the second strategy focuses on regulating the degradation-rate by reconfiguring discharge across multiple cycles. Both strategies will inevitably affects the performance of energy delivery to the grid, reducing the profit per discharge. However, this reduction can lead to a significant improvement in battery life. By designing an optimal controller for both strategies, we try to find the best compromise for this trade-off.

3.2. Control framework

For the design of the controller, we consider the system to be controlled written in a discrete-time state-space representation:

$$x_{k+1} = A(\rho_k)x_k + B(\rho_k)u_k + E(\rho_k)d_k\,, \tag{12}$$

with respect to the state vector defined as $x_k \in \Re^n$, the control input variable $u_k \in \Re^m$ and the disturbance input of $d_k \in \Re^p$. The variability of the system is determined by a varying parameter vector ρ_k. When the varying parameter ρ_k is bounded and it belongs to a convex polytopic region Ω_ρ limited by N vertices of the polytopic set $\theta \in \Omega_\rho \subset \Re^L$ defined by ρ_k boundaries. Then, we can write ρ_k as a convex combination of vertices $\theta^{(i)}$ as follows:

$$\rho_k = \sum_{i=1}^{N} \alpha_k^{(i)} \theta^{(i)}, \tag{13}$$

where $\alpha_k^{(i)} \geq 0$ and $\sum_{i=1}^{N} \alpha_k^{(i)} = 1$.

Such a modeling approach is known as polytopic modeling, which enables the construction of robust control designs by guaranteeing stability within the boundaries of the convex set. Since the system is subject to variations due to stochastic disturbances in discharge conditions or changes over time in γ due to aging, this approach will ensure stability for all variable conditions that the discharging process and its dynamics face.

3.2.1. SoC rate control design

According to Eq. 1, SoC decreases dynamically as follows:

$$SoC(k+1) = SoC(k) + SoC'(w(k)) \tag{14}$$

Here, $w(k)$ represents the decision variable that can be adjusted to solve a control problem, specifically a tracking reference problem. To address this problem, we introduce an integrator error tracking $z(k)$ to be minimized. The system to be stabilized is thus defined as:

$$w(k+1) = u(k) \tag{15}$$

$$z(k+1) = z(k) + T_s \cdot (\widehat{SoC}'(w(k)) - SoC'_{ref}(k)) \tag{16}$$

where $u(k)$ represents the control decisions at each sample k, with T_s as the decision rate. $SoC'_{ref}(k)$ is the desired decrease rate of SoC. The linear decrease behavior of $SoC(k)$ imposes a desired rate given by:

$$SoC'_{ref}(k) = \frac{SoC_{min} - \widehat{SoC}(k)}{t_{max} - k} \tag{17}$$

where t_{max} and SoC_{min} are the maximum discharging time and the minimum SoC chosen by the user. $\widehat{SoC}(k)$ can be estimated through online algorithms such as presented in (Didier et al., 2021) with a higher sampling rate.

By choosing the current rate adjustments as the decision variable $w(k)$, we obtain

$$SoC'(w(k)) = \frac{-T_s \cdot 100}{(3600 \cdot C_n)} \gamma(k)(I_{\text{grid}}(k) + w(k)).$$

Now we can define the system matrix as follows:

$$A_k = \begin{bmatrix} 0 & 0 \\ T_s \cdot \rho(k) & 1 \end{bmatrix} \text{ and } B_k = \begin{bmatrix} 1 \\ 0 \end{bmatrix}, \tag{18}$$

where $x(k) := [w(k)\ z(k)]$ and $\rho(k) = \frac{-T_s \cdot 100}{(3600 \cdot C_n)} \gamma(k)$, with $\rho(k) \in [\rho_{\text{min}}, \rho_{\text{max}}]$ imposed by minimum and maximum values of γ and nominal capacity.

Finally, we propose to calculate the decisions here using a feedback control law such as:

$$u(k) = -Kx(k). \tag{19}$$

To find the optimal control gain K that minimizes the error z, the system matrices are used to solve a robust Linear-Quadratic Regulator (LQR) problem (see Appendix A) with a Linear Matrix Inequality (LMI) solution.

3.2.2. Aging rate control design

According to Eq. 8, the increase of γ can be expressed as:

$$\gamma(k+1) = \beta(w(k))\gamma(k)$$

In line with the SoC rate control, $w(k)$ denotes the decision variable adjusted to solve a control problem, particularly a tracking reference problem, and an integrator error tracking $z(k)$ is also employed for minimization. The system to be stabilized is thus defined as:

$$w(k+1) = u(k) \tag{20}$$

$$z(k+1) = z(k) + T_s \cdot (\widehat{\beta}(w(k)) - \beta_{ref}(k)), \tag{21}$$

where $\widehat{\beta}(w(k))$ represents the estimated increase rate of γ, T_s is the control decision rate. β_{ref} denotes the current desired increase rate. The exponential growth behavior of γ imposes a desired rate given by:

$$\beta_{ref}(k) = \frac{1}{(t_{max} - k)} \ln\left(\frac{\Delta\gamma_{ref}^{(n)} + \hat{\gamma}(0)}{\hat{\gamma}(k)}\right) \tag{22}$$

where $\hat{\gamma}(0)$ is the estimated γ at the beginning of the cycle and $\hat{\gamma}(k)$ at each control calculation, t_{max} is the imposed maximum discharging interval, and $\Delta\gamma_{ref}$ is the chosen increase increment of the current cycle, which can be calculated in different ways; we propose calculating it based on the value desired of γ for a chosen number of cycles N as follows:

$$\Delta\gamma_{ref}^{(n)} = \frac{1}{2 * (N - (n-1))} \ln\left(\frac{\gamma_{ref}^{max}}{\hat{\gamma}(0)}\right) \tag{23}$$

n represents the current discharge cycle, while γ_{max} denotes the desired level of γ in cycle N. In this scenario, the vehicle is expected to operate in two shifts: during the day in the parking lot and the remainder of the day on regular routes, which counts as an additional full discharge. Although real-

world usage may introduce random degradation during the vehicle's operational shift, we assume that the cumulative effect of these fluctuations does not surpass the degradation equivalent to two full discharges of the vehicle.

According to Eq. 8, the dynamic of β is defined by $\beta(w(k)) = c_3 R_n(SoC(k))(I_{grid}(k) + w(k))^2$. Now, the matrix of the system can be defined as:

$$A_k = \begin{bmatrix} 0 & 0 \\ T_s \cdot \rho(k) & 1 \end{bmatrix} \text{ and } B_k = \begin{bmatrix} 1 \\ 0 \end{bmatrix} , \quad (24)$$

where $x(k) := [w(k)\ z(k)]$ and

$$\rho(k) = 2 * c_3 R_n(SoC(k)) I_{grid}(k),$$

with $\rho(k) \in [\rho_{min}, \rho_{max}]$ imposed by minimum and maximum values of internal resistance and current rate imposed by the grid, and variations on c_3. For this strategy, we also propose utilizing a feedback control law

$$u(k) = -Kx(k),$$

where the control gain K is determined through a robust control LQR problem.

4. Results: V2G scenarios

The degradation battery model presented is used here to simulate an aging battery. The control framework is employed to achieve the objectives of the two different discharge strategies. Firstly, let us describe the simulation scenario used to obtain the results, and then analyze the outcomes of such approaches for battery health management.

4.1. System Description

In real-life scenarios, uncertainties are inherent in the aging process of systems. Various sources of randomness contribute to these uncertainties, stemming from factors such as internal resistance, open circuit voltage, and ambient temperature fluctuations. The interplay of these factors leads to diverse aging acceleration rates, ultimately resulting in varying the battery's lifespan.

The introduced degraded battery model is utilized to simulate the controlled system. The model's parameters, including internal resistance and open-circuit voltage as functions of SoC, are detailed in Appendix B.

The simulated scenario considers the stochastic nature of battery parameters and discharging conditions. The simulation parameters treated as stochastic sources are listed in Table 1.

These conditions vary randomly, as detailed in Table 1, and are subject to change with each simulation of the 20 consecutive days of V2G discharge. For example, Figure 3 outlines the user-defined parameters for each discharge event, including the minimum desired SoC (SoC_{min}) and the maximum discharge duration (t_{max}). These settings collectively determine when the discharge should halt, in conjunction with the minimum voltage, as elaborated in the preceding problem formulation.

Table 1. Simulation parameters

Parameter	Value	Unit
T_{amb}	$\mathcal{N}(23, 3)$	°C
C_1	$\mathcal{N}(2.5, 10^{-2})$	Ah
R_{min}	$\mathcal{N}(0.02, 10^{-2})$	Ω
E_o	$\mathcal{N}(4.2, 10^{-2})$	V
$SoC(0)$	$\mathcal{N}(90, 10)$	%
ϵ_γ	$\mathcal{U}(2e-4, 12e-4)$	-
t_{max}	$\mathcal{N}(4, 1)$	h
SoC_{min}	$\mathcal{N}(10, 1)$	%
P_{grid}	$\mathcal{N}(175, 300)$	W

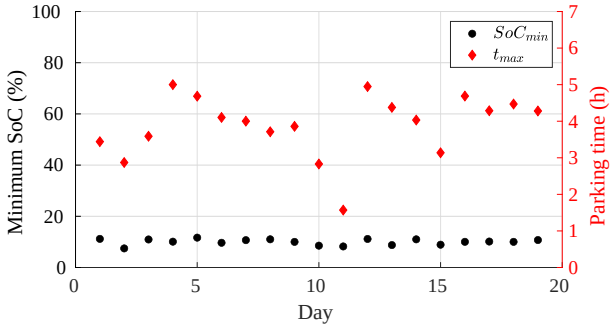

Figure 3. User settings for 20 days in consecutive discharge scenarios.

It is assumed that the battery operates in two shifts: during the day in the parking lot and the rest of the day on regular routes, which contributes to additional aging. Thus, at the start of each new day $n \in [1, N]$, the initial value of $\gamma^n(0)$ is defined as:

$$\gamma^{(n)}(0) = \gamma^{(n-1)}(t_f) + \epsilon_\gamma , \quad (25)$$

where $\gamma^{(n-1)}(t_f)$ represents the level at the end of the last discharging day, and ϵ_γ denotes a random positive additional increase.

Figure 4 displays, then, the initial SoC, $SoC(0)$, representing the battery's starting level upon arrival at the discharge station for the current shift. Additionally, it depicts the additional degradation factor since the last discharge, denoted as ϵ_γ.

Finally, the resulting discharge will depend on the discharging conditions, which will vary with each discharge event. The discharge halts once one of the stop conditions is met. Figure 5 showcases the outcomes of simulations of discharge scenarios without a discharge control. It illustrates diverse discharge histories observed over 20 consecutive days, emphasizing the system's variability influenced by the stochastic nature of battery parameters and discharging conditions.

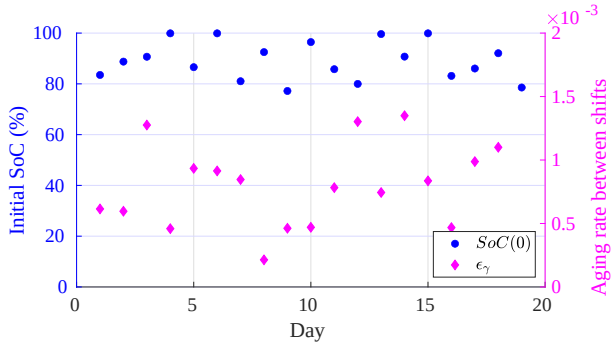

Figure 4. Initial conditions for 20 days in consecutive discharge scenarios.

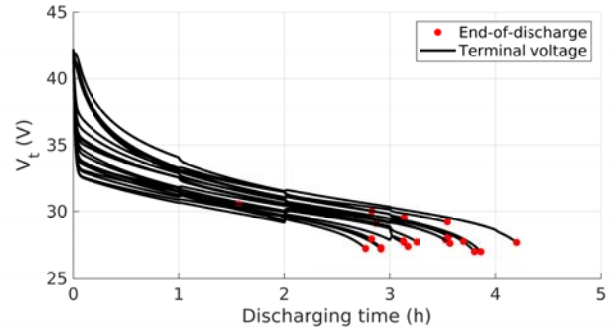

Figure 5. Simulated energy discharge for 20 days in consecutive discharge scenarios for a battery pack of 10 cells.

4.2. Control implementation

In this work, two control strategies are employed to mitigate battery aging, utilizing a feedback control $u(k)$ for the current rate, expressed as $I(k) = I_{\text{grid}} + w(k)$.

SoC Rate Control: For the implementation of the first strategy's control, Eq. (15) is utilized. Employing robust LQR techniques with the previously defined system matrices and simulation parameters, the resulting control gain K is determined as follows:

$$K = [0.011726,\ -70.399]. \tag{26}$$

The initial value for the integral action is calculated according to Eq. (15) as:

$$z_0 = \frac{w_0 + K(1)w_0}{-K(2)}. \tag{27}$$

where the initial decision parameter is chosen to be $w_0 = 0$. Note that, in practice, $w(k)$ is equivalent $u(k-1)$.

Aging rate control: For aging control, Eq. (20) is employed to minimize the reference tracking error. The rate adjustment is accomplished through a feedback control $u = -Kx(k)$, where K is also computed by solving a robust LQR problem with the provided model parameters, yielding the following values:

$$K = [0.9987,\ 5444.5]. \tag{28}$$

It is expected an aging rate reference to be determined according to Eq. (23) using the following parameters:

$$n \in [1, N],\ N = 20,\ \gamma_{\text{ref}}^{\max} = 1.025.$$

Here, $\gamma_{\text{ref}}^{\max}$ is the desired aging parameter value at the conclusion of 20 days, which is set to be lower than the expected value of standard discharging, but could be chosen to respect a prognostic and health management constraint.

4.3. Simulation results

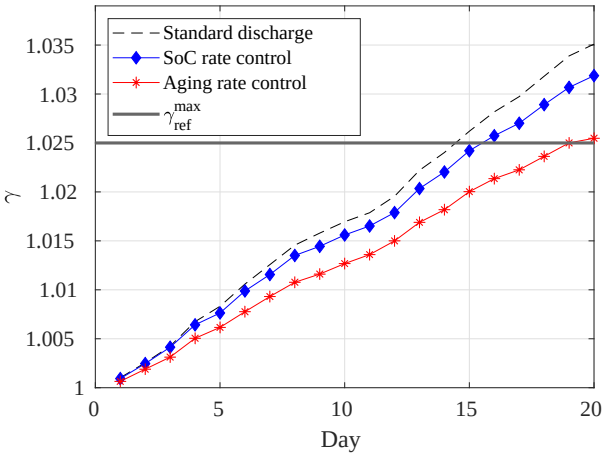
When implementing the control of the SoC decrease rate or the aging control (increase of γ) for the 20 consecutive days scenario, we obtain the respective aging curves of both strategies as shown in Figure (6a). Each day of discharging service resulted in an increase in the rate of γ and energy sold to the grid, as shown in Figure (6b) and Figure (6c), respectively.

The total energy sold through the SoC rate control strategy surpasses that of the γ rate control. This is because the latter prioritizes tracking the desired γ growth rate over maximizing energy discharged. In particular, SoC rate control surpasses standard discharge in total energy when it focuses utilizing the entire available discharge time. Moreover, when examining the aging rate, standard discharge emerges as the least favorable option. SoC rate control effectively mitigates aging by regulating the current rate, although it remains susceptible to random fluctuations determined by the discharge conditions. Conversely, aging rate control continuously adjusts the aging rate to achieve the required γ value by the end of the 20 cycles.

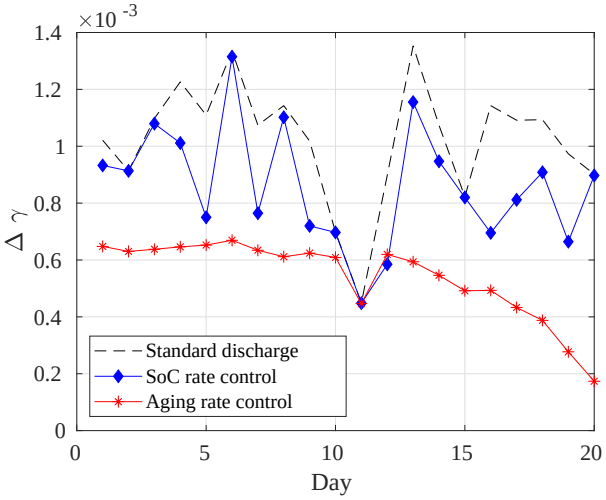
By considering 1.025 as the maximum γ rate (instead of $\gamma = 2$), the total energy sold by the battery in 20 days would be comparable to that of other strategies, as it undergoes more cycles below the maximum γ threshold. Additionally, aging rate control provides the advantage of effectively managing capacity fading. By considering the 20-day rate as a reference and considering the total aging interval ($\gamma = 2$), the battery can reach half of its maximum capacity in about 800 days with aging rate control, a level of certainty not achievable with the other strategies.

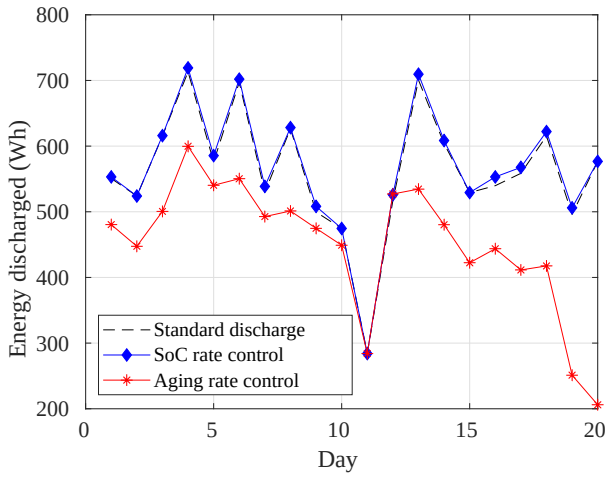
5. Conclusion

This work introduces two health-aware strategies for grid energy sales in a V2G service. The first strategy focuses on managing discharge to maintain the SoC above a specified minimum within the discharge interval, optimizing usage and



(a) Final values of $\gamma^n(t_f)$





(c) Total energy discharged to the grid

Figure 6. Results of 20 days ($N = 20$) of discharging for power selling using different strategies.

mitigating stress factors like discharge current. This strategy embodies a basic approach, based on stress factor mitigation, offering a V2G service that considers aging process. The second strategy aims to regulate the aging increase rate during the discharge event to maintain the SoH below a specified maximum within the interval discharging days. Both strategies employ adaptive control of grid demand, designed with robust techniques and error minimization. Results show the first strategy reduces the final aging, represented by the stress factors index, while increasing total energy sold at the discharging end. Conversely, the second strategy prioritizes desired degradation increase rates, potentially compromising energy sold, but it succeeds in managing the aging process. Specifically, the degradation rate regulation strategy ensures that the aging factor reaches the desired level within the specified timeframe, which proves beneficial for lifetime control. Furthermore, it still ensures the sale of energy close to the standard discharge behavior. In summary, this paper's contributions include:

- Incorporating aging effects such as capacity decrease and resistance increase into the discharge behavior of a battery model.
- Health-aware discharging approaches using degradation-rate regulation and discharge-rate regulation.

Certainly, there is significant potential in incorporating SoH and SoC estimations integrated with closed-loop HAC frameworks to effectively manage battery health. Future work involves integrating control approaches with SoC an SoH estimation approaches to validate performance when used in conjunction, particularly in embedded applications. Furthermore, the utilization of other control optimization techniques, such as Model Predictive Control (MPC), to align with different objectives, such as charging process, is encouraged. An extension of this work could involve comparing it with alternative approaches addressing the same issue. Finally, this study lays the groundwork for a charging-discharging parking service with energy selling that integrates strategies for the management of battery lifetime.

APPENDIX A - LQR PROBLEM

Consider a linear system represented in state-space form as:

$$\dot{x} = Ax + Bu$$

where x is the state vector, and u is the control input.

The Linear Quadratic Regulator (LQR) problem is a control strategy designed to create an optimal feedback controller for such linear systems while minimizing a quadratic cost function and stabilizing the system. The objective of the LQR problem is to minimize a quadratic cost function, defined as:

$$J = \int_0^\infty \left(x^T Q x + u^T R u\right) dt \tag{29}$$

Here, Q is a positive semidefinite weighting matrix that penalizes deviations of the state from its desired trajectory, and R is a positive definite weighting matrix that penalizes control effort or deviations of the control input from its desired values.

The optimal control law u is then determined to minimize Eq. 29 and stabilize the system. When the control law is defined as

$$u = -Kx$$

K is the optimal gain matrix found through a stability guarantee function equivalent to the Riccati Equation, which depends on the existence of a positive definite matrix P.

APPENDIX B - MODEL PARAMETERS

In battery discharging, the values of R_n and V_{oc}, as depicted in the equivalent model, vary as functions of $SoC(k)$. These variations can be expressed by the following equations:

$$R_n(SoC(k)) = M * \left(R_{min} + \frac{K_3}{SoC(k)} + \frac{K_4}{100 - SoC(k)}\right) \tag{30}$$

$$V_{oc}(SoC(k)) = M * \left(E_o - K_1 \ln\left(100 - SoC(k)\right) - \frac{K_2}{SoC(k)}\right) \tag{31}$$

$$C_n = M * C_1 \tag{32}$$

Table 2 presents the parameters of the model used for simulation. These parameters are obtained using data from (Fricke, Nascimento, Corbetta, Kulkarni, & Viana, 2023).

Table 2. Battery model parameters

Parameter	Value
M	10
T_s	0.02 s
a	$\exp\left(\frac{-T_s}{50}\right)$
c_3	10^{-8}
K_1	0.27
K_2	0.45
K_3	0.25

ABSTRACT

The maintenance industry is undergoing a major transformation as it embraces the shift towards Industry 5.0. The focus of Industry 5.0 is on the integration of human intelligence with advanced technologies. It emphasizes interaction and collaboration between humans and machines and aims to combine the strengths of both. The efficiency of prognostics and health management (PHM) for maintenance in industrial contexts can be enhanced by improving this human-machine interaction and collaboration. This paper investigates the human-centric aspects, with a focus on PHM systems for facilitating the enablement of Industry 5.0 in maintenance. Acknowledging human as an active participant, this study explores their integral role in designing and developing PHM systems. The data collection for this study has been based on available literature, active and passive observations, and unstructured interviews and discussions with experienced industry professionals. As a result of the analysis of collected data, this study identifies and highlights potential areas for research and exploration. The research in these areas can advance the understanding and application of human-centric PHM strategies within Industry 5.0 in maintenance contexts. This is expected to improve the resilience and sustainability aspects of the industrial ecosystem and facilitate the shift towards Industry 5.0.

Keywords— Maintenance, Prognostics and Health Management, Industry 5.0, Human-centric

1. INTRODUCTION

The industrial revolution over the years has led to systematic developments and advancements in all sectors of society. Industries have grown dramatically, starting with the mechanical revolution of the "steam engine" era (Industry 1.0), progressing towards electrical breakthroughs (Industry 2.0), developing further into the computerization and automation era (Industry 3.0), and now towards cyber-physical systems (Industry 4.0) (Leng et al., 2022). Even though Industry 4.0 is still under constant research and development, the concept of Industry 5.0 is being actively defined, discussed, and explored by academia, industry, and policymakers. It aims to extend, complement, and build on the technological advancements of its predecessor, Industry 4.0 (Raja Santhi & Muthuswamy, 2023).

The concept of Industry 5.0 is based on integrating human-centric aspects with advanced technologies for enhanced productivity and operations (Nahavandi, 2019). It emphasizes on human-centric aspects like human-machine collaboration, worker well-being, empowering workers with enhanced decision-making, and personalized/customized systems that can enhance the industry's sustainability and resilience aspects (Adel, 2022; Industry 5.0: Towards More Sustainable, Resilient and Human-Centric Industry - European Commission, n.d.). Unlike its predecessors, where the key factors were automation and technology which gave the idea of the technologies as a partial replacement for humans, Industry 5.0 seeks to integrate the strengths of both humans and machines to optimize industrial processes. In this context, it involves the integration of human intelligence, creativity, and experience, with the capabilities of advanced technologies such as AI, data analytics, IoT, etc. (Ghobakhloo et al., 2023)

PHM leverages data analytics, condition monitoring systems, digital twins, and other advanced technologies to forecast potential failures and issues before they occur, allowing proactive maintenance actions to be taken. This shift towards predictive maintenance, facilitated by PHM, helps minimize unplanned downtime, optimize maintenance costs, and improve overall asset effectiveness (Zio, 2022).

Industry 5.0 will further facilitate PHM in maintenance by focusing on human-centric aspects, which will enable maintenance workers to leverage PHM data and insights to make more informed, adaptive, and resilient maintenance decisions.

The purpose of this study is to advance the understanding and application of human-centric PHM strategies within Industry

5.0 maintenance contexts and make the industrial ecosystem more resilient and sustainable.

The objectives of this study are:

1. To investigate the human-centric aspects of Industry 5.0 in maintenance, focusing on PHM systems.
2. To identify the potential areas for research and exploration for advancing the understanding and application of human-centric maintenance strategies within the context of Industry 5.0.

2. METHODOLOGY

This study was conducted using a mixed-method research approach to investigate the human-centric aspects, with a specific focus on PHM systems for facilitating the enablement of Industry 5.0 in maintenance. The methodology followed consisted of the following components:

- Literature Review: A review of existing literature was conducted on Industry 4.0 and 5.0, human-centric aspects, PHM systems, and maintenance efficiency to establish a theoretical foundation for the study.
- Observations: To understand the practical implementations and dynamics of human-machine interactions in industrial maintenance, active and passive observations were made. This included observing industrial professionals utilizing PHM systems in real-world settings to see how they interact with these systems during their daily operations. Observing demonstrations of maintenance systems in laboratory settings during lab visits, which included a diverse audience ranging from students to industry professionals.
- Unstructured Interviews and discussions: Conducted unstructured interviews and discussions with asset managers from companies serving as knowledge partners for rail vehicles and public transport agencies in Sweden. These interviews/discussions were conducted during workshops, seminars, and regular meetings. They provided strategic insights into the adoption and challenges of PHM systems. They additionally provided us with valuable insights from maintenance worker's perspective enabling us to gather firsthand information on their experiences, challenges, and perspectives regarding the integration of human aspects into PHM systems.
- Data Analysis: Qualitative analysis of data collected from literature surveys, observations, and interviews to identify key themes, patterns, and challenges associated with human-centric PHM strategies in Industry 5.0 maintenance contexts.

3. LITERATURE REVIEW

A review of existing literature was conducted on Industry 4.0, and Industry 5.0 in connection with maintenance and PHM systems to establish a theoretical foundation for the study. Since human-centricity is a key factor in moving towards Industry 5.0, we conducted a literature review on human-centric aspects in maintenance and PHM. These considered reviews were from the period 2014 - 2024. To help understand the Industrial Revolution journey, works focusing on the revolutions thus far were also considered. These works dates from 1956 till the present. Key search terms included "Industry 4.0 AND PHM", "Industry 4.0 AND maintenance", "Industry 5.0 AND PHM", "Industry 5.0 AND maintenance", "Human-centric AND PHM", and "Human-centric AND maintenance". In total, the study was conducted with 26 relevant works of literature.

3.1. Industrial Revolutions Leading to Industry 5.0

The Industrial Revolutions, over the years, have helped in shaping the current industrial landscape. Starting in the late 18th century, the first industrial revolution was enabled by the mechanical revolution and the usage of steam power resulting in faster production processes (Martinelli et al., 2021). Subsequently came the 2nd Industrial Revolution, which focused on the electrical revolution for mass production techniques and implementing assembly lines. Industry 3.0 brought the digital revolution with IT and automation transformations which resulted in significant technological advancements and societal changes.

The current Industrial Revolution i.e. Industry 4.0 saw an increase in Cyber-Physical Systems, IoT and AI which focused on the integration of technology with physical assets. The focus has been primarily on the technological aspects, with limited attention paid to the human and social factors within organizations (Moraes et al., 2023). Extending this is the concept of Industrial 5.0, which works alongside the technological advancements till Industry 4.0 but puts humans in the centre of it. Figure **1** shows an advancement of industrial processes from an abstract level.

The revolutionary journey from the first industrial revolution to Industry 4.0, which focused on a technology-driven approach emphasizing digitalization and advanced technologies like digital twins, AI and cybersecurity, laid the foundation for Industry 5.0 (Nagano, 2019). Industry 5.0, as introduced by the European Commission, (*Industry 5.0 - European Commission*, n.d.) represents a shift towards a user-centric and value-driven approach, emphasizing the crucial role of humans in the industrial process and promoting principles of social well-being, sustainability, and human-machine collaboration (Beaudreau, 2018; Verma et al., 2022).

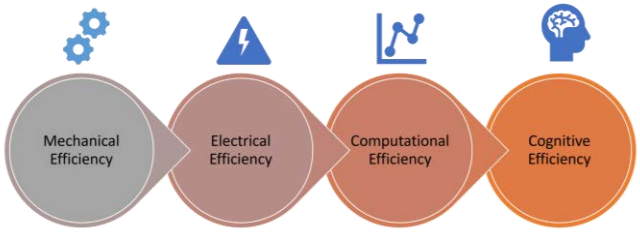

Figure 1: Advancing of Industrial Processes

Industrial revolutions have had significant impacts on maintenance practices, influencing how industries manage and upkeep their machinery and equipment. Table **1** (adapted by (Poór et al., 2019) shows the relationship between industrial revolutions, their enablers and key maintenance facilitators(Coleman, 1956). It is important to note that the mentioned enablers and maintenance facilitators extend and complement their predecessor's enablers and maintenance facilitators respectively.

Table 1: Industrial Revolutions- enablers and key maintenance facilitators

Industrial Revolution	Enablers	Key maintenance facilitators
Industry 1.0	Mechanical Revolution, Steam Power	Visual Inspection
Industry 2.0	Electrical Revolution, Mass production	Instrumental/Tool Inspection, Preventive Maintenance
Industry 3.0	Digital Revolution, Automation	Sensors, CMMS, Predictive Maintenance
Industry 4.0	Cyber-Physical Systems, IoT, AI, ML	Data Analytics (Predictive Analytics), Digital Twins, Condition-Based Maintenance
Industry 5.0	Human-Machine Collaboration, AI, ML	HSI, Advanced Predictive Analytics, AR/VR, Blockchain

3.2. Industry 5.0 and its implications for the maintenance industry

According to the European Commission (*Industry 5.0 - European Commission*, n.d.; *Industry 5.0: Towards More Sustainable, Resilient and Human-Centric Industry - European Commission*, n.d.), implementing Industry 5.0 means placing the well-being of humans at the centre of the industrial processes. It encourages the usage of advanced technologies to focus beyond productivity and efficiency and emphasizes the well-being of the human workforce while considering the planet's resource constraints. It builds on the existing industrial revolution i.e. Industry 4.0 and compliments it while focusing on three key factors, Human-centricity, Sustainability and Resilience (Figure 2).

Industry 5.0 emphasizes the collaboration between humans and machines, focusing on enhancing human creativity and well-being while leveraging advanced technologies like big data analytics, IoT, collaborative robots (cobots), Blockchain, digital twins, and future 6G systems (Adel, 2022; *Industry 5.0 - European Commission*, n.d.).

The impact of Industry 5.0 on the maintenance industry is profound. It implies the usage of modern advanced technologies with a human-centric approach to sustainable and resilient maintenance processes. It involves data-driven decision-making that addresses potential maintenance faults before they lead to breakdowns, optimising operational efficiency, reducing downtime, keeping customers satisfied, and contributing to sustainability efforts by focusing on repair and recycling rather than replacement (Psarommatis et al., 2023).

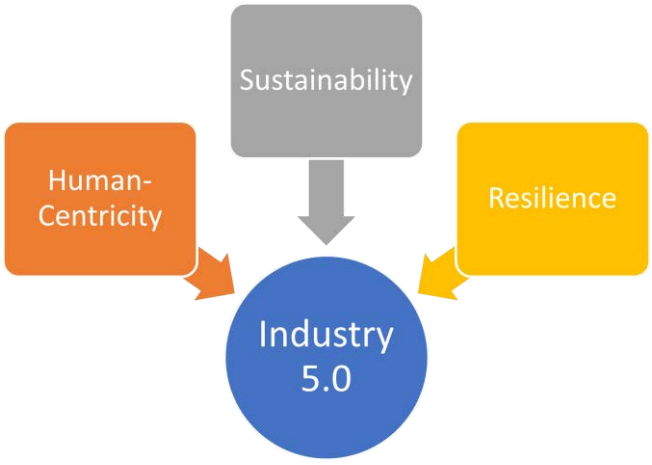

Figure 2: 3 pillars of industry 5.0

3.3. Prognostics and Health Management (PHM) Systems and Industry 5.0

PHM systems are designed to monitor the health of industrial assets. In the context of Industry 5.0, PHM systems can be seen as a cornerstone for the integration of modern advanced technologies like big data analytics, IoT, and A) with human-centric approaches within industrial maintenance practices. It enhances the efficiency and effectiveness of maintenance

practices, operational efficiency, and sustainability of industrial operations. (Biggio & Kastanis, 2020) (Adel, 2022).

Industry 5.0 places human well-being at the centre of industrial processes. PHM systems support this approach by empowering maintenance workers with real-time insights and decision-support tools. By providing workers with data-driven insights about equipment health and performance, PHM systems help integrate human intelligence with these insights to make informed decisions, optimize maintenance activities, and ensure the safety and well-being of workers in industrial environments (Kumar et al., 2023).

PHM systems also play an important role in ensuring the sustainability and resilience of industrial maintenance processes. By forecasting asset failures and scheduling maintenance actions at optimum times, these systems help to minimize waste and reduce the environmental impact of manufacturing operations contributing to the sustainability factor(Ghobakhloo et al., 2024). Additionally, PHM systems contribute to the implementation of smart factories, which are a key aspect of Industry 4.0 and Industry 5.0, by providing real-time insights into the health of industrial assets and enabling more efficient and effective maintenance strategies which contribute to enhancing the resilience of the industrial assets (Kumar et al., 2023).

Predictive maintenance (PdM) which is facilitated by PHM systems monitors the health of industrial assets, predicts potential failures, and optimizes maintenance schedules based on the predicted future state of equipment components. By adopting a human-centric approach to PdM within the Industry 5.0 framework, organizations can enhance decision-making processes, increase trust between decision-makers and predictive models, allocate resources effectively, and improve overall maintenance effectiveness(van Oudenhoven et al., 2023).

Therefore, the integration of human-centric maintenance practices within the principles of Industry 5.0 enables proactive management of maintenance needs, reduces costs, enhances operational efficiency, ensures equipment reliability, and contributes to sustainable maintenance practices by focusing on repair and recycling rather than replacement. This connection highlights the importance of predictive maintenance which is facilitated by PHM systems as a key enabler of Industry 5.0's vision for smarter, more efficient, effective, and human-centred maintenance processes.

3.4. Human involvement in designing and developing PHM systems

In the era of advanced technologies, a human-centric approach to developing PHM systems for industrial maintenance is not just desirable but essential. A human-centric PHM system empowers users with intuitive interfaces, actionable insights, and decision support tools to optimize maintenance strategies ultimately leading to more efficient and effective maintenance activities.

Involving domain experts and their insights into industrial processes, especially maintenance activities, aids in focusing on critical aspects that are prone to failure. Domain experts collaborate with developers early on to define system requirements tailored to operational contexts, and technician knowledge levels (Toothman et al., 2023). Humans can also consider factors like production load, environmental conditions, and other maintenance activities that may influence asset health, which algorithms might overlook (McDonnell et al., 2018).

Humans also play a critical role in selecting the relevant data points for training and monitoring equipment health, ensuring the quality of data used in PHM systems and interpreting system outputs (Siew et al., 2020). Additionally, Usability Engineering and Usability Requirement Analysis are critical areas where specialists ensure that PHM systems meet the maintenance personnel's needs and requirements in a user-friendly manner.

Usability Engineering aspects emphasize visually presenting clear explanations, minimizing cognitive load to enhance usability and ensure effective decision-making for maintenance personnel (McDonnell et al., 2014). This human-centred approach is essential to optimize the functionality and user-friendliness of PHM systems, making them more accessible and efficient for operators.

Usability Requirement Analysis, on the other hand, focuses on identifying and documenting the usability needs and objectives of the system. This involves gathering and analysing user requirements related to usability, accessibility, and user experience, providing a framework for designing and evaluating the user interface.

Customized PHM dashboards can prioritize relevant data points for specific tasks and assets, aiding in quicker issue identification and efficient maintenance actions. Alerts and notifications can also be tailored according to their criticality reducing information overload and ensuring timely response to critical issues(McDonnell et al., 2014).

Another interesting area is to investigate the legitimacy aspect of PHM systems for a necessary understanding of why such predictions were made, fostering trust in the system and the recommendations made by it. It will encourage confident decision-making by the technicians. This comes under the umbrella of Explainable AI for trust and continuous improvement. It enables debugging in case of incorrect recommendations, and human-in-the-loop learning for continuous improvement of algorithms. By understanding the reasoning behind predictions, humans can detect and address these issues, leading to improved accuracy and reliability of the PHM system (Amin et al., 2022; Nor et al., 2021).

4. RESULTS

This research highlights some key insights while integrating human-centric aspects with PHM systems within the context of Industry 5.0 and industrial maintenance.

Following are the findings for the objectives of this study:

Objective 1: To investigate the human-centric aspects of Industry 5.0 in maintenance, focusing on PHM systems.

Industry 5.0 places the well-being of humans at the centre of industrial processes. It emphasizes the collaboration between humans and machines. PHM systems play an important role in this approach, empowering maintenance workers with valuable insights and decision-support tools. These systems when integrated with human intelligence and data-driven insights can optimize maintenance activities and ensure worker safety and well-being.

Integrating human aspects into PHM systems involves real-time collaboration between human operators and machines and the incorporation of human-in-the-loop mechanisms. These possibilities aim to enhance the usability, acceptance, and integration of PHM systems within industrial work environments.

Objective 2: To identify potential areas for research and exploration for advancing the understanding and application of human-centric maintenance strategies within the context of Industry 5.0.

The identified areas for further exploration within the context of Industry 5.0 and industrial maintenance especially PHM systems include human-system interaction, Explainable AI, Usability Requirement Analysis and Usability Engineering. These areas highlight the need for exploring the dynamics of human-machine collaboration and identifying strategies to optimize human-system interactions for improved maintenance activities and enhanced decision-making. Observations and discussions with maintenance professionals have highlighted the critical role of seamless human-system interaction in enhancing operational efficiency. Additionally, future research will delve into Explainable AI, to enable maintenance personnel to understand the reasoning behind AI-generated predictions and recommendations, fostering trust in the system and facilitating human-in-the-loop processes for continuous improvement. Insights from unstructured interviews and discussions emphasized the importance of transparency in AI systems for maintenance workers. Furthermore, Usability Requirement Analysis will play a pivotal role in identifying and prioritizing user needs and preferences in the context of PHM systems. This area benefits significantly from feedback gathered through interviews and discussions with asset managers. Usability Engineering will play a crucial role in designing user-centric interfaces and interactions for PHM systems in the Industry 5.0 context to enhance the usability and user experience for maintenance personnel. Laboratory observations and real-world use cases have provided valuable insights into the need for creating more effective and user-friendly maintenance systems. Figure 3 shows the key insights of Industry 5.0 within the industrial maintenance context.

The transition to Industry 5.0 introduces several innovative challenges as compared to conventional maintenance activities. These include the integration of advanced technologies which require new skills and training for the users/workers. The focus shifts towards creating more responsive, robust, and resilient maintenance systems.

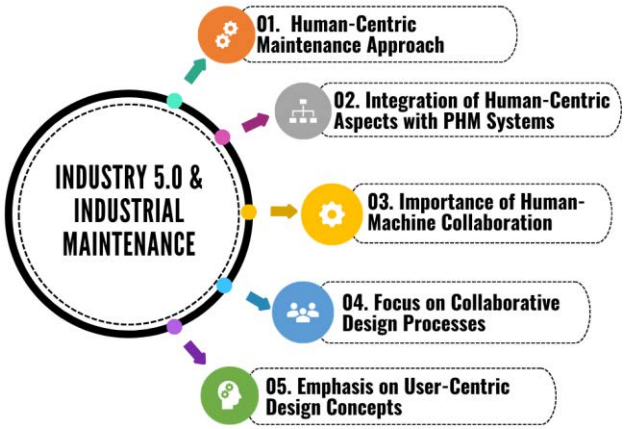

Figure 3: Key insights of Industry 5.0 within the industrial maintenance context

5. CONCLUSION

The maintenance industry is constantly developing and with the latest industrial revolution i.e. Industry 5.0, the shift is towards a human-centric maintenance approach. The research on industrial maintenance especially the PHM systems within the context of Industry 5.0 is important. It emphasizes the significance of the role of human involvement in optimising maintenance practices. The integration of human-centric aspects with PHM systems also enables industries to improve asset reliability and enhance operational efficiency. Furthermore, the findings emphasize the importance of human-machine collaboration, and data-driven decision-making in realizing the full benefits of Industry 5.0 in maintenance operations. While interviews primarily focused on railway experts, the findings can be extended to various industrial settings, indicating broader applicability. This research highlights the need to focus on collaborative design processes and user-centred approaches to ensure effective human-machine interactions, which are essential for the successful implementation of maintenance practices within the context of Industry 5.0.

The future research will be built on the findings and insights from this research. Future work will focus on achieving a more seamless and efficient human-machine interface, considering human-centric aspects during system design and implementation. As a result, maintenance activities will eventually be more effective and efficient. An important area of research is quantifying the effectiveness and efficiency of such human-centric PHM systems.

ACKNOWLEDGEMENT

We gratefully acknowledge the European Commission for its support of the Marie Sklodowska Curie program through the H2020 ETN MOIRA project (GA 955681). We also acknowledge the valuable support and resources provided by the eMaintenanceLAB in conducting this research.

ABSTRACT

Reliability of oil distribution transformers is paramount, ensuring a stable flow of electricity and shielding from potential fire hazards. The internal insulation system of these transformers utilizes a combination of oil and paper. As the oil circulates through the active part of the system, it collects gaseous and physical traces of existing or past defects or degradations, providing a holistic view of the transformer's health, and allowing for early detection of problems and predictive maintenance. While various and mainly data-driven methods have been developed to calculate a transformer health index from oil samples, they lack accuracy due to limited data. This paper proposes a novel hybrid approach that leverages both Artificial Intelligence and Subject Matter Expertise to enhance the health estimation of oil distribution transformers. Our methodology utilizes a substantial dataset exceeding 65,600 analyzed oil samples, coupled with the valuable knowledge of domain experts. This combined approach achieves an accuracy exceeding 95%, suitable for real-world industrial applications. Furthermore, we introduce a risk management feature that strengthens the ability to identify transformers at high risk of failure. Notably, the health index estimation is implemented as a semi-automatic process, retaining the "expert in the loop" principle for managing critical and ambiguous cases.

1. INTRODUCTION AND PROBLEM STATEMENT

Distribution transformers convert high-voltage electricity from transmission lines into usable power for homes, businesses, and industries. Their reliability is paramount, ensuring a stable and continuous flow of electricity, shielding us from power outages, and potential fire hazards. Regular inspections, advanced fault detection systems, condition monitoring, and proper maintenance are crucial for those transformers. The internal insulation system of a transformer is provided by both oil and paper. As the oil circulates through the active part of the system, it collects gaseous and physical traces of existing or past defects or degradations. Therefore, it provides a holistic view of the transformer's health, allowing for early detection of problems and enabling predictive maintenance. In such a process, oil samples are extracted and analyzed in the laboratory regarding their physical and chemical properties (dielectric strength, acidity, humidity, color, and dissolved gas concentration). Sample extraction and analysis are done on a regular basis that can range from a several months to year periodicity. The results are interpreted by experienced subject matter experts who attribute a Health Index (HI) to the transformer and guide maintenance actions that could be required. The huge number of oil distribution transformers currently in operation and the limited number of experienced subject matter experts available to estimate the HI of these devices, motivates to support them. Several methods were developed to automatically compute the HI. A review of HI automatic assessment techniques for distribution and power transformers was proposed by Quynh T. Tran, Kevin Davies, Leon Roose, Puthawat Wiriyakitikun, Jaktupong Janjampop, Eleonora Riva Sanseverino and Gaetano Zizzo (2020). Some of the techniques rely on on-line data, which is not the scope of this study. Most of the techniques that rely on off-line data are fully data driven. The HI estimations done by experts not only rely on standardized combinatory calculations, but also reflect the human expertise in interpreting results. Consequently, it is difficult to translate them into mathematical formulas and several studies implemented fuzzy logic approaches, as proposed by Ahmed E. B. Abu-Elanien M.M.A. Salama, and M. Ibrahim (2012). Whatever the data-driven algorithm used, these methods are poorly

explainable, which reduces their capacity to be adopted in real operations. Only some of them rely on hybrid approach combining expert knowledge, either for feature selection, as proposed by Khalil Ibrahim, R.M. Sharkawy, H.K. Temraz and M.M.A. Salama (2016), or for uncertainty management, using Bayesian modeling, as proposed by P. Sarajcev, D. Jakus, J. Vasilj, M. Nikolic (2018). Finally, while these approaches offer intriguing avenues, they rely on very limited data set, with fewer than 100 samples (Ahmed E. B. et al. (2012), P. Sarajcev et al (2018), Atefeh Dehghani Ashkezari et al. (2012), Jahanzaib Javid et al. (2021), Ahmed E. B. Abu-Elanien et al. (2011)). These restricted datasets are unlikely to encompass the exhaustive spectrum of parameter combinations, rendering them poorly fit for real-world implementation, especially considering the safety concerns.

Now, the motivation of this work is precisely to build a prognostics and health management solution that is suitable for industrial usage, meaning performant enough, resilient enough, and preserving safety in any case. The core of this work is an original hybrid approach relying on both Artificial Intelligence (AI) and Subject Matter Expertise (SME), making the most of AI and human expertise. Practically, this approach is supported by more than 60 000 oil samples that were analyzed and from which experts provided Health Index estimations. Indeed, the idea is to train a Machine Learning (ML) algorithm to estimate HI from oil samples analyses results (Figure 1). The performance criterion that is pursued is the global accuracy of the health estimation, with a special focus on the ability of detecting transformers at risk, for obvious security reasons. The solution is also expected to be explainable and to be suitable with an "keeping expert in the loop" approach. Indeed, the target solution is not a fully automated solution, but rather a mostly automated solution that will keep experts in the loop for managing the most ambiguous and critical cases.

The paper describes the health estimation global solution, starting with the data science steps, from data collection, data cleaning, outliers' detection, imputation for managing missing data, up to the model selection and validation. It also emphasizes the way subject matter expertise was combined with AI techniques. It describes the risk management method that was introduced to minimize the risk of failing to detect at risk transformers. Finally, it practically describes the global health evaluation process in an industrial context with a "keeping expert in the loop" approach that was mentioned above.

2. HYBRID HEALTH ESTIMATION METHOD

2.1. Introduction

The method that is used is said hybrid approach as it is based on both machine learning and subject matter expertise. The machine learning pillar is a standard approach from a data science point of view, supported by subject matter expertise at all stages (feature engineering, outliers' detection, missing value management, result validation). The expertise is also explicitly integrated in a rules-based approach that complements the machine learning approach to refine health estimation. The current section covers the following technical data science steps: data collection, data cleaning, outliers' detection and validation, missing values management, models benchmarking, including oversampling and/or subsampling methods, and rule-based classification.

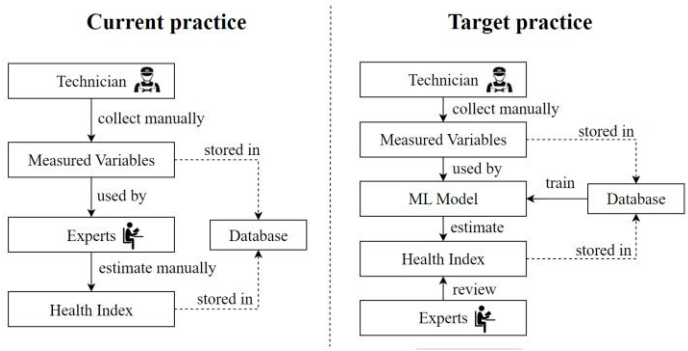

Figure 1: Current and target practice.

2.2. Data collection

This study focuses on distribution transformers which power is less than 3150 kVA and using mineral oil. Data from oil analyses over the past 10 years were used, representing approximately 65,600 analyses for 40,000 distinct transformers (as some of them have been analyzed several times all along their lifecycle). The predictive variables identified in the data are the levels of dissolved gases, color, acidity and humidity, as the dielectric strength. The target of our study is the Health Index (HI), which was estimated by experienced subject matter experts, based on the oil analysis result. Predictive variables and target are given in Figure 2.

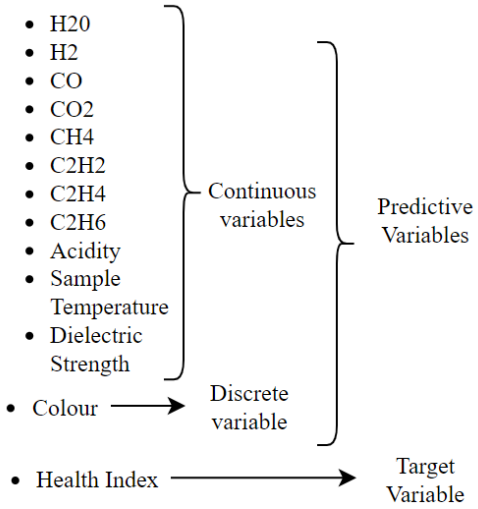

Figure 2: Predictive variables and target.

The distribution of the Health Index is intrinsically highly unbalanced: for most of the analyses the Health Index is evaluated by experts at 1 (around 90%), followed by a smaller number of analyses with a Health Index of 2 (around 9%), and finally an even smaller number of analyses with a Health Index of 3 (around 1%). A Health Index equal to 1 means that the transformer is perfectly healthy, a Health Index of 2 is an intermediate status showing some anomalies, non-serious at this stage but requiring some surveillance, and a Health Index of 3 means critical anomalies that require immediate maintenance actions.

2.3. Outliers' detection

The data cover more than 10 years of oil analyses carried out by technical experts. As the analysis process is manual, it may be possible to have some errors in the data. In this study potential errors were tracked using an anomaly detection approach. Then, each anomaly was reviewed, confirmed or not to be an error, by technical experts. The anomaly detection used in this study relies on a statistical test: the Hotelling's T-squared test. Hotelling's test is a multivariate statistical test used to determine if there are significant differences between the means of two groups in a multivariate space. In anomaly detection, it allows us to compare the mean vector and covariance matrix of a single data point (or a small group of data points) to those of a reference group. If the data point falls outside a certain threshold based on the T-squared statistic, it's flagged as an anomaly. When using Hotelling's T-squared test, it's important to ensure that the data follow a multivariate normal distribution, as it is an assumption it relies on. In the present case, dissolved gas concentrations follow an exponential distribution, so a logarithmic transformation was needed before running the test. Using a 99% confidence level for setting the T-squared threshold, 125 analyses (out of a total of 65,600 analyses, meaning 0.2%) were identified with potential errors. As atypical does not mean error, it was necessary to have those analyses reviewed by technical experts to confirm whether or not the presence of errors. In the end only 17 analyses were confirmed with errors and removed from the dataset. For the other analyses initially flagged the level of some dissolved gases was exceptionally high but perfectly credible.

2.4. Models benchmarking

To choose the machine learning algorithm that will be the basis of our hybrid approach, we perform a model screening, by doing a classification test with nine different algorithms, on all analyses for which no data are missing. The imputation method for managing missing data is studied later, after finetuning the hyperparameters of each algorithm. According to the results shown in Table 1 and obtained with a 12,000 analyses validation dataset, it appears that the most performant algorithm is the Random Forest Classifier. Accuracy is not the only performance criterion that we want to meet. Indeed, interpreting the model and validating, to some level, its consistency with the subject matter expert's way of working is another relevant criterion. A Random Forest algorithm doesn't allow to clearly identify the reasons behind a given prediction, as the final output is a combination of many decision trees, making it difficult to pinpoint the logic for each prediction. However, Random Forest algorithms usually embed feature importance techniques that show how much a specific feature contributes to the overall mode. Such a technique was used, and it could be verified that the top 3 most influencing features, Hydrogen (H2), dielectric strength and acetylene (C2H2), are consistent with the subject matter expertise, which historically allows to estimate the HI. Indeed, Hydrogen (H2) is the gas produced by most technical faults, so an analysis of oil sample done by experts always starts with this gas. The dielectric strength (also called rigidity) provide experts with a good indication of the water present in the transformer oil and therefore of the risk during operation: a too low dielectric strength induces a risk of flashover. Even in the field, this parameter is checked after certain maintenance operations, before restarting the equipment. Finally, acetylene (C2H2) is synonymous for experts with an electric arc, and therefore a major electrical fault. This consistency between algorithm feature importance and subject matter expertise gives trust in health estimation algorithm.

Table 1: Classifiers' performances obtained on the validation dataset.

Classifier	Accuracy	AUC	Recall	Precision
Random Forest	0.96	0.93	0.96	0.95
Extreme Gradient Boosting	0.96	0.92	0.96	0.95
Light Gradient Boosting	0.96	0.93	0.96	0.95
Gradient Boosting	0.96	0.93	0.96	0.95
Extra Tree	0.95	0.92	0.95	0.95
Ada Boost	0.95	0.85	0.95	0.95
Logistic Regression	0.94	0.82	0.94	0.93
Decision Tree	0.94	0.79	0.94	0.94
K Neighbors	0.93	0.67	0.93	0.90

2.5. Imputation of missing values

In the dataset used for the study (representing 65,600 analyses), the data corresponding to the dissolved gas concentrations are complete for all analyses (no missing value for any of the dissolved gases). Concerning the other

data, a value is missing for less than 10% of the analyses. Different approaches to impute missing values were tested. The goal of this step is to make the most of all analyses, even those for which a value is missing. First, the simplest imputation method was chosen as a reference: imputation by the mean. This method consists in replacing the missing values for a given feature by the average value of the feature itself. Then, the data imputation was tested using two other methods that follow a similar approach: iterative imputation. Rather than simply replacing missing values with point estimates, iterative imputation makes multiple passes over the data, using the observed values to estimate and fill in the missing values, and then repeating this process several times to improve the estimates. This allows for data variability and relationships between variables, providing more robust estimates. Iterative imputation methods may include statistical models or machine learning techniques to estimate missing values. wo variants were tested. The first one is a standard version of iterative imputation, that includes a linear regression to estimate missing values. This first variant is promising as there are significant correlations between some of the variables, as can be seen in Figure 3. Indeed, for each analysis, each input parameter can be quite well estimated thanks to the others. The second variant, also called Miss Forest, uses Random Forest models to predict and fill in missing data. It builds separate models for variables with missing data, using the available data to make accurate predictions. This method is effective for handling both continuous and categorical variables.

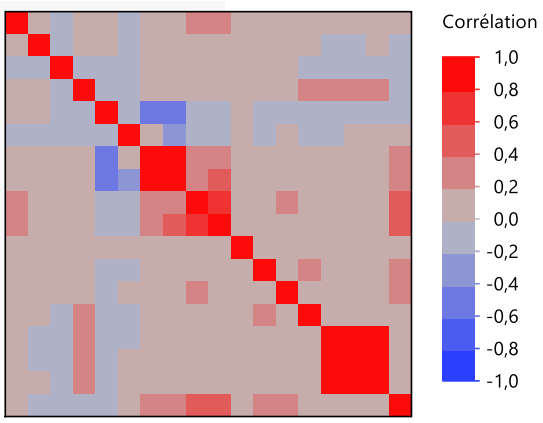

Figure 3: Correlation between parameters. Each row and each column are input variables (features).

Here we compare the output results of the Random Forest classifier using the three different imputers, on the analyses for which at least one value is missing. They all lead to the same accuracy, and according to the results shown in Table 2, it appears that the iterative imputation using a linear regression shows the best results in terms of precision for HI=1 class, recall for HI=3 class and proportion the falsely predicted HI 1 instead of 3. Therefore, the classic iterative imputer was chosen as imputation method.

Table 2: Imputation using iterative imputer, simple (mean) imputation, and Miss Forest.

Imputation method	Precision HI=1	Recall HI=3	Proportion of HI 3 diagnosed as HI 1
Iterative Imputer (Linear Regression)	**0.97**	**0.63**	**0.17**
Simple Imputation (Mean)	0.96	0.57	0.17
Miss Forest	0.96	0.57	0.38

2.6. Subject matter expert – Rule based Classification

2.6.1. Compliance with normative values

After having apply technical rules that must be respected to remain in compliance with the normative values, the expert predicted a Health Index. Concretely, these rules allow to frame the result. It is thus impossible in our context to highlight for a given analysis whose values would have exceeded the thresholds set by the normative standards.

2.6.2. Rules based on evolution through time

In most cases, a single analysis allows to set the HI of a transformer, but in some ambiguous cases, experts do use the past analyses of the same transformer (up to two additional past analyses) to refine their diagnostic. By combining last analysis results with the evolution in the dissolved gas concentrations between successive analyses, experts set the final HI. Such an approach was mimicked in the study to even improve the classification accuracy obtained from the last analyses, as shown in previous section. It led to a one-point increase in global accuracy.

2.7. Global scheme of the health estimation process

The global health estimation process, presented in Figure 4, is semi-automatic as the expert remains present in the process, to analyze and recommend maintenance actions for transformers whose Health Index is evaluated at 3, the most critical level. It is also hybrid because it relies on a machine learning core and on rules provided by the experts in the field.

It consists of three blocks:

- The machine learning prediction, based on the last analysis.
- The legal rules that ensure the compliance of any parameter of this last analysis.
- The expert rules that consider the evolution in dissolved gas concentration evolution through time, based on previous analyses.

The details of the process that includes those three main blocks are provided in Figure 4. In this figure, note that details about the cost matrix are provided in section 3.

Finally, once HI has been estimated, if it appears to be equal or superior to 2, an expert is asked to review the analyses and to provide recommendations in terms of maintenance and/or additional analyses to perform. It can also trigger a reclassification to class 1 (healthy transformer) if the expert concludes that a HI of 2 or 3 is not justified (Figure 5).

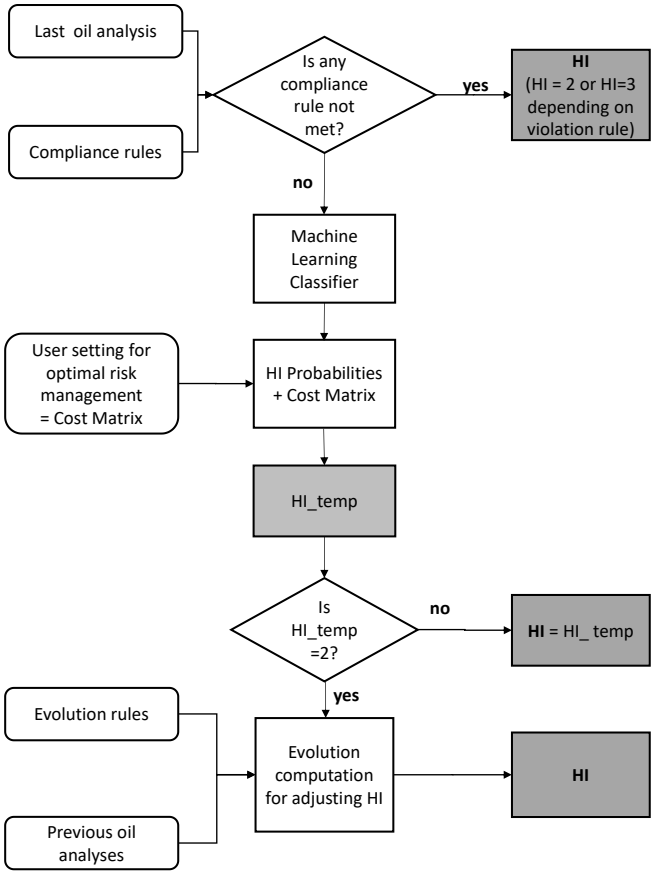

Figure 4: HI estimation synoptic. Inputs are on the left; computation are in the middle, and output is on the right.

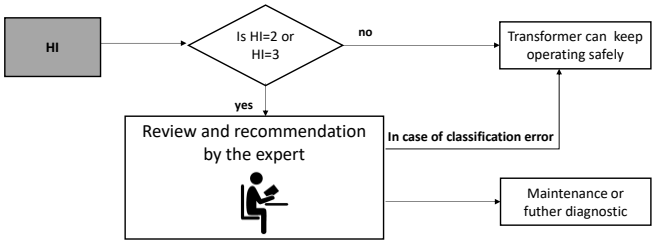

Figure 5: Health Index usage with "expert in the loop"

3. RISK MANAGEMENT FEATURE IN HEALTH ESTIMATION

3.1. Methodology

As described in the introduction, not detecting an at-risk transformer would lead to a risky situation that could have catastrophic consequences. On the other hand, wrongly categorizing a transformer as at-risk whereas it is healthy has minor consequences, as any at-risk transformer will be manually expertised. Indeed, the expert who would analyze such a transformer would set it back in the correct healthy category, with minor consequences, except the time spent for such analysis and action. This means that there is a different cost associated to false positive (healthy transformers wrongly detected as at-risk ones) and false negative (at risk transformers wrongly detected as healthy ones), with false negative being more penalizing than false positive. Also, such asymmetry depends on the context of usage. Indeed, having an at-risk transformer into the wild is always a situation to be avoided, but in some cases, it could be even more damaging than in other cases, considering the criticality of the systems that are supplied by the transformer (hospitals for instance) and considering the environment of the transformer and the risks in case of fire. In this context the goal is now to optimize the classification algorithm not regarding global accuracy, but to a cost function that considers various levels of false positive and false negative costs. Practically, we proceeded with the following steps:

- A cost matrix is defined, attributing some arbitrary weight to each of the errors, reflecting the higher cost of errors for false positive vs. false negative.
- From the classifier, the likelihood that the HI is 1, 2, or 3 is extracted thanks to the Random Forest that easily outputs a calibrated likelihood for each class.
- Considering the likelihood for each class and the cost of each possible choice for prediction, the HI is chosen so that it maximizes the total cost.

Figure 6 shows an example with three different settings (low, medium and high costs), with higher and higher cost for false negative. The goal of higher cost is to better detect at-risk transformers. Technically speaking, the goal is to increase the recall of at-risk transformers (HI=2 and, even more, HI=3). In this example, the likelihood of prediction of each HI is provided. Using a neutral cost matrix, the more likely HI would be selected. In this case HI is predicted as a 1. Using a medium cost matrix, because of the costs, HI is predicted as a 2 as it maximizes the global cost. Similarly, using a stronger cost matrix, named high, HI=3 is selected. The approach was generalized to 15 settings with increasing weights and tested on a 12,000 analyses validation dataset. This led to the results presented in Figure 7 and Figure 8, showing the expected effect on precision and recall: recall for HI=3 class increases as the setting gets more conservative (higher costs) and parallelly its precision decreases. Regarding HI=1 class, its precision increases and its recall decreases as the setting gets more conservative. As an intermediate class, HI=2 sees its precision decrease as the setting gets more conservative. Its recall first increases (as more analyses are correctly classified in HI=2 class, instead of HI=1 class) and then decreases: this because when the setting gets highly conservative the classification tends to incorrectly class HI=2 in the HI=3 class, as it can be seen in the confusion matrix (Figure 9).

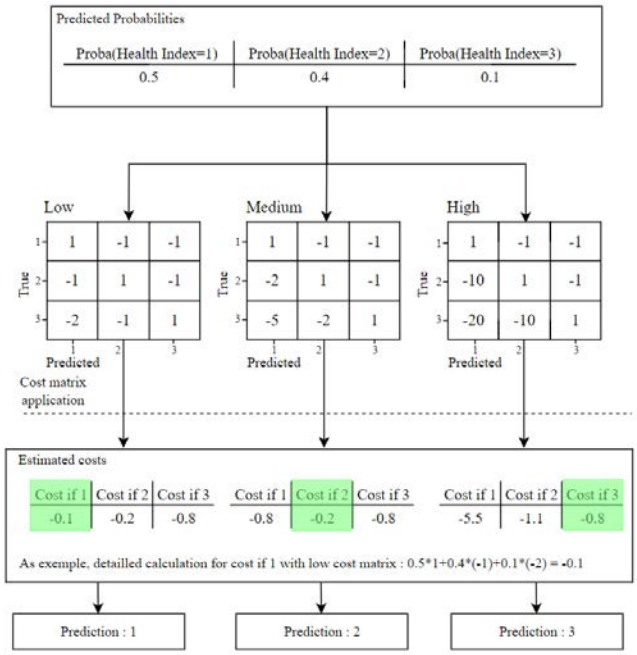

Figure 6: Illustration of cost matrix impact on prediction.

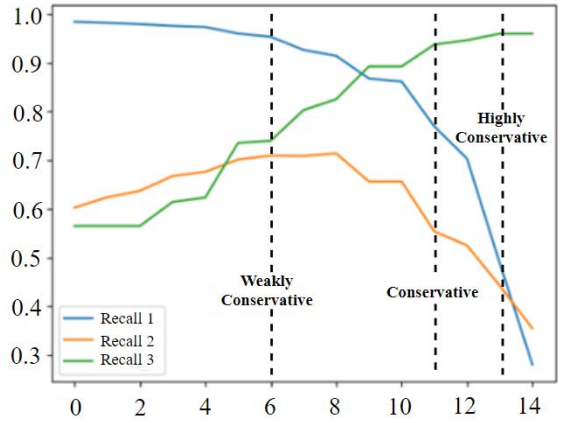

Figure 7: Recall obtained for HI equal to 1, 2 and with using increasingly settings, from 0 to 14.

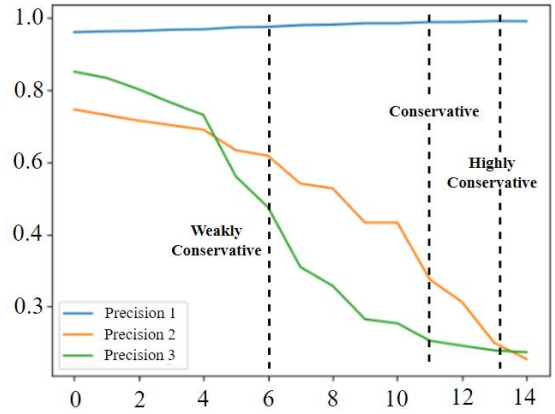

Figure 8: Precision obtained for HI equal to 1, 2 and 3 with using increasingly conservative settings, from 0 to 14.

In order to choose the best setting from the experts' point of view, we randomly selected 200 samples and provided the classification results for all the 15 settings, highlighting the correct results and the wrong ones (correct result means predicted HI equal to the HI estimated by the subject matter expert). This way, subject matter experts could easily see the conservatism level of each setting and choose the three settings that were the most pertinent to them, for covering the global range of criticality of the transformers' context. Those three settings, named weakly conservative, conservative and highly conservative cost matrices, are shown in Figure 7 and Figure 8.

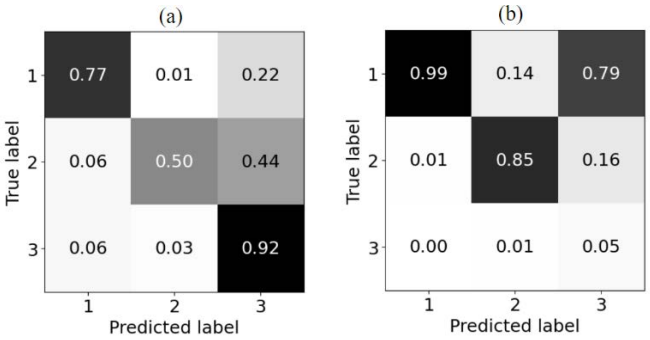

Figure 9: Confusion matrix normalized by rows and by columns for highly conservative cost matrix (respectively (a) and (b)). Results obtained on a 6k analyses dataset.

3.2. Results validation

The global algorithm (described in Figure 4) was tested on a new dataset of 6,000 analyses (called test dataset), using the three settings chosen by the subject matter experts. The results are shown in Table 3. They are consistent with the results obtained on the validation dataset. Particularly, precision for HI=1 class and recall for HI=3 class are very close. For instance, using the conservative cost matrix, precision for HI=1 class is 99% on the test dataset and 99% on the validation dataset, recall for HI=3 class is 95% on the validation dataset and 94% on the test dataset. Those performances and the risk management settings allow for industrial usage.

Table 3: Results obtained on the test dataset for weakly conservative, conservative, and highly conservative settings, focusing on precision for HI=1and recall for HI=3.

Total Number of Analyses=6000	Accuracy	Precision(HI=1)	Recall(HI=3)
Weakly Conservative Cost Matrix	**95%**	**0.98**	**0.75**
Conservative Cost Matrix	**91%**	**0.99**	**0.94**
Highly Conservative Cost Matrix	**76%**	**0.99**	**0.98**

4. CONCLUSION AND DISCUSSION

A semi-automatic, hybrid machine learning and expert-based approach for transformer maintenance has been developed. This approach is based on a very large number of analyses (65,600) carried out over more than 10 years and the technical experts who carried them out. It is called semi-automatic because the expert remains present in the process, especially to analyze and recommend maintenance actions for transformers whose Health Index is evaluated at 3, the most critical level. It is called hybrid because it relies on a machine learning core and on rules provided by the domain experts. The machine learning part goes beyond the application of combinatorial rules: it has captured the experience and practices of experts exposed to many analyses and their practical experience on many transformers, throughout their lifecycle, who are familiar with the signatures of faults and their probability of leading to more serious problems later. Like any machine learning algorithm, the performance of this solution relies on a big amount of data for training. Knowing that this solution is a hybrid solution that also relies on expertise, any industry with advanced expertise necessarily also possesses a large volume of data. Therefore, it is suitable to any industrial player in the field. As in most classification problems, it is not possible to simultaneously improve precision and recall, or in other words, minimize false alarms and minimize non-detections. This is why we have introduced a setting that allows us to prioritize one or the other, depending on the context of use.

Our overall health estimation system relies on:

- This machine learning-based estimation core.
- Legal and safety rules that need to be verified.

Calculations commonly used by experts based on the evolution of dissolved gas concentrations trough time to discriminate the most ambiguous cases.

- The expert who will confirm the critical cases (2 or 3) and provide an appropriate maintenance or further analyses recommendations.

This transformers health estimation enabling predictive maintenance is now deployed on the cloud as an API that is exposed to users whose use can also be done directly through a web application. Today, this process relies on discrete oil analyses; tomorrow, with more and more embedded monitoring in transformers, it is possible to perform real-time analyses. The hybrid approach can be preserved, but this time the machine learning core can rely on the time series and be even more sensitive to any degradation and more accurate in failure prediction.

Finally, it should be noted that this methodology is transferable to many other application domains beyond transformers.

ABSTRACT

The copious volumes of data collected incessantly from diverse systems present challenges in interpreting the data to predict system failures. The majority of large organizations employ highly trained experts who specialize in using advanced maintenance equipment and have specific certification in predictive maintenance (PdM). Prognostics and health management (PHM) connects research on deterioration models to strategies for PdM. Prognostics refer to the process of estimating the time until failure and the associated risk for one or more current and potential failure modes. Prognostics aim to provide guidance by alerting to imminent failures and predicting the remaining useful life (RUL). This eventually leads to improved availability, dependability, and safety, while also reducing maintenance costs. This research work diverges from existing established prognostic methodologies by emphasising the use of hybrid prognostics to predict the future performance of an aircraft system, especially the point in which the system will cease to operate as intended, often referred to as its time to failure. We have developed a new method that combines a physics-based model with the physics of failure (PoF) and a multiple-layered hyper-tangent-infused data-driven approach. The results are useful. The authors retrieved datasets for analysis using a laboratory aircraft fuel system and simulation model. Consequently, the comparative results demonstrate that the proposed hybrid prognostic approach properly estimates the RUL and demonstrates strong application, availability, and precision.

Keywords: health management; physics of failure; hybrid prognostics; aircraft fuel system; remaining useful life.

1. INTRODUCTION

The goal of prognostics is to accurately detect and report impending system failures—that is, to forecast the progression of failure. Prognostic methodologies used in prognostic and health management (PHM) achieve this objective through three distinct classifications: condition-based, usage-based, and traditional. Traditional prognostic approaches can be further classified as model-based, data-driven, or hybrid models (Gu & Pecht, 2008; Liao & Köttig, 2014).

Using failure physics (PoF), likelihood, and reliability models to come up with and use expressions is what model-based prognostic methods do. These models utilise the relationships between materials, manufacturing processes, and the dependability, robustness, and strength of a subsystem. This is typically achieved through controlled, structured experiments and life evaluations. Although modelling offers the potential for high accuracy, its implementation and utilisation in complex operational systems are difficult. The models comprise acceleration factor-incorporated reliability testing models, probability models, distributions, and reliability theory principles. Figure 1 shows the comparison between physics-based and traditional condition-based data (CBD) approaches to PHM.

Data-driven prognostic approaches, such as statistical and machine learning methods, are easier to use than model-based approaches but may result in less precise and accurate prognostic projections (Galar et al., 2021). As shown in Fu et al. (2023), statistical approaches include both parametric and nonparametric models. They also include K-nearest neighbour (KNN), a nonparametric method for classifying or regressing an item based on its nearby data points. Linear discriminant analysis (LDA) sorts many objects into groups, hidden Markov modelling (HMM) deals with systems that have hidden states, and principal component analysis (PCA) changes variables in a straight line. Hybrid approaches combine model-based and data-driven methods to enhance

accuracy and gain a deeper understanding of the interactions between parameters and objects. The complexity of computational processing is one of the limitations.

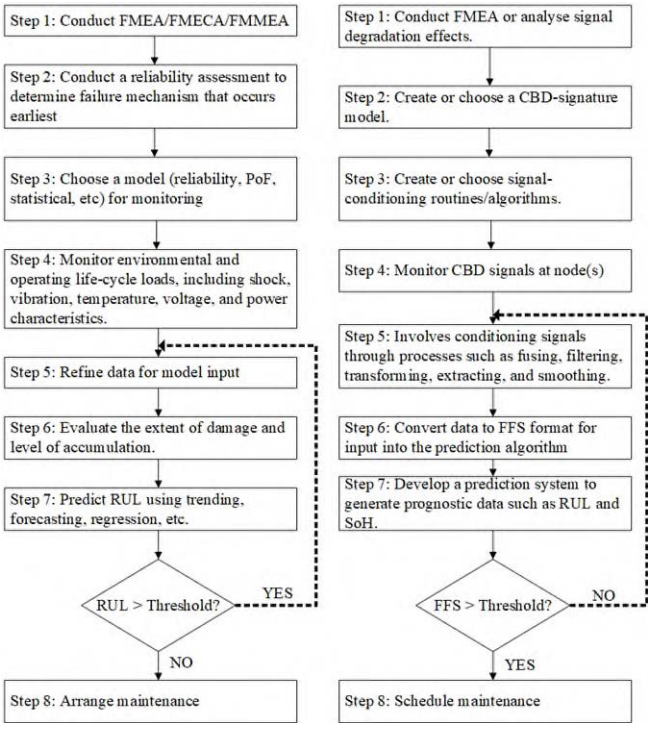

Figure 1. Diagram comparison of model-based and CBD-signature approaches to PHM (Hofmeister et al., 2017).

Figure 2 illustrates an alternative representation of a fault tree for aircraft fuel error-identified systems. Failure Mode and Effects Analysis (FMEA) and Failure Mode, Effects, and Criticality Analysis (FMECA) are used in this study to investigate a fuel-error defect and find the most likely failure mode. This could be air flow, pressure, temperature, or the fuel pump.

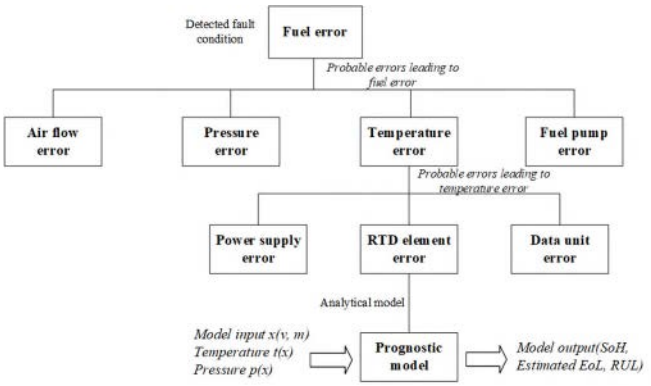

Figure 2. Example of fuel error leading to the application of prognostic model (Douglas Goodman et al., 2019)

In this instance, we conclude that a temperature inaccuracy is the probable factor responsible for the fuel error. The fault tree indicates that three failure modes, namely the power supply, resistive temperature detector (RTD), or an air-data unit, are likely to cause the temperature error. We use an appropriate analytical model to generate prognostic data in the event of an RTD failure.

1.1. Hybrid prognostic mechanisms

A hybrid technique combines physics-based and data-driven prognostics in two phases: offline and online. The initial phase involves creating the nominal and deterioration models, as well as establishing the faults and performance criteria required to predict the remaining useful life (RUL) of the system. The second phase entails using models and thresholds to identify fault initiation, assess the state of system health (SoH), and forecast future SoH and RUL. Data from experiments and synthetic datasets from simulations that replicate real-world settings often validate and optimise the models. We create and utilise sensors to gather data from operational systems, with the aim of monitoring and maintaining the systems' health. The hybrid model offers a higher level of precision compared to employing solely a physics-based or data-driven approach. A physics-based model generates particularly accurate prognostic information when adjusted to sensor data. One drawback is the increased complexity involved in adapting the model to sensor data.

Hybrid models utilise a blend of multiple models to enhance accuracy. Many academics have overlooked hybrid modelling for fault diagnostics and maintenance decision-making. Ahmadzadeh & Lundberg (2014) examined three advanced models for predicting RUL: knowledge-based models, data-driven models, physics-based models, and hybrid prognostic models. Jardine et al. (2006) conducted an examination of machinery diagnostics and prognostics, showcasing the application of statistical, artificial intelligence, and physics-based prognostic methods in condition-based maintenance (CBM) to improve the precision of equipment RUL estimation. A few studies have especially concentrated on hybrid prognostic approaches to capitalise on the benefits of several prognostic models.

Hybrid prognostic methodologies have limitations because they rely on both model-based and data-driven methods. Inaccurate models, noisy data, or both may result in an incorrect RUL forecast. As a result, if not managed correctly, there is a significant likelihood of increased variance in mistakes. A hybrid strategy combines elements of physics-based and data-driven methodologies to leverage their advantages while mitigating their limitations, but it still retains some disadvantages of both. Elattar et al. (2016) developed a flowchart to assist in choosing a prognostic method, as shown in Figure 3.

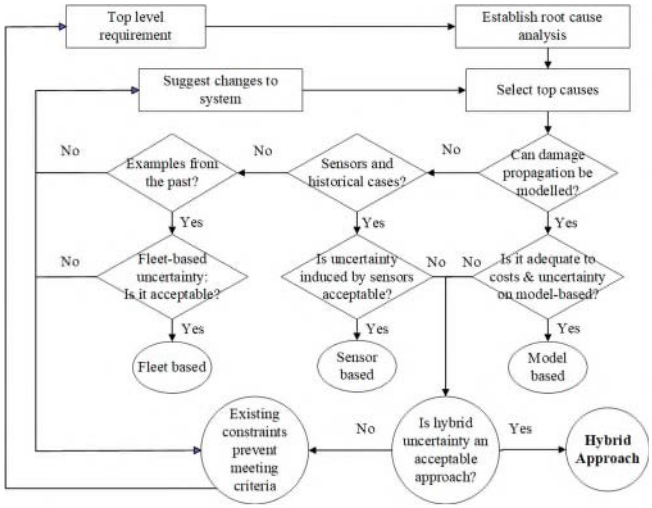

Figure 3. Workflow to select prognostic approaches (Elattar et al., 2016).

A hybrid strategy can effectively integrate data-driven and physics-based methods to optimise their respective strengths when managed appropriately. A physics-based method can address data deficiencies, while a data-driven model can address gaps in understanding the system's mechanics. Performing this fusion before estimating the RUL is known as pre-estimation. Fusion is a process that combines the results of various methods to determine the final RUL after predicting it. Li et al. (2019); Nieto et al. (2016); and Orsagh et al. (2003) used a fusion strategy for aircraft engine bearings to show that this method gives more accurate and long-lasting results than just using data-driven or physics-based approaches alone.

1.2. Prognostic application

In the aircraft sector, there are several instances of prognostic applications that are now in the developmental stage. The current aim of prognostic society is to create a PHM system capable of detecting and isolating problems in both the primary and subsystems of the aircraft. Additionally, this system will offer prognostic information for specific components (Losik, 2012; McCollom & Brown, 2011; Vohnout et al., 2012). PHM, which is critical to improving safety and lowering maintenance costs, has a significant impact on the choice of aircraft. The proposed architecture incorporates an external PHM system that will employ data mining techniques. Figure 4 depicts the forecasting applications.

There has been a notable surge in interest in prognostics due to their ability to improve the health management of intricate engineering systems. Prognostics are important because they allow us to predict future illness progression and treatment outcomes. Daily weather forecasting also employs this technology. Whether they are located on board or off board, prognostic software solutions have the potential to function in real-time or nearly real-time.

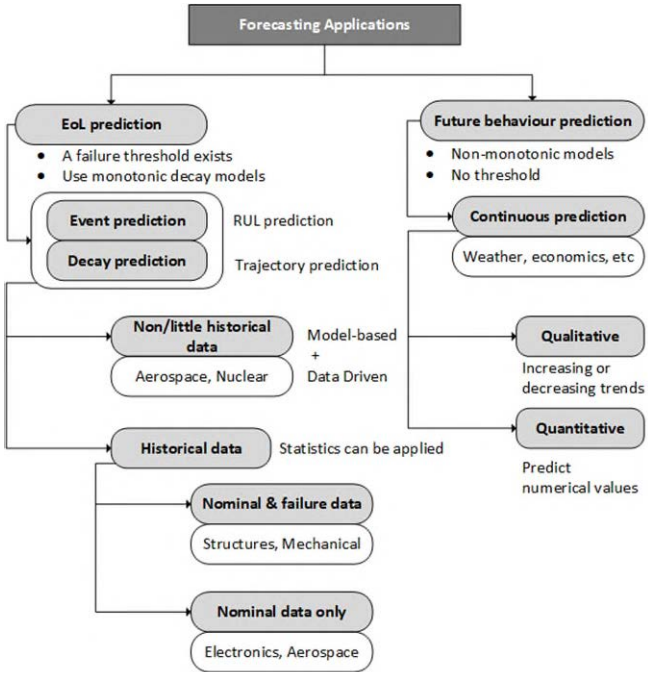

Figure 4. Forecasting applications.

Prognostics can be used offline, regardless of how long the monitored system has been in operation. Real-time prognostics uses the online data collected from the data collection system to accurately estimate the RUL and warn about an imminent breakdown. This allows the system to be reconfigured and the mission re-planned. The offline prognostics system utilises extensive system data from the whole fleet and applies intricate data analysis techniques that are not feasible to conduct in real-time on board due to resource and time constraints. An offline prognostic system in logistical support management can provide useful information for maintenance planning and decision-making.

2. AIRCRAFT FUEL DELIVERY SYSTEM

An aircraft fuel delivery system with three tanks usually consists of a central tank and two wing tanks. The central tank supplies fuel to the engine, and the wing tanks supply fuel to the central tank via pumping stations. Two centrifugal pumps, complete with check valves to prevent backflow, equip each station. Prime movers, operating at a constant angular velocity, power these pumps. Engineers designed the system with varying elevations between the tanks and the engine intake to facilitate fuel flow. This flow is regulated by two-way bidirectional valves that respond to the fuel levels in each tank. Figure 5 illustrates the design of the simulation model, which is based on the MathWorks library.

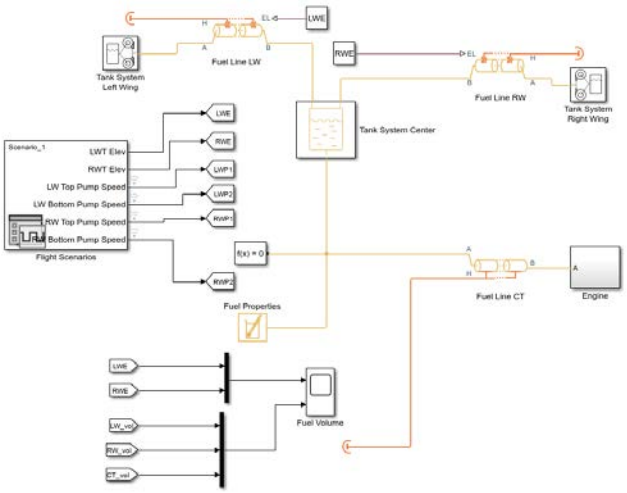

Figure 5. Aircraft fuel delivery simulation system.

The process of simulating this system involves modulating the fluid dynamics associated with the fuel flow, the mechanical design of the pumps and valves, and the control systems responsible for overseeing fuel distribution. The operation will examine the effects of aircraft manoeuvres, specifically changes in bank angle, on the reduction in pressure across the fuel lines. Figure 6 depicts the structure of the central tank in the simulation model.

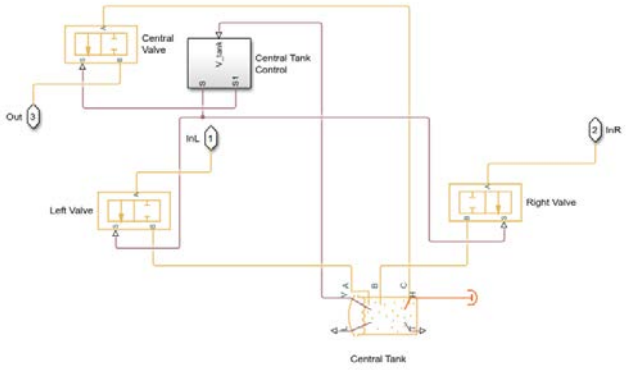

Figure 6. Central tank structure.

There is a storage tank in a thermal liquid network that maintains a constant pressure and allows for a variable number of inlets. The pressure at the liquid surface is considered to be equivalent to the pressurisation. It represents the hydrostatic pressure differential between the fuel surface and the inlets. When the liquid level drops below the inlet height, the port is exposed. It is connected to a partially filled pipe to simulate the ongoing decrease in liquid level within the pipe. In the simulation model, ports A, B, C, D, E, and F are thermal liquid conservation ports connected to the tank inlets. The thermal-conserving port H is associated with the liquid's temperature in the tank. The physical signals V, L, and T represent the liquid volume, liquid level, and liquid temperature, respectively. Bidirectional valves are also depicted within a thermal fuel network. The voltage input S determines the location of the spool. Positive spool displacement facilitates fuel flow by opening the connection between ports A and B. The disconnection is caused by reverse spool movement. We regard the aforementioned component as adiabatic. The system does not transfer thermal energy to its surroundings. Figure 7 illustrates the engine pump and its various subcomponents.

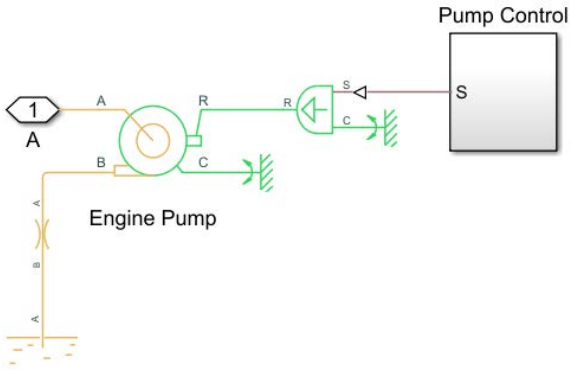

Figure 7. Engine pump and its subcomponents.

The simulation model also includes a centrifugal pump operating within the fuel supply system. We employ affinity laws to establish the relationship between the reference pump characteristics and the actual flow rate and pressure gain. We connect the thermal fuel conservation ports, identified as ports A and B, to the pump's input and outflow, respectively. The drive shaft and casing respectively connect to the mechanical rotational conserving ports, denoted as ports R and C. Mechanical orientation determines the shaft rotation for proper pump functioning, where the flow moves from port A to port B and the pressure increases. The pump's performance in the other direction is indeterminate and perhaps imprecise. Figure 8 shows the engine pump's various characteristics.

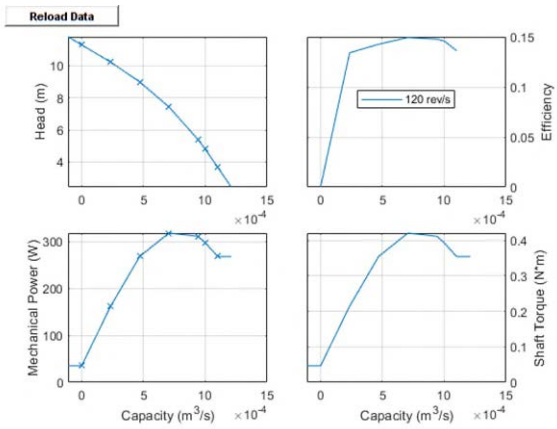

Figure 8. Engine pump characteristics.

It is also possible to get an ideal source of angular velocity from the system, which produces a velocity difference at its

ends that is proportional to the physical input signal. The source is considered ideal since it is thought to have sufficient power to sustain a defined velocity regardless of the torque applied to the system. The relative velocity is calculated by subtracting the absolute angular velocity of the terminal $C(W\_C)$ from the absolute angular velocity of the terminal $R(W\_R)$, denoted as $W = W\_R - W\_C$.

3. HYBRID PROGNOSTIC MODELLING AND RESULTS

3.1. Physical principles

The simulation model suggests a generic simulation of an aircraft's fuel supply system rather than directly replicating a specific real-world aircraft's fuel system. The model encompasses common components of an aviation fuel system, including:

- Multiple fuel tanks: commercial and military aircraft typically have wing tanks and a centre tank to evenly distribute weight and improve fuel economy. The model provides certain starting pressurisation and volume capacities for the tanks, essential for maintaining fuel flow under different flying conditions.
- The specifications for centrifugal pumps and valves, such as bidirectional valves and check valves, demonstrate the intricate systems used to control fuel supply from the tanks to the engines.
- It contains essential information regarding the fuel line's length, diameter, and resistance properties, crucial for accurately modelling fuel flow within the system.

The simulation provides a valuable resource that can be customised or expanded to accurately replicate the fuel system of a particular aircraft. Factors such as tank sizes, pump capacity, and system layout may be able to be adjusted in accordance with the aircraft's technical requirements. Table 1 presents the initial circumstances and parameters of the model.

The physics-based model often involves the monitoring of many parameters, including pressures, temperatures, fuel levels, flow rates, and valve functioning. These parameters are determined by the components involved, as well as their established failure modes. While conducting an analysis of a simulated aircraft fuel system, researchers strive to identify consistent patterns in:

- Fuel consumption rates during comparable operating conditions. Substantial variances could indicate inefficiencies or deterioration, such as pressure or temperature fluctuations in tanks or fuel lines that differ from the usual values, signalling possible problems.
- Valves and pumps have operational behaviour, including unforeseen operations or alterations in performance measurements.

Table 1. The initial circumstances and parameters of the simulated aircraft fuel delivery model

Components	Parameters	Specs
Initial Conditions	Temperature	333.15 K
	Pressure	0.1 MPa
Fuel Tanks	Pressurisation	0.1 MPa
	Minimum fuel volume	0.09463525 m^3
Wing Tanks	Initial volume	10 m^3
	Maximum capacity	12 m^3
Centre Tank	Pressurisation	0.1 MPa
	Initial volume	5 m^3
	Maximum capacity	284 m^3
Pumps	Reference density	920.027 kg/m^3
	Reference angular velocity	120 rev/s
	Angular velocity threshold	10 rad/s
	Operational ranges for angular velocity	0 to 200 rev/s
	Mover time constant	0.2 s
Valves	Maximum opening area	$\pi/4\times(0.03048)^2$ m^2
	Leakage area	1e – 10 m^2
	Cutoff time constant	0.1 s
	Maximum valve opening (2-Way directional valves)	5.1e-3 m
Fuel line piping	Length	5m
	Hydraulic diameter	3.05e-2 m
	Aggregate equivalent length for local resistances	2.56 m

To develop a physics-based model for an aviation fuel system, one needs to understand the basic concepts of fluid dynamics and the mechanical operations of these systems. Common mathematical formulas and concepts are summarised to reflect the physics of aviation fuel systems, establishing a solid foundation for developing a physics-based model.

The principle of mass conservation is applicable to the process of fuel transfer between tanks and its subsequent use by an airplane's engines. The generic equation provided can be used to analyse each tank:

$$\frac{dV}{dt} = Q_{in} - Q_{out} \quad (1)$$

Where:

- V is the volume of fuel in the tank.
- t is time.
- Q_{in} is the inflow of fuel into the tank, and
- Q_{out} is the outflow rate of fuel from the tank to the engines or to other tanks.

The application of Bernoulli's equation, which establishes a relationship between the pressure, velocity, and height head of the fluid, can aid in the analysis of fluid flow between tanks. This is especially beneficial when the tanks are located at varying heights or when calculating the necessary pressure for fuel transfer between them.

$$P + \frac{1}{2}\rho\nu^2 + \rho gh = constant \quad (2)$$

Where:

- P is the pressure within the fluids.
- ρ is the density of the fluid (fuel).
- ν is the velocity of the fluid.
- g is the acceleration due to gravity, and
- h is the height of the fluid column (which could represent the fuel level in the tank).

PID (proportional-integral-derivative) control effectively manages pump speeds or valve positions to maintain predetermined fuel levels in individual tanks. Fuel level sensors provide the input for this control mechanism. The conventional arrangement of a PID controller is as follows:

$$u(t) = K_p e(t) + K_i \int_0^t e(\tau)\, d\tau + Kd\frac{de(t)}{dt} \quad (3)$$

Where $u(t)$ denotes the control signal (e.g., pump speed), $e(t)$ denotes the error signal (difference between desired and actual fuel level), and K_p, K_i, and K_d denote the proportional, integral, and derivative gains, respectively.

In aircraft fuel systems, where turbulent flow is common, we can use the Darcy-Weisbach equation to calculate the pressure drops (ΔP) along a pipe length:

$$\Delta P = f\frac{L}{D}\frac{\rho v^2}{2} \quad (4)$$

The variables are defined as follows: f is the friction factor, L is the length of the pipe, D is the diameter of the pipe, ρ is the density of the fuel, and v is the velocity of the fuel.

3.2. Hybrid prognostic integration methodology

According to Chao et al. (2021), provided $X_{s_i} = \left[x_{s_i}^{(1)}, \ldots, x_{s_i}^{(m_i)}\right]^T$ are multivariate time-series data from condition monitoring sensors and their accompanying RUL $Y_i = \left[y_i^1, \ldots, y_i^{m_i}\right]^T$ for a fleet of N units $(i = 1, \ldots, N)$. Each observation $x_{s_i}^{(t)} \in R^p$ consists of a vector of ρ raw measurements taken at operating conditions $\omega_i^{(t)} \in R^s$. The length of the sensory signal for the i^{th} unit is determined by m_i, and may vary between units.

The overall cumulative length of the available data collection is $m = \sum_{i=1}^{N} m_i$. We designate the provided dataset more compactly as $D = \left\{W_i, X_{s_i}, Y_i\right\}_{i=1}^{N}$. The objective is to develop a predictive model $\mathcal{G}$ that can accurately estimate the RUL $(\widehat{Y})$ on a test dataset $D_{T*} = \{X_{sj*}\}_{j=1}^{M}$ consisting of M units, which $X_{sj*} = \left[x_{sj*}^1, \ldots, x_{sj*}^{k_j}\right]$ are multivariate time series of sensor measurements. The overall cumulative length of the test data set is $m_* = \sum_{j=1}^{M} k_j$.

The subsequent subsections provide a comprehensive analysis of each of these phases. Eker et al. (2019) proposed the following input and output processes for physical-based approaches, as depicted in Figure 9.

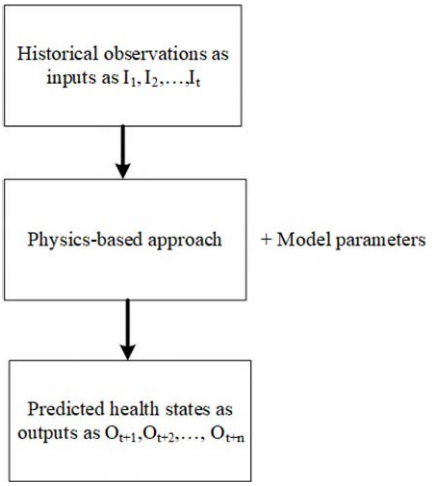

Figure 9. Input and output of the physics-based model.

The flowchart depicted in Figure 10 illustrates the operational mechanism of a hybrid predictive strategy employed in aeroplane fuel distribution systems. This approach combines physics-based and data-driven models. The commencement of the process occurs subsequent to the identification of the components and modes of aircraft failure, the process commences. The aviation fuel system is analysed using physics-based techniques and domain expert knowledge to estimate the short-term RUL. We conduct the analysis using either a real-world or synthetic dataset.

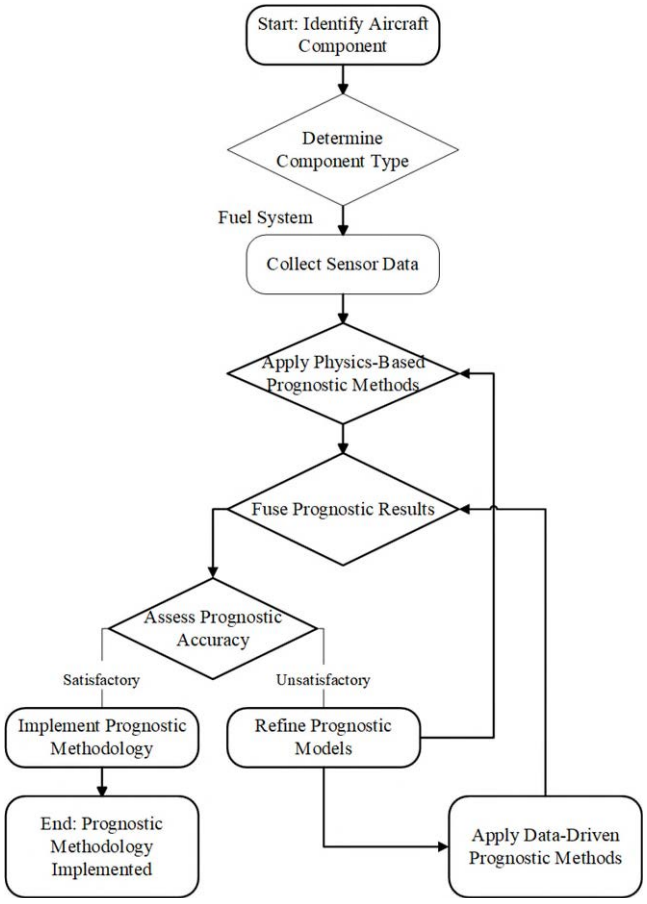

Figure 10. Illustration of fusion mechanism of a hybrid prognostic methodology for an aircraft fuel system

The prediction results will be assessed using several prognostic metrics, as demonstrated in the studies conducted by Chao et al. (2021) and Fu & Avdelidis (2023). The optimisation process will be carried out by comparing the accuracy results with the actual RUL. Once the desired outcome is attained, a hybrid prognostic technique will be included. As long as the engineering systems adhere to specific physical deterioration, the methodology flowchart can be used for other complicated systems.

Random holdback is the chosen approach for validation. The neural network consists of two layers in total. In the initial layer, three radial Gaussian activations are employed, whereas the subsequent layer utilises two times Sigmoid TanH and a linear activation function, which bears a striking resemblance to the activations used in two-layer models. We set the learning rate at 0.1, allowing for robust fitting. A single round of a tour is subject to a penalty approach. The authors of this paper used a variety of neural networks with different activation functions, including Sigmoid TanH, identity linear, and radial Gaussian. There are variations in the outcomes observed among the different models. Various characteristics were obtained, and the highest-ranked attributes that have the most impact on achieving the best result were selected. Figure 11 depicts the simplified neural network that yields the best results.

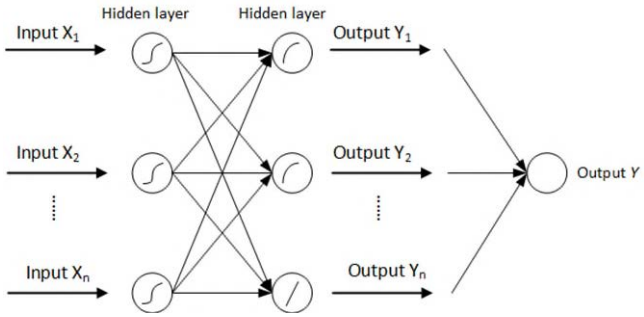

Figure 11. Simplified boosted neural network model NGaussian(3) NTanH(2)NLinear(1)

In its fitting routine, the boosted neural network employs a validation mechanism. Validation methods include holdback, K-fold, or the use of a validation column that performs the following actions to fit the model:

- The model parameters are subject to a penalty.
- The validation set adjusts the penalties applied to the parameters.

The actual-by-predicted plot calculates the comparison between the training's actual and expected values. The suggested methodology reveals the correlation between the observed value and the projected value on the training dataset. The ideal situation involves aligning all data points along a straight path where the anticipated values accurately match the observed values. The data points in this graph display a mostly linear trend that is primarily located close to the actual RUL value. This observation suggests that the projected values exhibit a degree of resemblance to the observed values. As a result, the model exhibits higher levels of predicted accuracy for positive values in comparison to negative values. Table 2 presents the results for both training and validation methods.

Table 2 suggests multiple measuring and evaluation measures to compare prognostic outcomes. Fu et al. (2023) provide comprehensive explanations for each rating metric. Table 2 demonstrates that the R^2 value is 0.9998 for both the training and validation stages, indicating a substantially identical outcome in both phases. The training procedure yielded a higher RASE value of 14.56 compared to the validation process value of 21.26, indicating that the prognostic algorithm exhibits superior performance during the training phase as opposed to the validation phase. We may attribute the tiny difference to the inadequate amount of training data, which led to less accurate predictions. Future optimisation and updates have significant potential to improve accuracy. MathWorks extracts the simulation data from the simulated fuel distribution systems, which you can view at https://zenodo.org/doi/10.5281/zenodo.10888497.

4. CONCLUSION

Prognostics are essential in PHM, comprising several elements like system monitoring, fault detection and diagnostics, failure prognostics, and operating management. Prognostic models in both industry and research commonly utilise physics-based and data-driven methodologies. Every strategy has unique benefits and drawbacks. The current work presents a hybrid prognostic model that efficiently incorporates the benefits of both approaches while reducing their limits whenever possible.

Hybrid prognostics were modified in order to incorporate the short-term forecast from physics-based prognostics. This concept has been used in aviation fuel distribution systems. The present research compares the RUL estimations achieved by the hybrid method with those acquired through several physics-based and data-driven methodologies. In real-world scenarios with insufficient data on long-term failures, the hybrid strategy significantly outperforms any of its component techniques.

ABSTRACT

A methodology for replacing finite element simulations with a fast-calculating surrogate model for fault tolerance in operating systems is presented. The study focuses on the TO220 rectifier system and explores methods to detect impending failures and calculate the resulting necessary load reduction. The finite element simulation model is described, highlighting the die attach as the relevant connection for failure. A surrogate model is developed using long-short-term-memory models to predict temperature and in-elastic strain. The surrogate model significantly reduces simulation time, allowing for the adjustment of load based on the system's current state of health. The rainflow counting algorithm is applied to calculate the number of cycles to failure, and the Palmgren-Miner linear damage accumulation relation is used to determine the damage and state-of-health. The dependency of the change in lifetime due to variations in scaling factor is evaluated and the results show that load reduction increases the lifetime of the system.

1. INTRODUCTION

The increased requirements for fault tolerance (e. g. for SAE level L3 and onward, defined by the Society of Automotive Engineers (SAE) in SAE International (2021)) requires, the operating system must continue to operate with reduced power until other measures are initiated. Therefore, the system must be able to detect the impending failure and start the fault handling. Furthermore, the result of the intervention must be predicted in order to apply right failure rectification. These requirements can be met by various methods, as mentioned by Moeller, Inamdar, van Driel, Bredberg, Hille, Knoll and Vandevelde (2024). For example, a system that regularly undergoes rest phases can run self-diagnoses processes by using standard load cycles during these rest phases. From the deviation of the resulting response to the response in the undamaged state, the damage and the resulting necessary reduction in load can be calculated (as shown in e.g. Chacko, Moeller, Kolas, Albrecht, and Rzepka (2024)). However, the disadvantage of this method is that the fault can be detected at the earliest in the first rest phase after the first measurable deviations have occurred. On the other hand, the advantage is that the calculation must not be carried out in the system itself, but can also be performed in the cloud, for example.

Alternatively, a digital twin of the system can be created and this representation can be digitally loaded in parallel with the real system. The digital twin then calculates the damage to the real system based on the real load. In order to achieve this, the digital twin must be capable of mapping the failure mechanism that occurs and calculating the damage from this. In addition, the calculation of the damage due to the load in the digital twin must be performed faster than the load is applied in reality (this depends on the available calculation resources). Only if both of these conditions are met the current state of health of the system can be mapped correctly and an appropriate regulation can be calculated.

In this work, the chosen system is a TO220 rectifier. The TO220 is a Silicon Carbide Schottky diode for ultra-high performance, low loss, high efficiency power conversion applications. For example, it can be used as a switched-mode power supply, AC-DC and DC-DC converter, in battery charging infrastructure, server and telecommunications power supply, uninterruptible power supply and as a photovoltaic inverter (Nexperia 2023). As already shown by Albrecht, Horn, Habenicht and Rzepka (2023), it is possible to generate a validated digital representation of this rectifier in the form of a combined multi-field FE simulation, from which the damage under real loads can be calculated. However, the calculation time of these FE simulations is

much too long. This paper shows how the FE simulation model can be replaced by a fast-calculating surrogate model. After a brief introduction of the TO220 rectifier and the corresponding FE simulation in section 2, the training and setup of the surrogate model and the calculation of the state of health are presented. Subsequently, this surrogate model is used to calculate the change in lifetime due to the reduction of the load.

2. Finite Element Simulation

The structure of the TO220 rectifier can be seen in the FE simulation model in Figure 1 and Figure 2. The die attach is the relevant connection regarding the failure (as shown in Albrecht et al. (2023)), representing the connection between the chip and the lead frame. The current flows from the contact via the bond wire to the die and is then transferred to the lead frame via the die attach. The materials heat up due to the current flow (Joule heating). The temperature is dissipated via the heatsink.

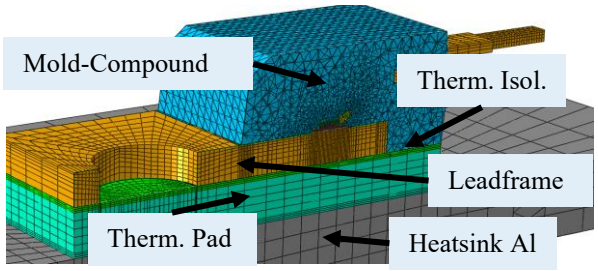

Figure 1: Finite Element model of the TO220 rectifier (cut view).

The FE simulation is based on a sequential approach, where the electric-thermal behavior is simulated first, followed by the thermal-mechanical behavior of the component. A current load profile is used as input for the electric-thermal simulation. The computed temperature field is then used as input for the thermal-mechanical simulation. From the thermal-mechanical simulation the in-elastic strain in the region of the die-attach corners (the relevant area for the failure) is extracted using an averaging approach.

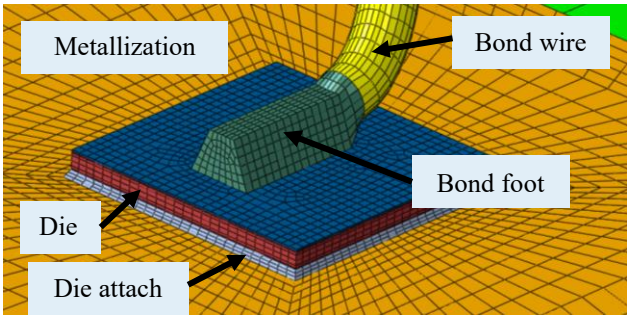

Figure 2: Finite Element model showing the die attach and the bond foot.

In order to calculate the state-of-health from the simulation result, the Coffin-Manson lifetime model

$$N_f = C_1 \Delta\varepsilon_{pl}^{C_2} \quad (1)$$

is used. With this model the number of cycles to failure N_f is calculated by using the in-elastic amplitude allocated to the cycle $\Delta\varepsilon_{pl}$ as well as two model parameters C_1 and C_2. In this calculation, the parameters identified by Darveaux and Banerji (1991) for Pb95Sn5 were used. Since real loads are used in this calculation rather than standard cycles, rainflow counting is carried out based on the temperature profile. The rainflow counting extracts cycles from the real load, and the corresponding change in the in-elastic strain is assigned to these cycles. From the number of cycles to failure N_f the state-of-health can be calculated (as shown in section 4). The methodology of calculating the state-of-health by using FE simulations is also shown in Figure 3.

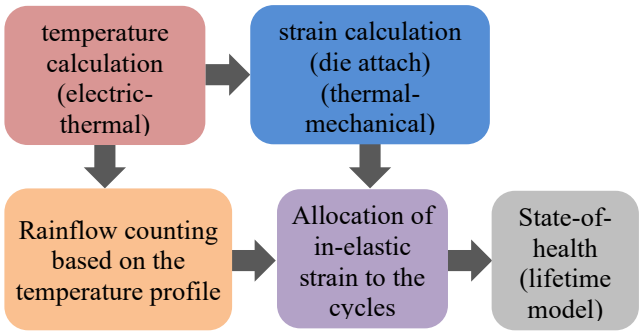

Figure 3: Applied methodology for the calculation of the state-of-health.

A crucial aspect of the FE simulation is the accurate description of the materials used in the component. Most of the materials exhibit strong temperature dependence, the bond wire and bond foot (both aluminum) as well as the lead frame (copper) are modeled by using linear elastic and bilinear kinematic hardening plasticity behavior and the solder in the die attach is modeled by using the Anand law. Especially the solder is highly non-linear and the material behavior depends strongly on the strain experienced in the past. Further details on the materials and the FE simulation in general are shown in Albrecht et al. (2023).

Using the calibrated model, a complete Worldwide harmonized Light vehicles Test Procedure (WLTP) mission profile was simulated by varying the electrical load over time. In order to obtain the current from the WLTP profile, an inverter module was added before the simulation. The temperature field from the electric-thermal simulation was used as input for the thermal-mechanical simulation and the stress as well as the strain in the die-attach corners is calculated and averaged. The results are shown in Figure 4.

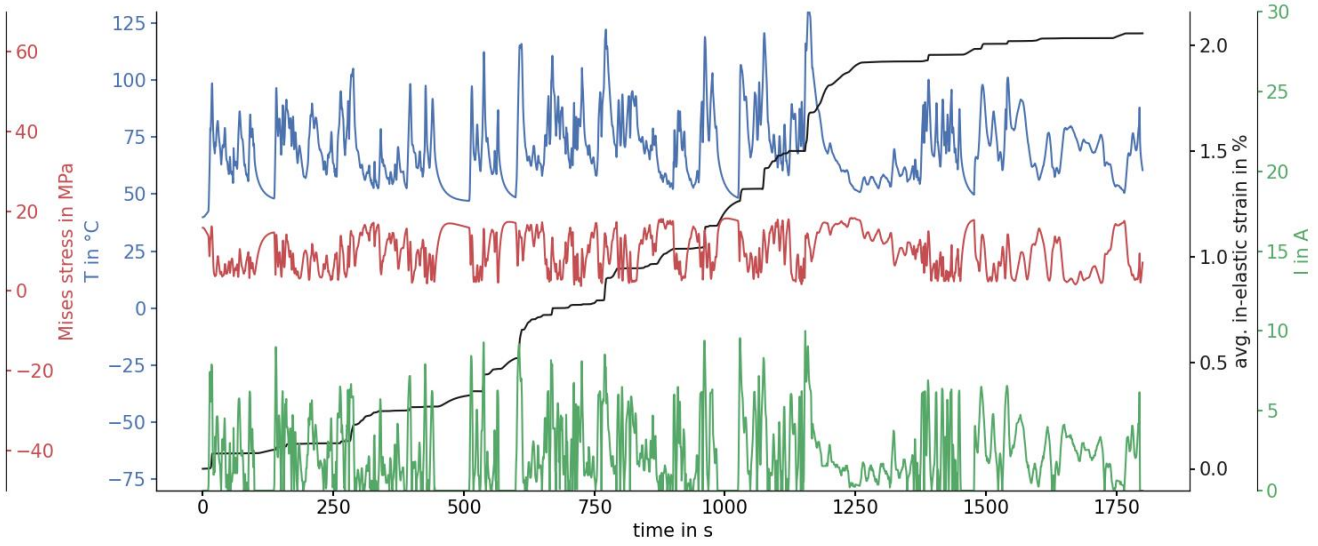

Figure 4: WLTP (current) mission profile (green) as well as some of the calculated results from the FE simulation: temperature (blue), von Mises stress (red) and the averaged total in-elastic strain (black).

3. SURROGATE MODEL

As mentioned before, the WLTP cycle can be simulated by using FE simulation and the results fit to experimental measurements. So, the FE simulation model is a digital representation of the TO220 rectifier. However, the simulation time for calculation the WLTP cycle of 1800s is round about two days. In order to reduce the simulation time, the finite element simulation must be replaced by a surrogate model.

Therefore, the restrictions are: The surrogate model must take the current as input and the temperature as well as the in-elastic strain as outputs. Additionally, the surrogate model must be able to store all information of the reality – and because the FE simulation fits to the reality also all information of the FE simulation model. Due to this, the type of the surrogate model cannot be chosen randomly.

As described before, the materials of the TO220 rectifier are highly non-linear and also strongly dependent to the history. Due to this, as model type the long-short-term-memory (LSTM) model is used (Hochreiter & Schmidhuber (1997)). LSTMs are effective in capturing long-range dependencies in sequential data and have the ability to remember information over long periods of time, as for example shown in Zheng, Ristovski, Farahat and Gupta (2017). Analogous to the FE simulation, two different LSTM models were trained: one model to predict the temperature and one model to predict the in-elastic strain. The training data were produced by the FE simulation model and as the LSTM model is to be applied to real loads, the simulation data from the WLTP cycle is used for training. The training/validation split is 80/20 % and the Adam optimizer (Kingma & Ba 2014) is used. In order to generate additional data that the model had not seen in training, the mission profile was varied using different methods and a total of six variations were calculated using FE simulation. The shown mean absolute error / mean absolute percentage error (MAE/MAPE) is calculated on all seven mission profiles. The models are trained without considering the time. So, for the data a constant time step of 10 Hz is used.

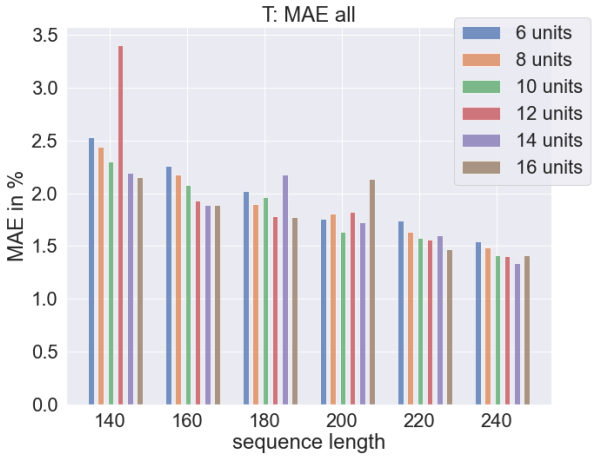

Figure 5: MAPE for variation of the sequence length and the units for the LSTM predicting the temperature.

For the LSTM there are many parameters, such as sequence length, number of unit layers, number of units per layer, features, predictions, learning rate etc. These parameters are optimized by a combination of a variation study and a hyperparameter variation. Exemplarily for the LSTM predicting the temperature, which only uses one unit layer, in Figure 5 the MAPE for the variation of the sequence length and the number of units in the unit layer is shown. The increase of the sequence length (the history taken into

account) significantly increases the prediction quality. Simultaneously, increasing the sequence length reduces the difference between the models with different units.

For predicting the temperature, the LSTM model with the current as feature, a sequence length of 240, one unit layer with 14 units is chosen. The prediction quality (also for all seven mission profiles) is shown in Figure 6.

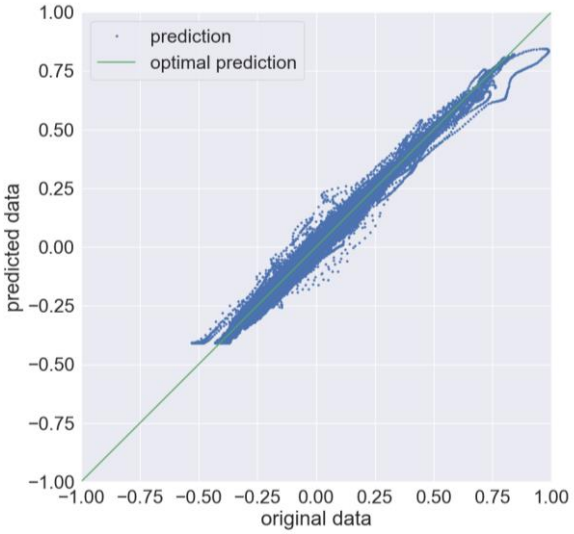

Figure 6: Prediction quality of the LSTM for temperature prediction. The green line indicates the optimal prediction.

As mentioned before, for the prediction of the in-elastic strain a second LSTM model is trained. Therefore, the features are the current together with its first and second derivative and also the temperature (predicted by the other LSTM) together with its first derivative. The result of the parameter variation and hyperparameter variation gives a model with two unit layers with 16 units and 10 units respectively. The sequence length is identified to 200.

The in-elastic strain is a continuously increasing quantity where the changes are constantly added up. Therefore, not the in-elastic strain itself was predicted, but the incremental in-elastic strain. In post-processing after the prediction itself, the in-elastic strain is calculated from the incremental in-elastic strain via integration. Due to this in Figure 7, where the predictions quality for the (total) in-elastic strain is shown for the seven mission profiles, seven connected lines of prediction points are visible.

The application of integration also means the integration of errors. This has both advantages and disadvantages. Assume that only one error occurs at a specific point in time. Then, from this data point onwards, a deviation can be seen in all subsequent data points in Figure 7. This deviation will also be included in the MAPE calculation. On the other hand, a further, opposing error can cancel out the original error. Nevertheless, the prediction is sufficiently accurate, as also can be seen in Figure 8.

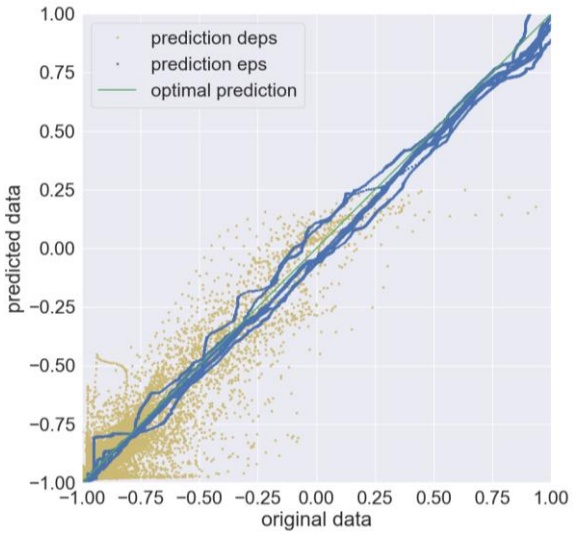

Figure 7: Prediction quality of the LSTM for in-elastic strain prediction. The yellow points indicate the prediction quality for the incremental strain, the blue for total strain.

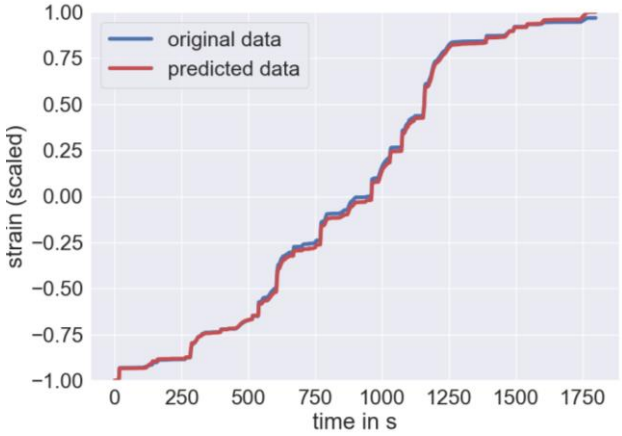

Figure 8: Comparison of the result of the FE simulation (blue) and the LSTM model prediction (red) for the WLTP cycle. The strain is scaled to (-1, 1).

So, with this surrogate model a reduction of the calculation time from two days to 19 seconds (7 seconds for the prediction of the temperature and 12 seconds for the prediction of the strain) for the WLTP cycle of 1800 seconds is achieved.

4. State-of-Health and Remaining Useful Life

As mentioned before for the FE simulations, the rainflow counting algorithm is applied in order to transfer the load profile and the resulting continuously increasing in-elastic strain into separate cycles. By using Coffin-Manson lifetime model (equation (1)), which describes the shape of the strain

Wöhler curve in the low cycle fatigue range, the number of cycles to failure $N_{f,i}$ for each cycle i is calculated. The inelastic strain $\Delta\varepsilon_{cr,i}$ for each sub-cycle per cycle (closed cycles within a larger cycle) is subtracted. From the number of cycles to failure the damage per cycle

$$D_i = 1/N_{f,i} \tag{2}$$

is calculated. Then Palmgren-Miner linear damage accumulation relation (proposed by Palmgren (1924) and further developed by Miner (1945)), is used to sum up all damage contributions

$$D = \sum_i D_i = \sum_i \frac{1}{N_{f,i}} \tag{3}$$

From this, the damage can be transferred into the state-of-health

$$SoH = 1 - D \tag{4}$$

Subsequently, the state of health was calculated for a series of WLTP cycles, whereby initially the WLTP cycles were not changed for the entire period. With this a lifetime of 143 days is calculated. In addition, when a health status of 50% was reached, the load level of the WLTP cycle was reduced. This is used to simulate a reduction in power in response to the damage reached. As shown in Figure 9, this reduction in power significantly increases the lifetime.

Consequently, this model can be used to adjust the load of the TO220 rectifier to the current state of health. Due to the short calculation time of the surrogate model, the influence of the load reduction on the lifetime can be predicted. This allows to adjust the load in a targeted manner, which is necessary for a control.

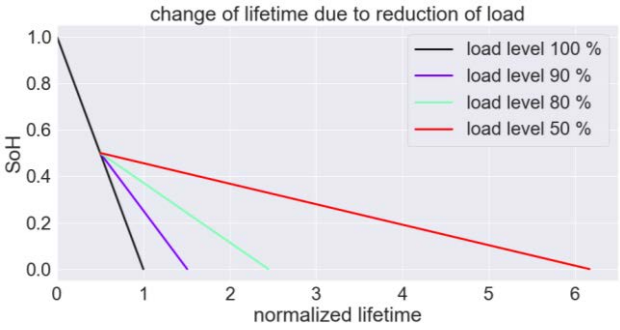

Figure 9: Change of the lifetime due to the reduction of the load level of the WLTP cycle.

5. Conclusion

In this work the methodology of replacing the FE simulation model by a surrogate model is shown. The amount of calculation time is massively reduced and due to this the surrogate model will be implemented on a micro controller in order to finalize the digital twin.

For the prediction of the temperature the final trained model is a LSTM model with just one unit layer and six units therein. Due to this low complexity, in future work a change to a less complicated model type will be taken under consideration.

Additionally, the surrogate model is currently being trained with a complete WLTP cycle. This has the disadvantage that the generation of the training data requires a relatively large amount of resources. However, it can be assumed that it contains multiple pieces of information that are not necessarily required for training the surrogate model. For this reason, the training of the surrogate model is to be simplified in future work. The WLTP cycle and other realistic load profiles will be analyzed using methods from time series analysis (e.g., the matrix profile, what is presented in Imani, Madrid, Ding, Crouter, and Keogh (2018) or Mercer, Alaee, Abdoli, Singh, Murillo, and Keogh (2021)), the relevant patterns and anomalies will be determined and calculated as separate profiles, weighted and specified in the training. This reduces the effort required to generate the training data.

ABSTRACT

The prediction of Remaining Useful Life (RUL) in aerospace engines is a challenge due to the complexity of these systems and the often-opaque nature of machine learning models. This opaqueness complicates the usability of predictions in scenarios where transparency is crucial for safety and operational decision-making. Our research introduces the machine learning framework that significantly improves both the **interpretability** and **accuracy** of RUL predictions. This framework incorporates SHapley Additive exPlanations (SHAP) with a surrogate model and Network Theory to clarify the decision-making processes in complex predictive models and enhance the understanding of the hidden pattern of features interaction. We developed a Feature Interaction Network (FIN) that uses SHAP values for node sizing and SHAP interaction values for edge weighting, offering detailed insights into the interdependencies among features that affect RUL predictions. Our approach was tested across 44 engines, showing RMSE values between 2 and 17 and NASA Scores from 0.2 to 1.5, indicating an increase in prediction accuracy. Furthermore, regarding interpretability the application of our FIN, revealed significant interactions among corrective speed and critical temperature points key factors in engine efficiency and performance.

1. INTRODUCTION

In the interdisciplinary domain of Prognostics and Health Management (PHM), the accurate prediction of Remaining Useful Life (RUL) for industrial assets has become paramount (Ren et al., 2023). As aerospace, automotive, and manufacturing sectors increasingly depend on the reliability of their machinery, accurately predicting maintenance needs has become essential for ensuring safety, maximizing efficiency, and reducing costs. This necessity has driven the shift from traditional prognostic methods to advanced machine learning techniques (Calabrese et al., 2020; Deutsch & He, 2018). These modern methods utilize large datasets to effectively identify complex patterns and trends in machinery wear and tear, significantly enhancing our ability to predict equipment failures (Duc Nguyen et al., 2019).

However, the application of ML in PHM is limited by significant challenges, such as models interpretability. The "black box" nature of many ML algorithms, particularly those based on deep learning, obscures the decision-making processes underlying their predictions. This opacity is a considerable concern in fields when understanding the 'why' behind a prediction is as critical as the prediction itself, necessitating models that stakeholders can trust and interpret (Baptista et al., 2022; Kononov et al., 2023; Vollert et al., 2021).

Historical reliance on reliability and physics based models for RUL estimation, though effective, often staggers upon the complexities inherent in real-world operational scenarios. These traditional methods necessitate detailed domain knowledge and often lack the flexibility to adapt to different types of machinery (X. Li et al., 2018; Si et al., 2011; Yan et al., 2021). The integration of machine learning into PHM, especially with the advent of sophisticated algorithms and the increased availability of sensor data opens a new opportunities in RUL prediction. This new technologies is characterized by learning from historical performance data, detecting subtle patterns, and predicting future outcomes with increased accuracy (A. Li et al., 2018; Yang et al., 2020).

The diversity and complexity of data in PHM, combined with the unique operational characteristics of different machinery, pose additional obstacles. These factors complicate the task of creating generalized models that are both accurate and interpretable across varied contexts (Lakkaraju et al., (2016). The need for models that can adapt to such diversity while

providing clear insights into their predictions is pressing (Rudin et al., 2022).

In response to these challenges, our research presents a framework that integrates Network Theory with SHapley Additive exPlanations (SHAP) to enhance the accuracy and the interpretability of ML-based RUL predictions. Our contributions are manifold and aim to bridge the gap between complexity and explainability:

I. **Application of a SHAP Theory**: We use a surrogate Model to translate complex interactions from deep learning models into SHAP interaction values.

II. **Application of Network Theory and FIN**: The SHAP interaction values are mapped onto the Feature Interaction Network. This mapping provides a detailed analysis of feature interdependencies to improve our understanding of the factors that affect the reliability of machinery.

III. **Integration of SHAP and Network Theory**: The proposed method combines SHAP values with Network Theory to develop an "augmented" Feature Interaction Network (FIN). This network helps clarify and quantify how different features interact and influence RUL predictions.

The novelty of this research lies in the fusion of network theory with feature importance methodologies to decode the nuanced interplay of operational parameters. By applying a Feature Interaction Network (FIN), a structural map of feature interdependencies further enriched by the integration of SHAP values, we were quantifying and explain feature contributions. Central to this approach was the novel application of surrogate models, facilitating the distillation of SHAP interaction effects into discernible edge strengths within the FIN. Concurrently, the combination of mean absolute SHAP values with network centrality metrics allows positioning a more comprehensive description of feature significance and influence. This research aims to envelope an innovative yet pragmatic set of tools, that can enhance Explainability and interpretability of predictive maintenance practices.

The paper is organized as follows: Section II surveys related literature, establishing the context for our contributions. Section III details our methodology, highlighting the synergistic use of SHAP analysis and Network Theory to decode ML model decisions. Section IV discusses the empirical findings, focusing on the insights gleaned from the FIN and its practical implications for PHM. Section V concludes, reflecting on the impact of our work and suggesting directions for future research in enhancing model transparency and reliability.

2. BACKGROUND AND LITERATURE REVIEW

In the field of prognostics and health management (PHM), the ability to accurately predict the Remaining Useful Life (RUL) of machinery is gaining traction (Lei et al., 2018; Ramezani et al., 2019; Zhao & Addepalli, 2020). This increased popularity is largely driven by advancements in machine learning and deep learning technologies. (Berghout & Benbouzid, 2022; Chen, Wu, Zhao, Guretno, Yan, Member, et al., 2021; Ferreira & Gonçalves, 2022). This review aims to summarize recent developments in RUL prediction, highlighting the evolution of methodologies and techniques across various industrial sectors.

The significant improvements in RUL prediction began with the innovative preprocessing of sensor data. For instance, Ensarioğlu et al., (2023) introduced a method that combined difference-based feature construction with a hybrid 1D-CNN-LSTM model, enhancing prediction accuracy significantly. Among the more notable preprocessing techniques is the sliding time window method, which organizes time-series signals into segments of equal length for more consistent input data (Guo et al., 2022). While effective, this method can be labor-intensive and somewhat dependent on the operator's expertise. Another valuable technique is the short-time Fourier transform (STFT), which considers the time correlation of signal sequences, providing a robust basis for subsequent analyses (Liu et al., 2022; Zhang et al., 2023). Also, the integration of long and short-term memory networks (LSTMs) with convolutional block attention modules has improved our understanding of neural decision-making processes (Remadna et al., 2023). The application of deep convolutional variational autoencoders equipped with attention mechanisms has improved the spatial distribution of features, thereby enhancing the interpretability of predictive models (Cheng et al., 2022).

The interpretability of machine learning techniques in RUL prediction has seen significant advancements, particularly through the integration of attention mechanisms and feature fusion frameworks. An attention-based deep learning framework was developed to effectively combine handcrafted and automated features for accurate RUL prediction, demonstrating high efficiency performance on real datasets (Chen, Wu, Zhao, Guretno, Yan, & Li, 2021). Remadna et al., (2023) proposed a fusion of an attention-based convolutional variational autoencoder with an ensemble learning classifier, achieving high accuracy and improved interpretability. Watson (2020) highlighted the conceptual challenges in interpretable machine learning (IML), emphasizing the need for clarity in target definitions and the importance of error rate considerations and testing for IML algorithms. Additionally, Xu et al., (2022) introduced an approaches combined deep learning with other techniques such as particle filters and knowledge distillation to enhance feature extraction, interpretability, and model compression for efficient RUL prediction.

Ye & Yu, (2023) introduced the Selective Adversarial Adaptation Network (SAAN), an approach to domain adaptation employing selective feature interaction for effective knowledge transfer in machine RUL prediction under variable conditions. Kobayashi et al., (2023), also highlighted the critical need for transparency and interpretability in AI models, emphasizing the significance of Explainable AI (XAI) and Interpretable Machine Learning (IML) in RUL prediction in digital twin systems. Zou et al., (2021) proposed an approach for RUL prediction in small data scenarios using a fully convolutional variational auto-encoding network, effectively addressing underfitting issues and demonstrating superior performance in degradation feature extraction and failure threshold determination compared to traditional models.

LIME was proposed by(Ribeiro et al., 2016) as a local model-agnostic approach to interpretability. It has been since then used extensively in prognostics and health management. LIME is a local-model because it approximates the learning model with an interpretable simplified surrogate around a single prediction. As a model0agnostic approach, LIME is a generic and works with any underlying predictive model.

This method has been particularly useful for RUL prediction, as it allows engineers to understand the impact of different features on the predicted outcomes. For instance, Khan et al., (2022); Serradilla Oscar et al., (2020) demonstrated the efficacy of LIME in explaining RUL predictions, enabling a deeper understanding of the degradation patterns and contributing factors, thus facilitating more informed maintenance decisions.

In a recent study, Alomari et al., (2023)developed a comprehensive method for predicting the Remaining Useful Life (RUL) of aircraft engines. Our approach integrates advanced feature engineering, dimensionality reduction through principal component analysis, and a range of feature selection techniques, including Genetic Algorithms, Recursive Feature Elimination, Least Absolute Shrinkage and Selection Operator Regression, and Feature Importances from Random Forest models. A significant innovation in this research is the introduction of the Aggregated Feature Importances with Cross-validation (AFICv) technique. This method enhances the selection process by prioritizing features based on their mean importance also establishes a selection criterion that retains features contributing up to 70% of the cumulative mean sum which is effectively simplifies the model complexity. Another finding in our research is introducing a novel PCA-based interpretability framework to provide actionable insights and enhance the practical utility of our findings for domain experts in the aerospace industry.

2.1. Data Description

The N-CMAPSS dataset (Chao et al., 2021) is a dataset that uses real flight conditions from a commercial jet to simulate the operative conditions (w) within its model. This dataset provides synthetic degradation trajectories for a fleet of turbofan engines, effectively replicating various unknown initial health states under authentic flight conditions. It includes eight distinct datasets derived from 128 engines, each illustrating seven unique failure modes. These modes predominantly affect the flow (F) and efficiency (E) of key engine components such as the fan, low-pressure compressor (LPC), high-pressure compressor (HPC), high-pressure turbine (HPT), and low-pressure turbine (LPT).

Flight conditions within the N-CMAPSS model are categorized into three distinct classes based on the length of the flight. The details of these flight classes, along with the specific failure modes for each dataset, are meticulously documented in Table 1 (4 datasets were used only from the entire original dataset). Additionally, the dataset provides extensive information on the scenario descriptors as in Table 1, and measurements and virtual sensors, which are thoroughly described in the turbofan Jet engine schematic representation Figure 1 and Table 2. This structured approach in modeling the failure modes and operational conditions forms the backbone of the current model development, offering a realistic and detailed perspective of engine degradation under varied flight scenarios.

Table 1 N-CMAPSS Datasets overview

Name	# Units	Flight Classes	Failure Modes
DS01	10	[1 - 2 - 3]	1
DS02	9	[1 - 2 - 3]	2
DS03	15	[1 - 2 - 3]	1
DS05	10	[1 - 2 - 3]	1

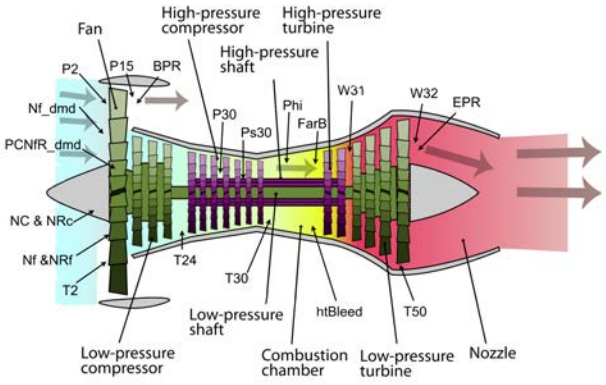

Figure 1 Turbofan Jet Engine Schematic Representation

2.2. Data preprocessing and feature selection

Standardization was applied to the dataset, as detailed in equations 1-3, normalizing each feature to have zero mean and unit variance. This step was essential for ensuring consistency across different data scales and enhancing the efficacy of the subsequent feature selection and machine learning models:

$$Standardization \quad Z = \frac{x - \mu}{\sigma} \tag{1}$$

$$Mean \quad \mu = \frac{1}{n}\sum_{i=1}^{n}(x_i) \tag{2}$$

$$Standard\ Deviation \quad \sigma = \sqrt{\frac{1}{n}\sum_{i=1}^{n}(x_i - \mu)^2} \tag{3}$$

Feature selection is critical in prognostics and health management, offering substantial benefits for applications such as RUL prediction and fault detection. By eliminating redundant features, this process effectively reduces the input dimensions for machine learning models, thereby enhancing their performance by focusing on the most informative attributes (Alomari et al., 2023; Aremu et al., 2020).

In this study, features are selected based on their statistical variability. Sensors that exhibit zero standard deviation, indicating no variation and thus no predictive value, have been excluded. An example of this selection process can be seen in Figure 2, which illustrates how sensors are chosen based on their variability over time. In Figure 2, features such as 'T2', 'W50', and 'Nc' exhibit fluctuating values, whereas other features remain constant, indicating they provide limited informational value to the mode.

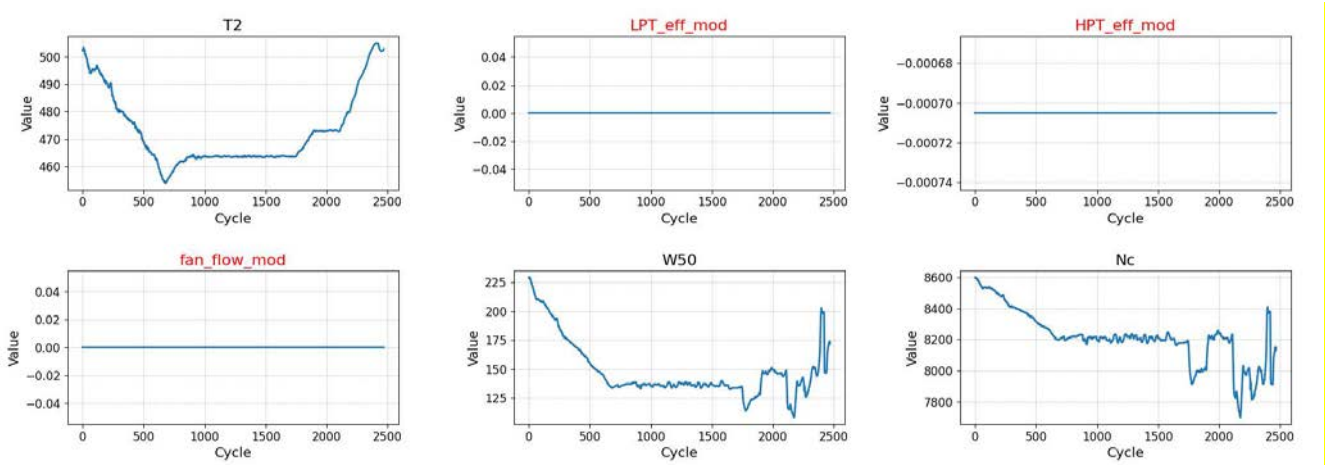

Figure 2 Variability Analysis of Sensor Data for Feature Selection

This selection was specifically tailored to exclude sensors with negligible fluctuations or redundant information, focusing instead on those providing significant insights into engine performance and wear. The final selected features are listed in Table 2.

Table 2 list of the selected features

alt	Mach	TRA	T2	T24
P24	Ps30	P40	P50	Nf
T30	T48	T50	P15	P2
Nc	Wf	T40	P30	P21

3. METHODOLOGY

The methodology, illustrated in Figure 3, is based on a composite model integrating Deep Gated Recurrent Units (GRU), Convolutional Neural Networks (CNN), a customized Time Distributed Attention mechanism, and an innovative Feature Interaction Network (FIN). The goals are to improved the precision and interpretability of RUL predictions for aircraft engines.

The GRU layers illustrated in Figure 4 capture the temporal correlations within the sequential engine data, while the CNN layers distill critical spatial features, thereby enhancing the model's capability to identify salient patterns indicative of engine failure. The custom attention layer defined in Figure 5 allows to selectively simplify temporal events within the engine's operational history, further refining the model's predictive accuracy.

To enhance interpretability, the FIN, constructed using SHAP (SHapley Additive exPlanations) values shown in Figure 10, quantifies the impact and interactions of individual features. The node's size within the FIN is representative of the mean absolute SHAP values. This allows better demonstration the feature importance visually. Edge weights are defined by SHAP interaction values, illustrating the strength of the interaction between each pair of features.

The methodological combination of GRU, CNN, attention mechanisms, and SHAP-driven FIN proffers a multidimensional interpretable approach, in the field of aerospace prognostics and health management.

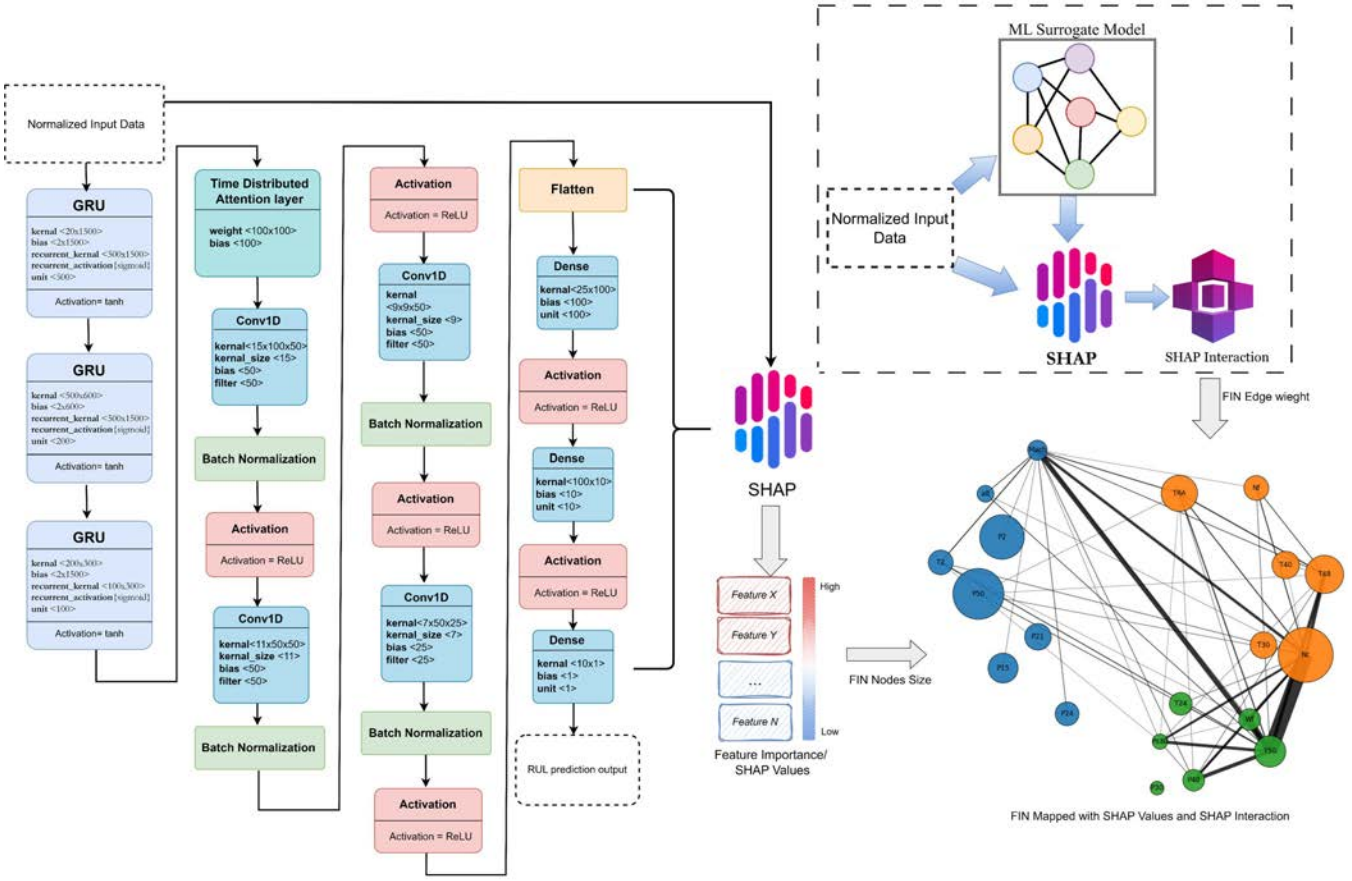

Figure 3 proposed model for RUL prediction and FIN

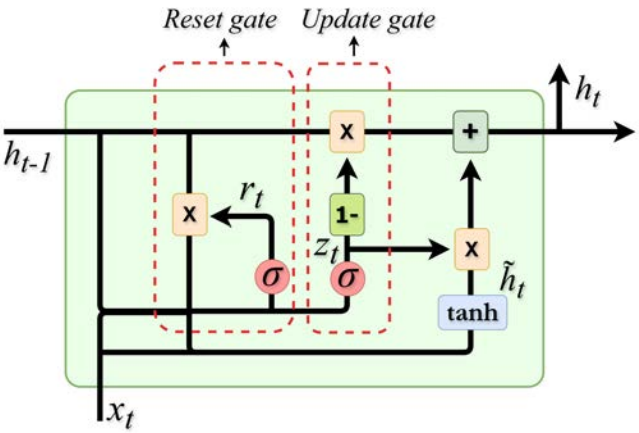

Figure 4 Gated recurrent unit (GRU) neural network structure

The GRU, presented in Figure 4, introduced by (Cho et al., 2014), is a type of recurrent neural network designed to model temporal sequences and long-range dependencies more effectively than standard RNNs. They simplify the recurrent module while retaining the ability to capture dependencies in time-series data, making them computationally efficient and powerful for tasks such as speech recognition, language modeling, and sequential prediction, which are crucial in PHM contexts (Cao et al., 2021; Zhou et al., 2022, Zhou et al., 2023). The core functionality of GRUs relies on the modulation of information flow across sequence steps, controlled by the update and reset gates.

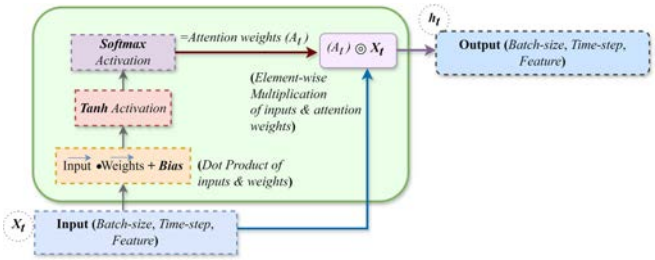

Figure 5 time-distributed attention mechanism

After the GRU layers, a customized Time Distributed Attention mechanism (see Figure 5) was used to improve the model's ability to focus on the most critical features within the sequential data. It applies an attention mechanism to each time step independently. This is achieved by computing an attention score for each feature using a learned weight matrix and bias vector. The scores are then normalized via a softmax function to create attention weights, which are subsequently used to scale the input features. This process allows the model to dynamically prioritize significant information, thereby improving the interpretability and accuracy of RUL predictions.

3.1. SHapley Additive exPlanations (SHAP)

In the field of explainable artificial intelligence (XAI), Shapley Additive exPlanations (SHAP) (Lundberg et al., 2017) values are a central tool for quantifying the contributions of individual features to a model's prediction. Rooted in cooperative game theory, SHAP values, formally described in Equation (4), enable the measurement of each feature's influence by comparing the model's output with and without the presence of the feature. This approach not only fosters transparency but also imbues the analysis with a rigorous mathematical foundation.

SHAP is crucial to PHM (Alomari & Andó, 2024) where understanding the impact of various features on the prediction of system failures or maintenance needs is paramount. SHAP values facilitate this by attributing precise, quantifiable contributions of individual features to the overall prediction of system health, thereby enabling more accurate and timely decision-making.

$$\text{SHAP}(j) = \sum_{S \subseteq N \setminus \{j\}} \frac{|S|!\,(|N| - |S| - 1)!}{|N|!} [f(S \cup \{j\}) - f(S)] \quad (4)$$

S - is a subset of features
N - is the set of all features
$|S|$ - denotes the cardinality (size) of set $\boldsymbol{S}$
$f(S \cup \{j\})$ - is the prediction with both the features in set $\boldsymbol{S}$ and feature $\boldsymbol{j}$
$f(S)$ - is the prediction with just the features in set $\boldsymbol{S}$

Equation (4) computes the contribution of feature j by iterating over all possible subsets S of the remaining features in N and comparing the difference in the prediction when feature j is included versus when it is excluded.

3.2. Network Theory

Network Theory (Borgatti & Halgin, 2011) provides a framework for understanding the structure and dynamics of complex systems by visualizing them as networks of nodes (features) and edges (interactions). This approach is especially useful in PHM, to reveal the complex interdependencies between system components. By applying Network Theory to create a Feature Interaction Network (FIN), we can perform both visual and quantitative analyses of how individual system features interact and collectively impact overall system behavior (see Figure 6). The decision to use a FIN was deliberate; it helps in mapping out the relationships and dependencies among features effectively and also simplifies the understanding of complex data structures for engineers and domain experts.

To accurately model the interactions within a FIN, the Graphical Lasso (GLasso) algorithm (Friedman et al., 2008) was utilized. GLasso effectively determines the conditional independence structure between variables (features), offering a sparse representation of the feature interaction network. The mathematical formulation of Glasso (Equation 5) is centered on optimizing the following objective function:

$$\min_{\Theta} - \log\det(\Theta) + tr(\mathcal{S}\Theta) + \lambda\|\Theta\|_1 \quad (5)$$

Here, Θ represents the precision matrix (inverse covariance matrix) to be estimated, $\mathcal{S}$ is the empirical covariance matrix of the data, $log\ \det(\Theta)$ ensures the positive definiteness of Θ, $tr(\mathcal{S}\Theta)$ is the trace term encouraging fidelity to the observed data, $\|\Theta\|_1$ denotes the L_1 norm imposing sparsity, and λ is a regularization parameter controlling the degree of sparsity. By solving this optimization problem, GLasso identifies significant interactions while discarding the insignificant, resulting in a FIN that highlights the most crucial feature relationships.

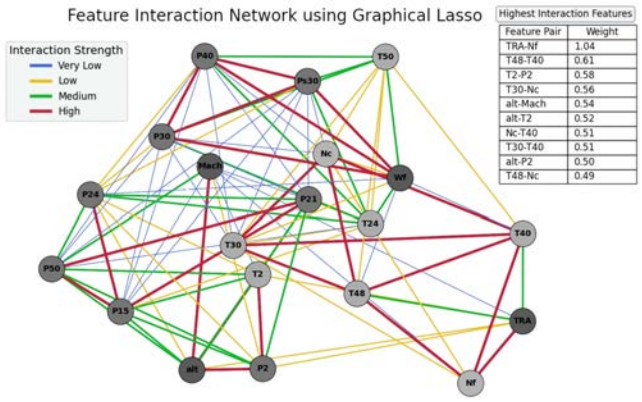

Figure 6 Basic FIN graph with interaction strength

Within the framework of Network Theory, centrality measures serve as tools to compute the prominence of individual nodes. The centrality measures, namely degree centrality for direct linkages, betweenness centrality for intermediary influence, and closeness centrality for overall accessibility are presented in equations (6-8), are instrumental in discerning the structural backbone of the Feature Interaction Network.

Degree centrality $(\boldsymbol{C_D})$ of a node v is defined as the fraction of nodes it is connected to. It reflects the immediate influence of a node within the network.

$$C_D(v) = \frac{\deg(v)}{N-1} \tag{6}$$

Where $\deg(v)$ is the degree of node v (i.e., the number of edges incident to v and N is the total number of nodes in the network. Degree centrality helps us pinpoint features that exert considerable control over the system's behavior, thereby identifying potential points of proactive maintenance and intervention.

Betweenness centrality $(\boldsymbol{C_B})$ of a node v quantifies the number of times a node acts as a bridge along the shortest path between two other nodes.

$$C_B(v) = \sum_{\mathcal{S} \neq v \neq t} \frac{\sigma_{st}(v)}{\sigma_{st}} \tag{7}$$

Where σ_{st} is the total number of shortest paths from node $\mathcal{S}$ to node t and $\sigma_{st}(v)$ is the number of those paths that pass through v, it highlights the node's role in facilitating interactions between other nodes. Identifying such nodes helps in strategizing interventions that can prevent cascading failures in engine operations.

Closeness centrality $\boldsymbol{C_c(v)}$ measures how close a node is to all other nodes in the network, indicating how easily information can flow from the given node to others.

$$C_c(v) = \frac{N-1}{\sum_{u \neq v} d(v,u)} \tag{8}$$

Where $d(v,u)$ is the shortest path distance between nodes v and u, and N is the total number of nodes in the network. Features with high closeness centrality are likely to affect the system more rapidly, making them critical targets for monitoring and early preventive maintenance.

Community detection algorithms, such as the Louvain method (De Meo et al., 2011) given by equation (9), partition the network into communities or clusters of nodes that are more densely connected with each other than with the rest of the network. This segmentation can reveal modular structures within the feature set, suggesting subsystems within the engine that have distinct behaviors.

$$Q = \frac{1}{2M} \sum_{ij} \left[A_{ij} - \frac{k_i k_j}{2m} \right] \delta(c_i, c_j) \tag{9}$$

The following definitions characterize the parameters of the algorithms

- A_{ij} represents the weight of the edge between nodes i and j. For unweighted networks, A_{ij} is 1 if there is an edge between i and j, and 0 otherwise.
- $k_i \; and \; k_j$ are the sum of the weights of the edges attached to nodes i and j, respectively.
- m is the sum of all the edge weights in the network.
- $c_i \; and \; c_j$ are the communities of nodes i and j
- δ is the Kronecker delta function, which is 1 if $c_i = c_j$ (i.e., nodes i and j are in the same community) and 0 otherwise.

The goal of the Louvain method is to maximize Q through a heuristic approach that iteratively groups nodes into communities.

3.3. Evaluation metrics

The proposed model evaluation was conducted using the N-CMAPSS datasets (DS01, DS02, DS03 and DS05), focusing on the accuracy of Remaining Useful Life (RUL) predictions. The performance of our proposed model was primarily assessed by measuring the discrepancy between the predicted and actual RUL values. For this purpose, we employed two key metrics: Root Mean Square Error (RMSE) and NASA Score (Saxena et al., 2008), as defined in equations (10 - 13). These metrics, calculated over the number of data points (n), provided a comprehensive understanding of the model's

predictive accuracy and reliability in various operational scenarios presented within the N-CMAPSS datasets.

$$RMSE\ (P_{RUL}, T_{RUL}) = \sqrt{\frac{1}{n}\sum_{i=1}^{n}(P_{RUL} - T_{RUL})^2} \quad (10)$$

$$\text{NASA Score}_i = \begin{cases} exp\left(-\frac{\Delta_i}{10}\right) - if\ \Delta_i < 0 \\ exp\left(-\frac{\Delta_i}{13}\right) - if\ \Delta_i \geq 0 \end{cases} \quad (11)$$

Where:

$$\Delta_i = RUL_{predicted\ i} - RUL_{true_i} \quad (12)$$

$$NASA\ Score = \frac{1}{n}\sum_{i=1}^{n} NASA\ Score_i \quad (13)$$

4. Results and Discussion

Our enhanced approach to predicting Remaining Useful Life (RUL) uses an integration of Deep Gated Recurrent Units (GRU), Convolutional Neural Networks (CNN), and a custom Time Distributed Attention mechanism. This tailored combination has advanced the accuracy of RUL predictions by effectively capturing complex temporal and spatial patterns within engine operational data, crucial for early and accurate fault detection. The inclusion of the Custom Attention Layer allows for identifying critical features and time steps, significantly refining the interpretability of our predictive models. The effectiveness of these innovations is substantiated by our empirical results presented in Tables 3 and 4. Table 3 includes a comparison of some of our results with three methods from the literature, while Table 4 presents the results for the remaining engines, for which no direct comparisons to existing studies could be made.

Across the different datasets, the model demonstrates proficiency in RUL prediction, as evidenced by the calculated Root Mean Square Error (RMSE) and the NASA prognostics score, with a significant performance in the critical RUL phase. This is important since the latter half of life where accurate prediction is most vital. Particularly significant are the outcomes on DS02 and DS03, where the model achieves RMSE values as low as 2 cycles for the critical RUL, alongside correspondingly low NASA-scores, highlighting the model's precision in the most consequential phase of the engine's lifecycle.

The visualization of the RUL prediction and critical RUL of two engines, 9 and 12, from DS01 and DS03, respectively, along with their SHAP values, is presented in Figures 7 and 8. These figures illustrate the model's ability to track the Remaining Useful Life (RUL) over engine cycles accurately, with a particular focus on the critical RUL phase. The SHAP interpretation plots highlight the influence of various sensors on the model's predictions.

For Engine 12, significant features include 'Nc' (corrective speed), 'P50' (pressure at the fan outlet), and 'T2' (temperature at the fan inlet). The high SHAP values for these features indicate their substantial impact on the RUL predictions. Specifically, 'Nc' demonstrates a strong correlation with the engine's operational efficiency, reflecting its role in adaptive speed control. Similarly, 'P50' and 'T2' provide crucial insights into the pressure and temperature dynamics, essential for accurate prognostics.

In Engine 9, the SHAP values reveal 'Nc', 'T50' (temperature at the engine outlet), and 'P2' (pressure at the fan inlet) as key contributors. The interactions between 'Nc' and 'T50' (as they have opposite influence) suggest that the corrective speed adjustments are heavily influenced by thermal conditions at critical engine points. The significant SHAP values for 'P2' underscore the importance of pressure measurements in anticipating engine failures.

Table 3 Prognostics performance assessment comparison with different methods

Dataset	**Engine**	RMSE Proposed	RMSE Literature (Koutroulis et al., 2022)	RMSE Literature LR+ (Maulana et al., 2023)	RMSE Literature MLP+ (Maulana et al., 2023)
DS02	11	4.7	5.1	11.4	11.5
	14	6.1	11.9	10.9	11.1
	15	4	5.8	8.9	18.2
DS03	13	3.9	6.8	--	--
	14	3.2	5.1	--	--
	15	2.1	3.04	--	--

Table 4 Comparative assessment of RMSE and NASA-Score metrics for RUL prediction across engine units

Dataset	Engine	RMSE	RMSE Critical RUL	NASA-Score	NASA-Score Critical RUL
DS01	**7**	8.4	7	1.1	0.9
	8	6	4	0.6	0.5

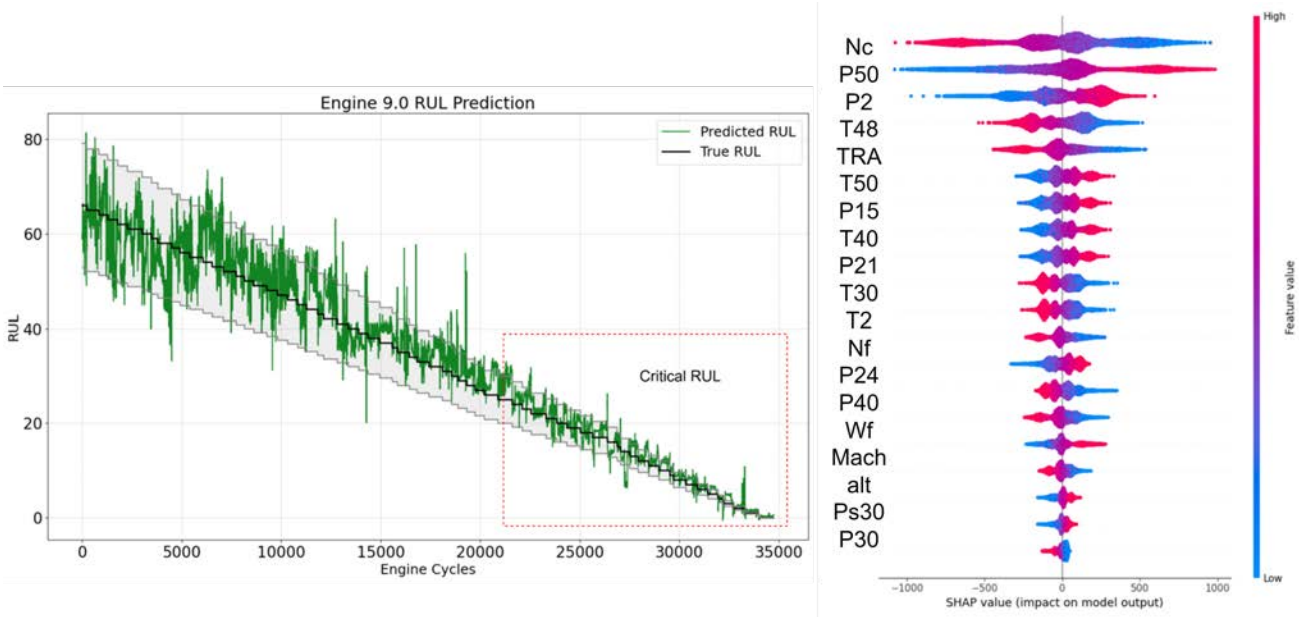

Figure 3 RUL prediction of engine 9 of DS01 with SHAP summary

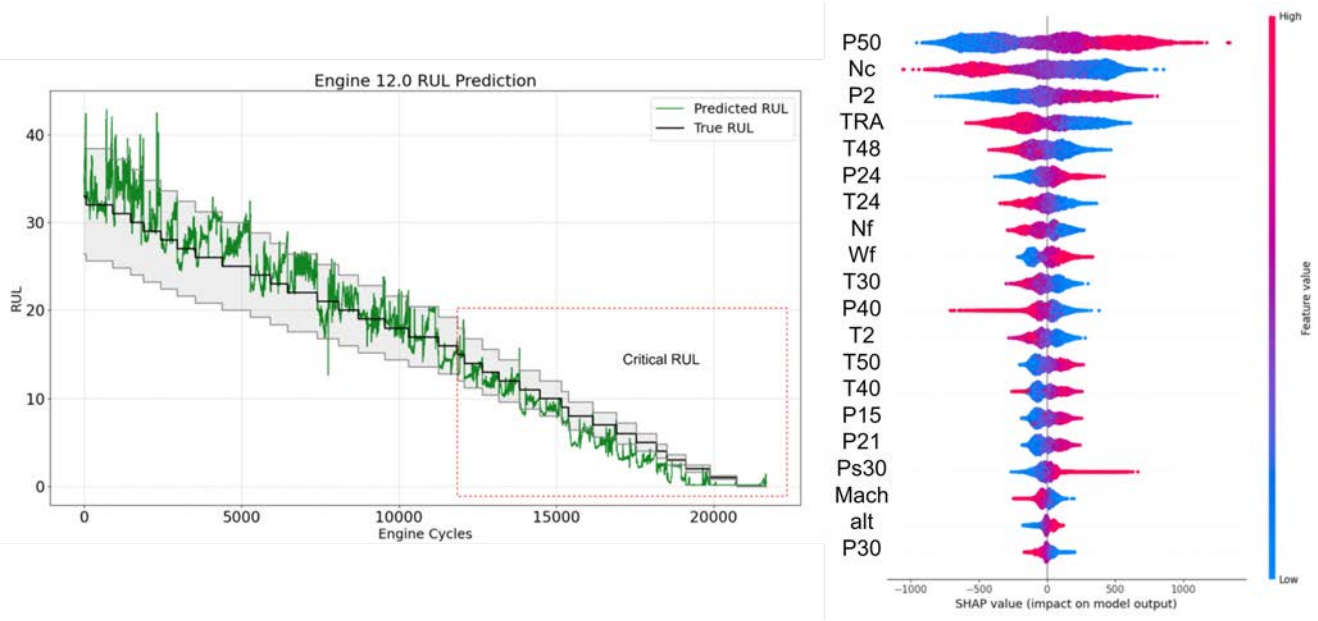

Figure 4 RUL prediction of engine 12 of DS03 with SHAP summary

The Feature Interaction Network (FIN) in Figure 8 provides an overview of the complex relationships inherent in the proposed predictive model for Remaining Useful Life (RUL). Through community detection algorithms, it has discerned distinct clusters within the network, indicative of underlying structures where subsets of features exhibit tightly knit interactions, potentially alluding to functional modules within the engine's operational parameters. The community color-coding allows to observe the modular nature of feature interdependencies, which may correspond to different physical or operational aspects of engine performance. Additionally, the betweenness centrality analysis reveals key nodes such as 'TRA,' 'P24,' and 'P15' that act as critical conduits in the flow of information through the network, signifying their roles in the model's inference processes.

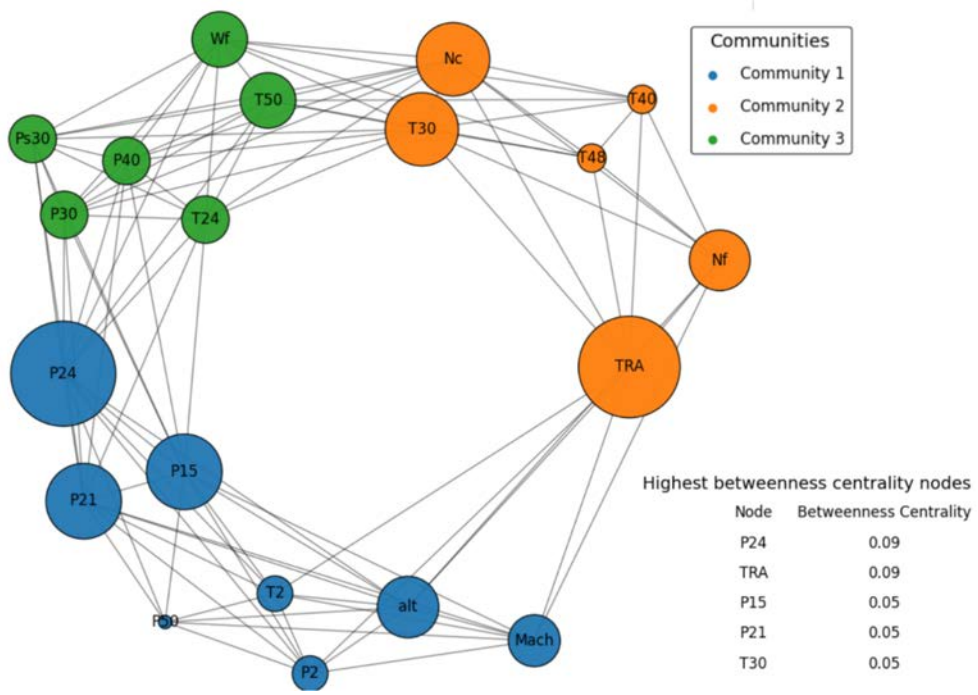

Figure 5 FIN with betweenness centrality and community detection

In Figure 10, we illustrate an innovative Feature Interaction Network (FIN) that leverages SHAP values to illuminate the complex dynamics within our predictive model for Remaining Useful Life (RUL) of aerospace engines. This network diagram, empowered by a surrogate model, not only visualizes the relative influence of various engine features but also clarifies their interrelationships. Each node, scaled according to mean absolute SHAP values, reflects the magnitude of influence each feature holds over the RUL predictions, with larger nodes marking more influential features.

These nodes are distinctly color-coded to represent different communities or clusters of features that share similar behavior patterns within the predictive framework, highlighting how groups of related features collectively impact engine performance. The edges between nodes, whose thickness is determined by the SHAP interaction values, illustrate the strength of the interactions between feature pairs, revealing critical dependencies and synergies.

Key interactions such as those between 'NC' (corrective speed) and temperatures at critical engine locations ('T50' and 'T48') suggest a profound connection between engine speed adjustments and thermal conditions. This relationship is crucial for maintaining optimal engine performance, particularly under varying operational stresses. The interaction between 'NC' and 'T50' highlights how adjustments in engine speed can be crucial in managing the engine's thermal output to avoid overheating while maintaining efficiency.

Further, the interaction between 'T50' and 'Mach' (aircraft velocity relative to the speed of sound) underscores the significant impact of aerodynamic performance on engine thermal management. The relationship between engine thermal outputs and flight speed suggests that higher speeds may require adjustments in thermal management strategies to maintain engine integrity and performance.

Additionally, the 'NC - Mach' interaction points to a dynamic balancing act required between engine speed and aircraft velocity, indicating that engine control systems need to be highly adaptive to changes in flight dynamics. This adaptiveness is crucial for optimizing fuel consumption and minimizing wear and tear under different flight conditions.

Lastly, the interaction between 'T50' and 'P40' (pressure at the fan outlet) sheds light on how temperature and pressure management are interlinked, playing a pivotal role in ensuring the engine's thrust efficiency and overall stability. This insight is particularly valuable for developing more effective predictive maintenance strategies, aiming to reduce unexpected downtimes and extend the engine's useful life.

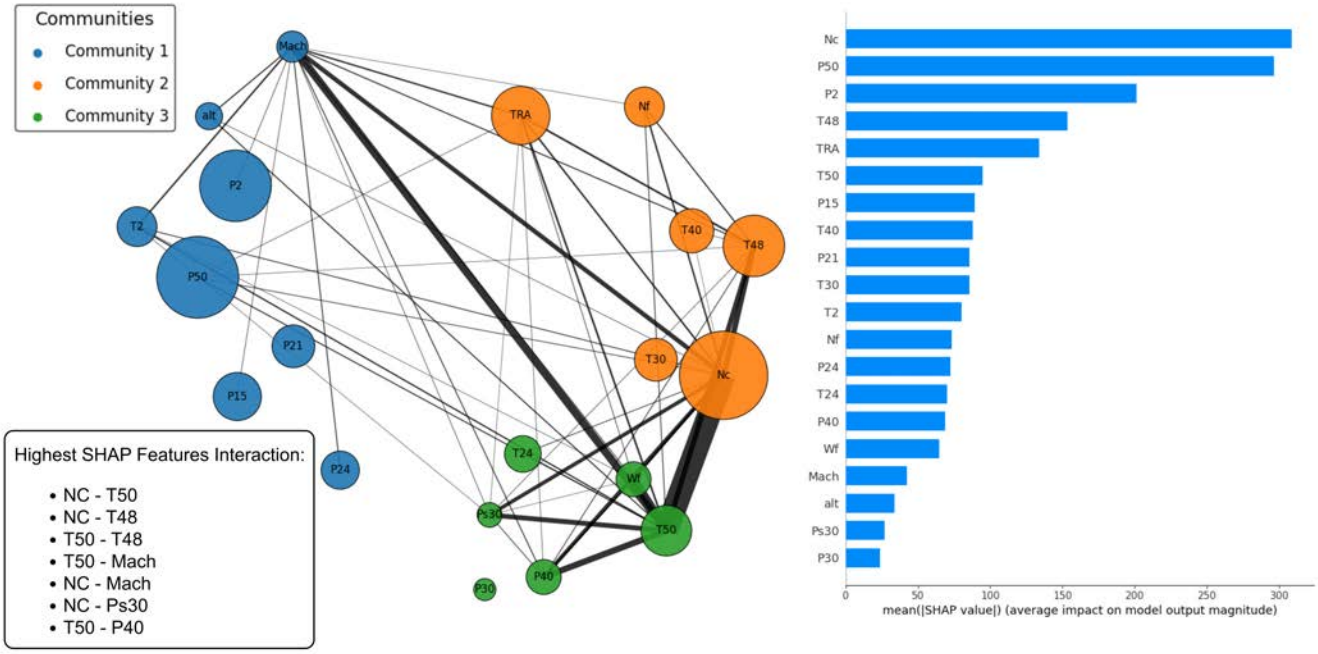

Figure 6 Feature Interaction Network (FIN) Visualizing Key Dependencies and Community Structures: This network map illustrates the Feature Interaction Network (FIN) with nodes sized according to their mean absolute SHAP values, which reflect the impact magnitude on the model's output. The nodes are color-coded by community, identifying clusters of tightly interconnected features that influence system behavior in distinct ways. Thicker lines between nodes indicate stronger SHAP

feature interactions, highlighting critical dependencies such as NC-T50 and T50-Mach, which are pivotal for understanding complex dynamics within the aerospace engine's operations

5. CONCLUSION

In conclusion, our research aims to advance the predictive maintenance field by developing a prognostic framework that combines cutting-edge machine learning techniques with innovative interpretative methodologies to predict the Remaining Useful Life (RUL) of aerospace engines. Utilizing a Surrogate Model, we have successfully mapped complex SHAP feature interactions into a well-defined Feature Interaction Network (FIN). This network, structured with nodes proportionally scaled by mean absolute SHAP values and connections defined by the strength of SHAP interactions, vividly represents the intricate relationships between operational parameters.

Our detailed analysis highlighted crucial feature interactions, notably between corrective speed and critical engine temperature, which are point factors essential for optimizing engine efficiency and performance. Furthermore, the application of community detection in the FIN has significantly deepened our understanding of these features, grouping related variables to illuminate how they collectively impact RUL predictions. This clustering clarifies the predictive model's structure and enhances the interpretability of the data, providing clear pathways for intervention.

The visual representation of the FIN is not merely an analytical tool; it acts as a vital conduit translating complex, data-driven insights into tangible, operational strategies. This visualization underscores the transformative potential of interpretative machine learning to convert abstract data into actionable intelligence, a resource of value in the high-stakes field of aerospace prognostics where the accuracy of predictions can directly influence operational safety and maintenance efficiency.

BIOGRAPHIES

Yazan Alomari is a Ph.D. candidate in Computer Science at Eötvös Loránd University, Hungary, since September 2020, with collaboration from TU Delft University, The Netherlands. His research focuses on leveraging large language models for Prognostics and Health Management (PHM) in aerospace, emphasizing predictive maintenance through AI insights. His work spans across artificial intelligence, machine learning, and data mining & analysis, aiming to enhance system reliability and operational efficiency. Yazan has also contributed to academia as a University Lecturer at Eötvös Loránd University, imparting knowledge in data science, machine learning, and digital manufacturing. His publications underscore advancements in aerospace PHM, eXplainable AI and machine learning interpretation, showcasing his commitment to advancing AI applications in critical sectors.

Marcia L. Baptista BSc. and MSc. in Informatics and Computer Engineering. Instituto Superior Tecnico, Lisbon, Portugal September 2008) is an Assistant Professor at the Aerospace Faculty of TU Delft since 2020. She holds a PhD from the Engineering Design and Advanced Manufacturing (EDAM) program under the umbrella of MIT Portugal. Her research focuses on the development of prognostics techniques for aeronautics equipment. Her research interests include eXplainable Artificial Intelligence (xAI), machine learning, hybrid modeling, maintenance and prognostics.

Mátyás Andó habil., Ph.D., is Associate Professor in Institute of Computer Science, at Faculty of Informatics of Eötvös Loránd University, ELTE, Budapest, Hungary. He teaches: Manufacturing Technologies, CNC programing, CAM systems. His research area: Improve the efficiency in the industry, I4.0 solutions (CNC machines, PLC, Welding, Image processing). Material sciences (polymer development, tribology, 3D printing). Membership: Hungarian Association of Mechanical Engineers – GTE, members of the Hungarian Academy of Sciences (Section of Engineering Sciences).

Integration of Condition Information in UAV Swarm Management to increase System Availability in dynamic Environments

ABSTRACT

The approach of prognostics and health management (PHM) focuses on the real-time health assessment of a system under its actual operating condition and even extending this by the prediction of the future state based on up-to-date system information. This pursues the aim to derive more advanced maintenance or asset deployment strategies in order to keep the operation of the system safe and reliable. In this context, the outcome of a PHM system is often used as a decision support. For a high fidelity system where the actual state is considered at every timestep and a decision is executed immediately based up on this information, Reinforcement Learning (RL) becomes a tool to find an optimized solution. Therefore the paper presents a methodology that integrates health and operational data into a RL approach in order to derive immediate operational strategies for lower degradation and higher safety and reliability. The approach is evaluated on the basis of a swarm of unmanned aerial vehicles (UAVs) that performs a complete-area path-coverage (CAPC) mission. It can be shown that the integration of health information as well as environmental data describing dynamic operating conditions lead to lower degradation and result in more reliable operations of the swarm while achieving a more flexible mission performance compared to pre-divided swarm-missions. Varying states are also taken into account, which emphasises this approach to be a highly dynamic PHM system application.

1. INTRODUCTION

To avoid fatal incidents, safety and reliability are two major objectives for developments in the aviation industry (Tumer, 2011). While safety refers to system operations without causing harm or damage to people, property or the environment, reliability focuses on the ability of a system to perform its intended functions without failure or degradation over time (Stapelberg, 2009). The latter is the motivation to develop PHM functionalities where system states are predicted in order to derive decisions for maintenance strategies to increase reliability, availability and save costs. It is evident that usage leads to some level of degradation. Implementing a specific usage strategy can mitigate this degradation, resulting in extended system functionality and improved operational reliability, even in systems that have already experienced degradation. This approach is called prescriptive maintenance which complements PHM approaches by utilising their outputs, namely state detections and remaining useful life (RUL) predictions. While traditional PHM approaches try to extend system usage through a more precise calculation of the RUL, prescriptive maintenance guarantees for a reliable usage of systems that already show remarkable degradation (Marques & Giacotto, 2019). Combining usage specific degradation with a PHM based condition assessment is subject of this paper, which provides a prescriptive maintenance strategy using reinforcement learning.

The system used in this paper to implement the condition-based operational optimisation is a UAV swarm. The high-level mission goal of the swarm is the CAPC which applies to time-critical reconnaissance missions and also covers a common problem definition in the field of multi-agent (MA) robotics. The following reasons emphasize the suitability of this system and use-case for the developed approach:

- **Mission reliability:** System functionality of every swarm member needs to be guaranteed in order to be able to fulfill high level mission goals of a complete area coverage. While operational capabilities of a single UAV are limited, a swarm has the advantage of achieving more challenging mission goals in shorter time. The time-factor is crucial, for example, in search and rescue missions or forest fire observations.
- **Autonomy:** UAVs do not have a pilot on board. This means that various functionalities have to be automated. System state detection, as part of a PHM approach, is a decisive one in order to guarantee for reliable system functionality.
- **Redundancy:** Every individual swarm member represents a redundancy in the swarm structure. Individual

tasks can be distributed reasonable within the whole swarm in order to define a specific usage based upon environmental conditions. This guarantees a flexible task assignment that allows for optimization strategies.

In current research literature, the aspects of the integrated approach developed in this paper are considered separately. The basic idea of using PHM for a dynamic reliability assessment is described by the authors from (Heier, Mehringskötter, & Preusche, 2018). The paper emphasises the connection of PHM and reliability topics to develop decision support tools. The authors in (Bougacha & Varnier, 2020) use PHM as a driver for decision support. They pursue the primary goal of achieving higher reliability, availability and operational safety. Especially health and RUL indicators are utilized from the PHM approach in order to establish a decision-making process. Early approaches of in-mission decision making based on system states are discussed in (Andersson et al., 2015) and (Alighanbari, 2004). The latter even includes changes within the environment where the UAVs need to react to. In addition not only one UAV is part of the mission but a swarm of UAVs is considered. Data-driven approaches and machine learning techniques were not as easy accessible and developed as they are nowadays, leaving potential for the problems presented in these papers. A more recent consideration can be found in (Darrah, Quiñones-Grueiro, Biswas, & Kulkarni, 2021) where they use an online state observation to update parameters that optimize the prognosis for specific mission profiles. The better prognostic performance can than be used to derive more precise decisions but the focus of this paper is on a single UAV.

While the previously mentioned literature deals with linking PHM approaches with reliability, the following literature analysis focuses on deploying multi-agent swarm operations in a digitized environment. A baseline for multi-agent path-coverage is shown in (Cho, Park, Park, & Kim, 2021) where different grid-based map representations are compared. Even though hexagonal grids show certain advantages, such as increased navigation capabilities, the use of a cubic grid based map representation seems to be a suitable choice for the CAPC mission. Another approach for efficient swarm applications is described in (Mahmoud Zadeh, Yazdani, Elmi, Abbasi, & Ghanooni, 2022) and focuses on data acquisition. This approach could be interesting when deploying the swarm management approach from this paper in the real world and a good concept for data acquisition is needed. Nevertheless it describes the possibilities of UAV swarms. No CAPC is performed, but the distance between UAVs for better sensor measeruments is taken into account and considered as a useful approach. In (Radzki et al., 2021) travel uncertainties for a complete UAV fleet get determined. The result is used to optimize the usage of a UAV fleet but no in-mission decisions are made. This approach rather solves a scheduling problem than dealing with in-mission decisions to react on environmental conditions and system changes.

In order to make dynamic in-mission decisions, the approach of this paper uses reinforcement learning. This allows a large amount of heterogeneous data to be taken into account, which can change spontaneously in a sequential simulation. The successful application of reinforcement learning to a similar problem statement can be seen in the following literature. Using RL to control a swarm of buoys is described in (Kouzehgar, Meghjani, & Bouffanais, 2020). The goal is also the CAPC mission but input data differs in contrast to the deployment of UAVs. More comparable is the approach in (Puente-Castro, Rivero, Pazos, & Fernandez-Blanco, 2022) where a CAPC mission is performed with UAVs. The focus lies on the high level mission goal and enables the identification of relevant parameters for the coverage task. In addition (Xiao, Wang, Zhang, & Cheng, 2020) propose an approach to solve a CAPC task as well. No considerations of external factors or systems states are integrated into the approach but it helps to get an overview to solve the high level mission goal of CAPC. The closest approach is presented in (Theile, Bayerlein, Nai, Gesbert, & Caccamo, 2020) where power limitations of UAVs are integrated into a RL approach. The CAPC mission is specified as the target, but in fact more of a path-finding algorithm is implemented, which appears to be too permeable for reconnaissance missions and power limitations do not reflect the link between usage and degradation.

This paper uses the individual results from the literature stated above to develop an integrated solution for the condition-based organisation of a UAV swarm for the CAPC task using reinforcement learning. The general approach, including the experimental setup, is presented in Section 2. The results of the approach, applied to the described use case, are presented in Section 3 and analysed in Section 4. The paper concludes with a summary and an outlook on future work in section 5.

2. METHODOLOGY

To solve the task of a CAPC mission performed by multiple UAVs with respect to their health condition, a reinforcement learning method is implemented in python using RLlib (Liang et al., 2018). RLlib is only one of many possibilities to implement RL, whereby the following aspects are favourable for this paper:

- It is open-source
- It allows the integration of own simulation-environments
- It contains the option of implementing multi-agent reinforcement-learning (MARL) approaches

For the learning algorithm the Proximal Policy Optimization (PPO) is chosen. To date, this is the only MARL-capable algorithm in RLlib, so the implementation in comparable libraries should also be considered.

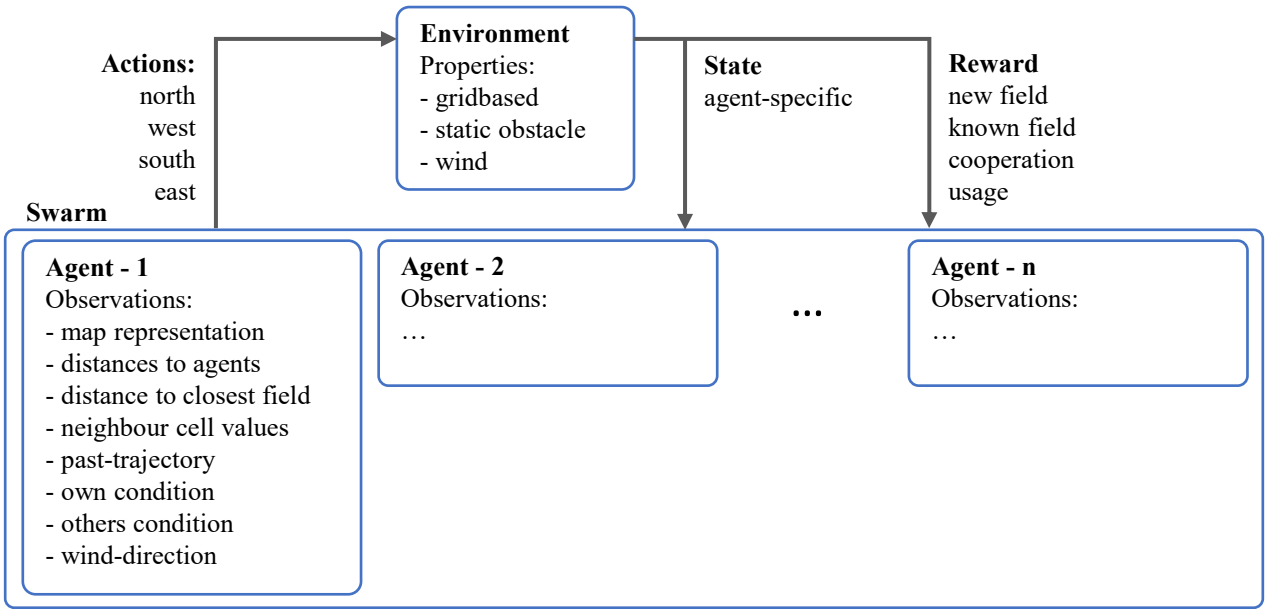

Figure 1. Framework for the multi-agent reinforcement-learning algorithm with consideration of system condition and environmental influences

The MARL method is similar to the standard RL framework where an agent is interacting with an environment through choosing actions and consequently receiving a reward. The basic principle of the MARL method with respect to the given task is shown in Figure 1. The methodology is based on the single-agent RL approach described in (Wiering & Van Otterlo, 2012) and extended with specifications to implement a MARL specific model. As it is the task to cover a certain area through creating a trajectory based on the movement decisions into the four main directions, a squared grid based environment is beneficial. This presupposes that a search is carried out along the search path with a certain radius, whereby simplified squares are assumed for coverage of a certain area that has been observed through a fly-over. While a third dimension could be used for deconfliction, it is neglected in this case to simplify the complexity of the system. The focus is on optimising a UAV swarm so that not only one agent interacts with the environment, but the actions of several UAVs are orchestrated and used as input for the environment. The action space thus becomes a vector that represents the four main directions of possible movements into north, east, south and west direction for every agent that takes part in the mission. The observation for every agent is derived from the state of the environment and takes agent-specific information into consideration. The reward rates the agents behavior and thereby helps the RL-algorithm to learn and successively improve the accumulative reward that is gathered in one mission. Every component of the MARL model is described in more detail in the following sections.

2.1. Environment Design

The MARL approach assumes multiple agents that cooperate together and interact with an environment through the execution of actions. The action of an individual agent changes the environment and in reverse calculates a reward that is fed back to the agent. In order to be aware about the actions to take the agent receives a state representation from the agent's point of view in form of observations. An environment model is necessary to provide a realistic and dynamic interaction between the environment and the agent, allowing the MARL model to learn and improve its decision-making through trial and error for a lot of training runs, which is ultimately understood as training process.

The use-case specified environment design is based on a grid based representation of a search field, that needs to be covered by a swarm of agents, the UAVs. The visualization of the environment used in this paper is shown in Figure 2 and subsequently described in detail.

The cell shape is square. This leads to four primary directions of movement, where the distance from the center of one cell to the center of its neighboring cells remains consistent. Cells that have been discoverd are displayed in beige, not visited cells are colored in green. Cells that are obstacles are colored as bricks and the wind direction is indicated as yellow arrows left and on top of the searchfield-cells. Assuming that the UAV proceed with a constant speed, the travelling distance of one timestep within the environment model is constant, which is also fits to the square shaped cells. When an UAV moves from one cell to another, it increments the value assigned to

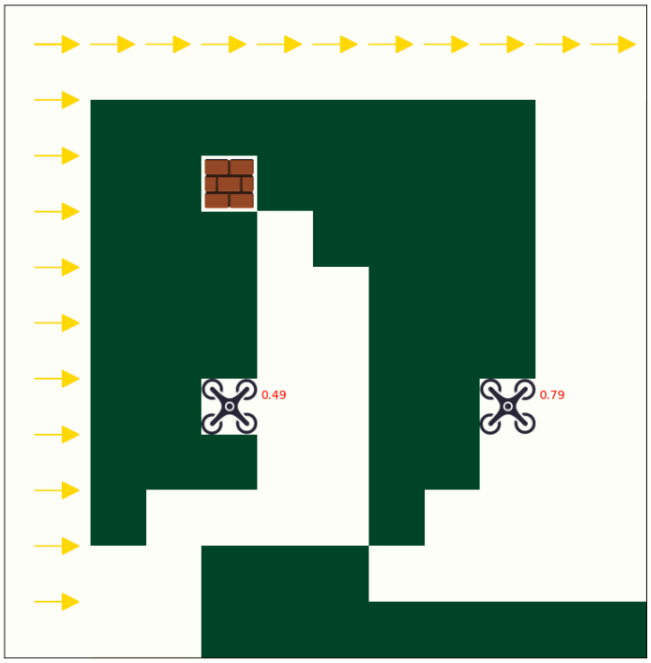

Figure 2. Environment design for a UAV-Swarm CAPC-Mission with external factors and varying system conditions

the cell by one, representing the number of visits to that cell. The highest value within the map is ten, which is utilized both for static obstacles and as a termination condition if an UAV visits a single cell too often. As an observation, which is described in detail in subsection 2.1.2, the UAV draws the map information and fortifies it to a potential map. In addition to the search field representation, the environment also incorporates a wind simulation. The wind simulation is used to specify the main influence on the system usage. A detailed description of the influence of wind on UAVs can be found in (Wang, Wang, Ali, Ting Ting, & Wang, 2019). It is assumed that the UAV is able to fly at constant speed under any wind condition. This results in a different power demand, depending on the direction of movement of the UAV and the prevailing wind direction. Higher power consumption means greater stress on the components and therefore increased degradation. The swarm configuration enables a system management where degraded UAVs take over the coverage of the search field crosswind and are thus exposed to lower degradation, while intact UAVs can take over more demanding trajectories against the wind and can absorb higher degradation without noticeable increasing the risk. The risk mitigation can be derived from the general assumption of degradation taken from (Kim, An, & Choi, 2017). While at the beginning of a system life the degradation is mainly characterised through wear represented through a linear progression, the degradation grows exponentially at the end of a system life, which results in higher chances for unexpected system failures.

Within the environment design wind is considered as constant while the direction of wind can change between the missions. Generally missions are treated individually so that the condition of one UAV gets defined at the beginning of a mission as well. The condition is chosen arbitrarily between 0.1 and 1, representing UAVs with high degradation when a low value is chosen and UAVs with a good condition if a value is chosen that is close to one.

The upcoming sections explain the design of the remaining parts of the MARL approach: the action space, the observation space, and the reward function. Additionally, it covers how missions are initialized and outlines the experiments conducted to assess RL-algorithm performance.

2.1.1. Action Space

The grid-based representation of the search field enables movements along the four main directions, from cell center to cell center, ensuring an equal traveling distance. The actions are defined as a single value from zero to three, representing the four main directions. The movement than is executed on a global scale, which means that based on the chosen value from the movement vector, the UAV moves to the north, west, south or east. In contrast, an UAV-centred approach could be chosen, which changes the direction of flight depending on the chosen action previously. In this case, four actions would also be conceivable, one value for continuing to fly straight ahead, one value each for a left or right turn and one value for reversing the direction of flight. In the remainder of the paper, however, the global approach is pursued further.

2.1.2. Observation Space

The UAVs draw an self-centered observation from the environment after changing it with their action. The observation space contains the following:

- **Map representation**: The UAV gets a matrix that counts the visits of the fields. In addition other UAVs as well as obstacles are highlighted with a value of the maximum allowed visits for one run. The latter is used for the termination condition and is described in more detail in section 2.1.4.
- **Own position**: The UAV gets its current position after it moved. Because of the two dimensional characteristics of the environment the position is represented globally as a xy-position within the environment grid.
- **Distances to UAVs**: The UAV gets the distances in number of cells in xy-direction to all other UAVs that are operating for one mission.
- **Field distances**: The UAVs gets the distances in number of cells in xy-direction to the closest field that does not count any visit from any UAV.
- **Surrounding**: With the surrounding data the UAVs get a representation of the environment based upon their cur-

rent position. With a size of four by one the surrounding matrix contains the values of the local map representation based on the UAVs position into the four main direction. If the UAV operates close to the border of the search field, values that exceed the search field are represented with a value of ten which is equal to the value of obstacles or other UAVs which should not be visited and lead to a mission termination.

- **Movement history**: The movement history is a vector of the length of five which contains the direction decisions of the UAV in a chronological sequence. For every step of the UAV within the environment the last value of the sequence is deleted, the sequences and a the direction that the UAV moved during this step is added as the first entry to the vector.
- **Own condition**: The UAV needs to know its own condition to compare it with the condition of the other UAVs. It is a normalized value between zero and one and saved as a scalar in the observation space.
- **Others condition**: Due to the same reason as before the observation space of a single UAV also contains all the conditions of the other UAVs that are participating in the swarm mission.
- **Wind information**: As the wind information mainly is responsible for the usage and degradation of the UAV it is also integrated into the observation space as a two dimensional, directional vector.

Based on the observations of the environment and the UAVs behavior the RL-algorithm is able to coordinate the UAVs movements with respect to dynamic environmental states. The goal is to reduce intensive usage for UAVs with bad condition, which gets then compensated by the UAVs that are in good condition. This results in an overall lower degradation according to (Kim et al., 2017) where it is stated that the degradation of a system increases over usage time in two steps, firstly linear and afterwards exponentially. Further more it reduces the risk of sudden system failures which occur with a higher chance to the end of life of a system and therefore decreases mission risk and increases mission reliability. To allow the UAV to optimize its decisions it receives a reward after every step according to section 2.1.3. The UAVs also exchange and communicate information about their position and condition, enhancing their decisions even further, establishing swarm intelligence.

2.1.3. Reward Function

In order to get the UAV to perform as desired, it receives a reward based upon its decision and the changes that occur within the environment at every step and at the end of the mission. The major goal in the mentioned use-case is to completely cover a designated area. The sub task consists of the efficient coverage of this area with respect to the systems usage that in combination with the degradation state has an impact on mission reliability. Therefore the reward can be divided into two types. The step-wise reward that is applied at every step on every UAV and a sparse reward (Hare, 2019) that is applied at the end of a mission.

The step-wise reward consists out of a positive reward for visiting unseen cells of the environment. For every new cell the UAV receives a reward of $R_{new\_visit} = 1$. That causes the reward to increase linear for the exploration of new fields. This motivates the UAV to search for isolated cells. The UAV receives a reward of $R_{already\_visited} = -1$ if the cell was already visited. This encourages to discover new cells as fast as possible.

To support cooperative search the UAVs get an additional positive reward R_{coop} every step if there is more than one UAV active to complete the mission. This means that the swarm has to organize itself based on the environment representation and without crashing into an obstacle, another UAV or the boundary of the searchfield in order to achieve this reward. The formula for R_{coop} is as follows:

$$R_{coop} = \begin{cases} 1 & n_{UAVs\_active} > 1 \\ 0 & else \end{cases} \tag{1}$$

The reward function incorporates both the UAVs' conditions (AC) and usage conditions by comparing the direction of movement with the wind direction. It is assumed that flying against the wind (headwind) is more energy consuming than flying crosswind or with the wind (tailwind). Therefore an angular comparison of wind direction and movement direction is made and energy cost (EC) for the manoeuvre gets calculated as following:

$$EC = \begin{cases} 0 & Tailwind \\ 0.5 & Crosswind \\ 1 & Headwind \end{cases} \tag{2}$$

It is only possible to use this energy cost if a constant speed is assumed. This is also helpful for integrating the system behaviour into a reinforcement learning environment. This simplification is made in order to focus on and analyse the interactions of degraded systems and environmental conditions within the multi UAV environment. To link environmental conditions and degradation, the reward is conditionally calculated as follows:

$$R_{usage} = \begin{cases} 1 & AC > 0.5 \; and \; EC = [0,1] \\ -5 & AC > 0.5 \; and \; EC = 0.5 \\ -1 & AC < 0.5 \; and \; EC = [0,1] \\ 5 & AC < 0.5 \; and \; EC = 0.5 \end{cases} \quad (3)$$

It shows that R_{usage} is dependent on the wind direction and the UAV condition. An UAV in good condition is meant to fly against the wind. This means that the UAV has to fly with the wind after a certain amount of steps in wind direction in order to not leave the search field (which leads to a mission termination). For this reason, it is not possible to differentiate between flying with and against the wind. Accordingly the flight movements of the UAV in bad condition must inevitably take place increasingly in crosswinds to reduce the proportion of movement directions against the wind.

The cumulative reward values calculated for each UAV at every step are aggregated over an episode which stands for a mission until a termination criteria is met. Initially, rewards are determined individually for each UAV, and at the episode's end, the total rewards across all UAVs are summed up. The end of an episode is initiated by predefined termination conditions. An additional reward known as the sparse reward is introduced alongside the termination condition, both of which will be further detailed in the following subsection.

2.1.4. Termination Conditions

Termination conditions are necessary to end an episode which is equivalent to a mission. They can be triggered if the mission task is fulfilled, the UAV's behavior leaves specified boundaries or to prevent inefficiency where the episode is trapped in an infinite loop. With the problem at hand, the termination conditions are chosen as follows:

- **Completely covered:** The UAVs were able to visit every cell of the designated search field at least once. For completing the task the UAVs do not get a negative reward. This can also be interpreted as a sparse reward that motivates the UAV to perform the task as efficient as possible with regard to the coverage performance. If an UAV is not active at the end of an episode, it gets a negative reward as described in the crash termination condition.
- **Inefficient search:** The episode gets cancelled if one of the cells within the search field gets visited more than ten times. In that case the sparse reward is -100 minus the number of unexplored fields of the search field. This reward applies for every UAV of the swarm that is still active at that time. Otherwise the crash termination. Otherwise, crash termination has already been applied.
- **Crashes:** It is classified as a crash if an UAV shares the same cell with another UAV, an obstacle or if it leaves the search field. In that case the sparse reward is calculated the same way as it is calculated for the inefficient search and the crashed UAV stops exploring the search field.

The primary objective of the MARL approach is to maximize the accumulation of rewards within a single episode such that the reward function significantly determines the behaviour of the UAVs. Within section 4 the effects of changing the reward function will be discussed in detail.

2.1.5. Initialization

Certain initial conditions must be defined to start the simulation. This includes:

- **Number of UAVs:** The primary focus of the RL-algorithm pertains to the optimization of the concurrent operation of multiple UAVs. The parameter dictating the swarm size can be specified during the initialization phase.
- **Starting location of UAV:** The UAVs are meant to fly to the designated search field, therefore their starting position is always at the boarder of the search field. To maintain a certain distance to each other, every UAV starts from another side of the search field, representing different UAV bases and approaching directions.
- **UAV condition:** The condition of the UAV is determined through a random selection process within the interval of 0.1 to 1, with precision of two decimal places.
- **Map representation:** A map in form of an array, representing the search field coverage, that counts the visits of each cell. The map is adjusted during the course of the mission as described in section 2.1.
- **Wind direction:** An initial wind direction is defined in form of a two dimensional vector.
- **Obstacle position:** While the UAVs can be understood as moving obstacles, fixed obstacles are also defined within the initialization phase as high values in the map representation.

The parameters during initialization are adaptable to specific requirements, facilitating the experimentation and evaluation of the RL-algorithm across diverse scenarios. The next section provides detailed explanations on how the parameters are set up for the experiments conducted in this paper.

2.2. Design of Experiments

A Monte Carlo simulation was run to assess the capability of reinforcement learning in optimizing specific relationships, particularly focusing on the dynamic management of UAV degradation in response to varying environmental conditions during the execution of a CAPC mission. The experiments are set up almost with the same parameters but are randomized with the regard to the following parameters:

- UAV starting position

- Obstacle location
- Wind direction
- UAV condition

The training parameters such as number of episodes, batch size and RL-algorithm are chosen as it is proposed by the documentation of the Python library of RLlib. For the evaluation, the trained RL-algorithm that achieved the best result is used, which can be determined by analysing the average reward of the learning curve (3.1). The experiment consists out of 100 runs. The metrics used for the evaluation of the experiment is described in the following section.

2.3. Evaluation metrics

Two metrics are used for the evaluation of the experiments. The first metric counts the cells with an equal number of visits using the following pythonic algorithm:

Algorithm 1 Evaluation of Coverage Performance

```
cell visits = [0 for visits in range(0, max(visits))]
for cell in searchfield do
    if cell is not obstacle then:
        cell visits[cell in searchfield(visits)] += 1
```

The list of cell visits is then visually represented and should give evidence about the coverage performance of the trained RL-algorithm. The visualization can be seen in Figure 4 for the coverage performance of a completely trained RL-algorithm where the results for 100 missions are summarized with the help of errorbars. The goal is to avoid multiple visits of cells which shortens the mission time for complete area coverage.

The second metric compares the movement decisions made by the trained RL-algorithm based on the UAVs condition. The evaluation is performed using the following formula:

$$UAV\ Wind\ Load = \begin{cases} Headwind & WD \angle MD = 180° \\ Crosswind & WD \angle MD = \pm 90° \\ Tailwind & WD \angle MD = 0° \end{cases} \tag{4}$$

The case differentiation of loads the UAV experiences based on the wind is determined by calculating the angle between the wind direction (WD) and the direction of movement (MD). The UAV wind load can be linked to the UAV state and can thus be visualised in a bar chart (see Figure 5). By comparing the frequency of movement decisions in connection with the UAV state, it is possible to assess whether the RL learner has learnt to use the UAV swarm as efficiently as possible with a focus on the system-state.

3. Results

The following section presents the results from the experiment described in 2.2. First, the overall training process is pictured. This is followed by the results of the coverage performance, which enable the evaluation of the first sub-task of the RL approach. The results of the second sub-task are presented in the last subsection, showing an evaluation that focuses on the cooperation and degradation of the UAVs within the RL approach.

3.1. Learning performance

The goal of the reinforcement learning process is to increase the average reward successively over the number of training iterations. While a supervised learning approach compares the produced output of a network with labeled data and backpropagates the error, RL does not need labeled data and it is producing training data within the learning process. The reward function helps to choose the actions that lead to the best reward. This is not only considered at every single step within one training episode, but also at the end of one episode to increase the cumulative reward. The reward function used in this paper (described in subsection 2.1.3) should establish a multi-UAV cooperation to perform a complete area path coverage with respect to degradation that results from the individual system usage. The average reward achieved by the RL approach over the training process can be seen in Figure 3.

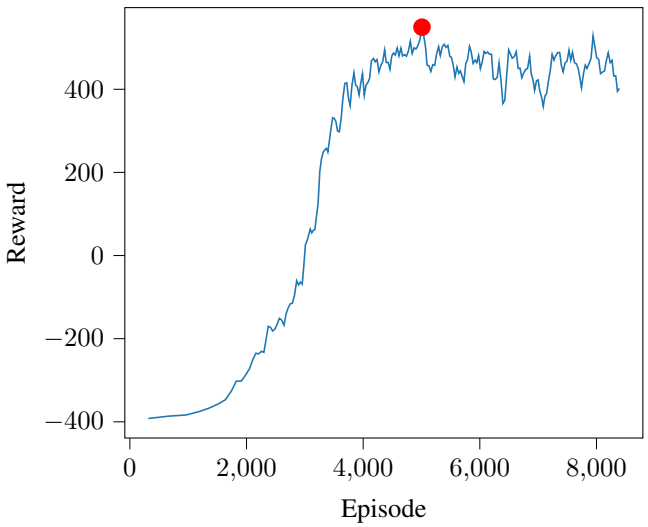

Figure 3. Cumulative training reward achieved by the RL approach over the training process

The training process starts with a high negative reward, which is comprehendable because the movement of the UAV is arbitrary and due to the starting position at the boarder of the search field, the UAV leaves the search field quite often at the very beginning of an episode, resulting in a high penalty and

low gathered reward for covering new fields and moving with usage considerations. The UAV then learns to not directly leave the search field but rather fly in a straight line until it reaches the opposite boarder. The average reward per mission increases slightly, which can be seen at the beginning of the reward curve. Subsequently the UAV learns to move in the right wind direction, paying respect to its own condition. It also learns to change direction at the boarder of the search field, resulting in a much higher average reward. This can be seen from the exponential increase in the reward curve. Afterwards it is harder for the UAV to consider the movement of the other UAVs, still it is able to optimize its movement pattern with respect to wind, information about the rest of the swarm and surrounding map data. The increase in the average rewards achieved per episode decreases again, whereby the reward curve reaches a saturation point. The convergence behavior at the end of the training does show instability, which can be explained by varying coverage and cooperation performance. Nevertheless, it can be concluded from the amount of the reward at the end of the learning process and the consideration of the reward function that the UAVs can achieve the first sub-goal in co-operation, namely searching the search field with slightly varying performance. Using the metrics that are described in 2.3 the coverage performance is discussed in more detail in the next section, as well as the level of cooperation where the developed metrics give more insight about the RL-algorithm performance.

3.2. Coverage performance

The primary goal is the CAPC. Only if the UAV is able to fulfill this kind of mission the cooperation performance with respect to the swarm condition can be compared and evaluated. To evaluate the coverage performance not only the complete coverage is considered but also the effectiveness of the coverage through counting the number of visits per cell. However, because this ideal solution conflicts with a search that takes environmental and systems conditions into account, coverage performance varies slightly at the end of the mission and cells of the search-field are visited more than once. Nevertheless the MARL approach is able to complete cover the search field area 92% of the time. This is not ideal but enough to evaluate the RL-algorithm performance. The result of the cell visit counts in order to evaluate the coverage performance can be seen in Figure 4.

The figure shows the number of cell visits on the x-axis and the frequency of occurrence of cells with the number of visits (from the x-axis) for a completed mission on the y-axis. The RL-algorithm was completely trained according to Figure 3. To get a representative behavior of the trained RL-algorithm 100 missions were performed for evaluation. The display with error bars clearly shows that the coverage performance is in a very good range. This is illustrated by the very low number of missions in which fields with zero visits

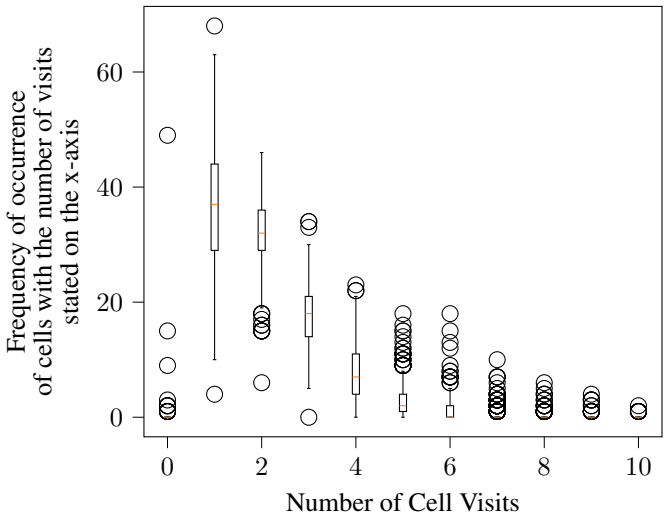

Figure 4. Evaluation of coverage performance by counting the number of fields with the same number of visits

remain at the end of a mission. The fields with zero visits are also categorised exclusively as outliers. A lot of outliers are also visible at fields with a high number of visits, which is also beneficial, because it means that the UAV learns that it should visit a single field as little as possible. This statement is confirmed by the highest value for single field visits. Overall, the distribution of field visits takes the form of a Weibull distribution that is used to describe the frequency of wind speed. Weibull distributions are also often used to describe the lifetime of technical components. Both aspects, namely wind and system lifetime are present within the presented framework and it is remarkable to see that the trained UAV shows such a behavior. Further analyses of the relationship between UAV behaviour and the Weibull distribution are pending.

3.3. Cooperation and degradation evaluation

The secondary goal of the trained RL approach is to coordinate multiple UAVs such that they are utilized according to their condition. This should encourage a usage suitable deployment of the swarm members in order to avoid sudden system breakdowns and increase reliability for the whole mission. To evaluate system usage with respect to environmental conditions, the number of movement decisions depending on the wind direction where the UAV conditions differ at least about 0.5 is counted. The result can be seen in Figure 5.

The barchart shows the decision of the UAVs with bad condition in blue and the decisions of the UAVs with good condition in orange. Only the values for which both UAVs were active are used, as otherwise cooperation is not possible. Furthermore, the values are normalised so that they can be easily compared with each other. It can be seen that the weaker UAV

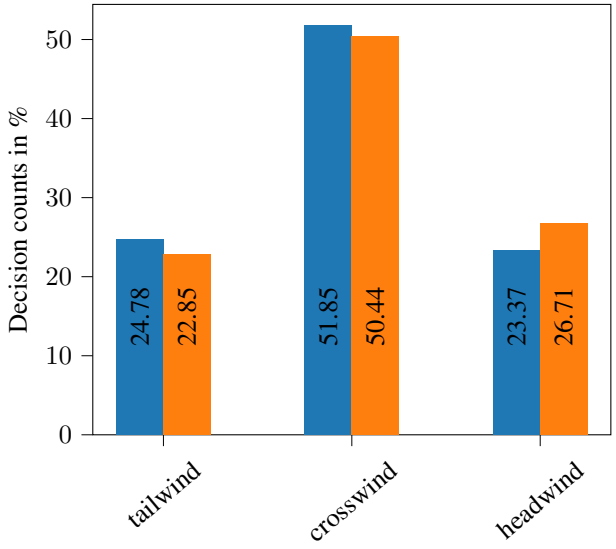

Figure 5. UAV decisions within a cooperative environment

chooses to move more into the direction in which it experiences crosswind. This part equally escapes the movement decisions against and with the wind. On one hand this suits the reward function. On the other hand this leads to less degradation for the weak UAV where it avoids moving against the wind. Choosing the major moving direction crosswind also avoids the UAV to fly against the wind after travelling a long distance with tailwind. Defining the right reward function is sometimes contradicting which gets discussed in the next section.

4. Discussion

During the implementation of the MARL approach, challenges arose with regard to the reward design and the superimposed objectives within the MA mission, which will be discussed below.

4.1. Reward Design

The reward design is very sensitive to minor changes. Also the weighting of the reward significantly changes the behavior of the UAVs. Not all intuitive rules for the reward achieve the desired effect, as the RL-algorithm incorporates the numerical values directly into its learning process. This is also partly dependent on the environment design. As shown in Section 3.3, no reduced degradation can be achieved by flying with the wind, as this inevitably requires flying against the wind from the search field boundary onwards. Another example is a weighted negative reward for multiple cell visits. It could be assumed that if not only a constant negative reward is used for cells visited several times, but the negative reward is multiplied by a factor derived from the number of visits per cell, better UAV behaviour is achieved. However, this is not the case, as the UAV is restricted in its free movement across the search field. Reaching an unvisited field directly would be associated with an increased negative reward. In order to find the right reward policy, the paper used a trial and error approach, so that there is further potential for optimisation at this point. This can also be realised through a different environment design that is connected with the reward assignment.

4.2. Superimposed Objectives

The MARL approach in this paper combines two goals, which creates a conflict between objectives. Both goals can only be achieved if compromises are made with regard to the individual goals. On the one hand, this complicates the reward design that comes into play at the end of a step. On the other hand, it makes evaluation methods more difficult. As this paper is a proof of concept and the assessment of performance is not the main focus, the topic of detailed evaluation should be the subject of further work.

5. Conclusion

This paper presents a MARL approach to solve a CAPC mission under the consideration of dynamic system states and other external factors which places a stress on the deployed systems. The topic dealt with is motivated by the reference to current research topics and specified by analysing the relevant research literature. A generalised methodology is derived that allows state and environment data to be integrated into a MARL approach. This approach allows individual UAVs to communicate with each other and perceive their surroundings as they navigate through the environment. The emphasis lies on designing the reward function, as it serves as the primary driver influencing the behavior of the UAVs, which is intended to utilize the swarm members in a resource-saving manner as an approach for optimisation.

A drone reconnaissance mission is used as a practical example to apply all components of the generalized methodology. The RL-algorithms performance is then evaluated regarding the learning process and the RL-algorithm performance. It can be stated that the completely trained RL-algorithm is able to solve the superimposed objectives of covering the complete area under consideration of the varying system state of the UAVs and a varying wind direction as an external factor. Through the integration of system condition and external loads through wind, the system usage is the main parameter that gets optimized. It turns out that due to the conflicting goals and the associated reward function, the behaviour of the UAVs follows a compromise. While the coverage performance decreases slightly, a more energy-efficient use of the drone swarm can be observed. With that, the methodology is able to recover from sudden system failures and guarantee a more reliable mission fulfilment. This extends existing approaches from current research literature through a highly dynamic in-mission decision process. In addition, a much freer

mission design is made possible by dispensing with segmentation of the search field.

With the promising results of this paper, an in-depth analysis of RL-algorithm performance based on relevant parameters is pending. Such an analysis can provide further insight about the design of the reward function and thus help to design the MA system for a desired behaviour.

ABSTRACT

Rolling element bearings are essential components for the proper functioning of many types of rotating equipment. Diagnosing faults in bearings has traditionally been done using signal processing techniques inspired by physics, wherein acceleration signals are analyzed using time-frequency analysis methods. To study the effect of bearing damage on acceleration signals, experiments are typically performed aiming for a natural propagation of a spall. However, the extent of spall severity during the test remains uncertain. It is possible to disassemble and reassemble the bearing for visual inspection. Nevertheless, previous studies observed that the vibration signal would drastically change if this operation was conducted repeatedly, impacting the identification of trends in the acceleration signal. The objective of this study is to provide a method which can assist with labeling the spall size in endurance tests without the necessity of disassembling and reassembling the test rig. To address this issue, a new algorithm, based on the load cell signal was developed to assess the spall size using low-speed measurements. This algorithm enables the identification of the circumferential angle at which the rolling element interacts with the spall and is only carrying a partial load. The algorithm has been validated through visual inspections conducted during the experiment. This algorithm makes it possible to estimate the spall size without the need for visual inspection in subsequent experiments. A labeled endurance test contributes to a better understanding of spall propagation, such as the effect of speed, load, and material properties on the propagation speed. This study demonstrates how the load signal can be used for fault labeling with relatively simple and common techniques. This approach will enable the tackling of advanced and more complex problems in future endeavors, such as fault severity estimation and even prognosis.

1. INTRODUCTION

Bearings play a crucial role in nearly all rotating machinery (Malla & Panigrahi, 2019), and monitoring their condition typically involves four stages: detection, identification, severity estimation, and prognosis (Bechhoefer & Schlanbusch, 2018). A substantial amount of research has been conducted on the subject, with a focus on the detection and identification stages, which have shown promising results. Bearing damage severity is typically defined as a function of overall vibration levels ((ISO), 2016). Unfortunately, these thresholds are very application dependent and difficult to generalize. A robust and objective method for severity estimation in bearings remains challenging.

One common approach to define severity is based on raceway spall size in the circumferential direction. Among the studies engaging spall size estimation, various types of sensor measurements are utilized. Common methods include accelerometers, some employing oil debris monitoring (ODM), and others utilizing optic fibers (Gazizulin et al., 2019; Madar et al., 2022; Medvedovsky et al., 2022). A review of different approaches is given in Zhang et al., 2022. Accelerometers are relatively common components in

machinery due to their ease of installation. Methods based on accelerometers typically try to identify the entry and exit points of rolling elements from the spall within the time domain (Epps I K, 1991; Moazen-ahmadi & Howard, 2016; Sawalhi & Randall, 2011). Some of these studies employ low-pass filters to detect entry and exit events (Moazen Ahmadi et al., 2016), a practice that may pose challenges due to its reliance on a rule of thumb. Additionally, these methods are often detecting very small defects, whereas numerous applications involve significant spall sizes. There are also severity estimation methods which utilize condition indicators, which are then employed to calculate a health indicator (Gebraeel et al., 2004; Ma et al., 2012). These methods offer increased robustness in noisy conditions compared to the aforementioned methods since they consider trends based on multiple sensor recordings over time. However, establishing a direct link between health indicators and spall size in rotating machinery poses challenges, primarily due to missing ground truth values of its spall size during operation.

Studies that use ODM can estimate the spall size by calculating the total mass of debris particles originating from the bearing (Madar et al., 2022; Portal et al., 2022). However, to use this method, certain geometric assumptions are made which might be invalid. Optic fibers are used to measure the strain on the housing bearing, and by tracking the changes in the signal, it is possible to calculate the length of the spall (Medvedovsky et al., 2022). Nevertheless, both of these methods require expensive equipment and are not suitable for every test rig or machinery.

Emulating the topography of a spall is a challenging task. Consequently, studies that have explored severity estimation in bearings often rely on artificial spalls with less realistic rectangular shapes. However, the interaction between the rolling element (RE) in the bearing and the artificial spall could be significantly different from the interaction with a real spall, which may result in higher impulses in the acceleration signal than those observed in natural spalls (Zhang et al., 2021).

One approach to achieve naturally growing spalls is through endurance tests. Nevertheless, for measuring the spall size in acceleration algorithm validation, it is necessary to disassemble and reassemble the test rig, which can significantly alter the vibration signal (Smith & Randall, 2015). Recent studies have shown, that for specific test rig setups a load cell can act as a proximity measurement for displacement containing a distinctive pattern related to the spall geometry (Zhang et al., 2022). Moreover, an observation is made that the load-cell signal is less sensitive to the re-assembly of a bearing compared to acceleration.

In this study we propose a unique algorithm to estimate spall sizes in endurance tests using load signals, which can be obtained without visually inspecting the spall. The algorithm is implemented at low speeds, enabling validation of spall dimensions during endurance experiments.

2. Experimental Setup

The endurance test was conducted in SKF Research and Technology Development (RTD). The test was performed on the R2 test rig (Harris, 2006), as shown in Figure 1, with the positions of the accelerometer and the load cell indicated. For measuring the rotational speed, a tachometer measuring two pulses per shaft rotation was used. In the experiment, two bearings were measured: the tested bearing, located on the left side of the test rig, and a reference intact bearing positioned on the right side of the test rig. Both bearings were monitored throughout the experiment. The algorithm developed in this study was primarily validated using the load-cell data acquired from the tested bearing on the left side. Throughout the experiment, sensor snapshots were recorded, defined as synchronized recordings of all sensors at a sample rate of 49152 Hz for 36 seconds.

To validate the load-based algorithm, a visual inspection was required. To simplify the process of disassembling and reassembling the test rig, a bearing with a design that allows easy access to the outer race was chosen. The selected bearing is a cylindrical roller bearing of the N209 ECP type. During the experiment, only a pure radial load is applied because this bearing type cannot sustain axial loads.

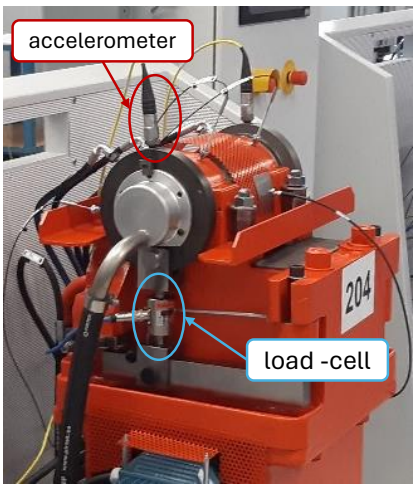

Figure 1: SKF R2 test rig; The accelerometer marked in red, load cell marked in blue.

2.1. Test Procedures

The test consists of two stages: (1) a damage initiation phase and (2) a spall growth phase. Both phases will be further explained in the following sections.

2.1.1. Damage Initiation Phase

In this phase, the purpose is to initiate a spall on the outer race of the bearing. To expedite this process, an initial small

damage was introduced to the outer race before the test. The damage was created using an electrical discharge machine (EDM) on the race surface. The EDM created a rectangular-shaped damage with circumferential and axial dimensions of 0.2mm and 2mm, respectively. In this phase, the bearing was subjected to high loads and speeds to induce growth. The decision to stop this phase was made based on an acceleration-based condition indicator (Harris, 2006), where an abnormal increase determined the stopping criteria.

2.1.2. Spall Growth Phase

The objective of this phase is to capture snapshots of the data measured by the sensors while growing the spall at a controlled pace. The protocol of this phase contains three stages that repeat each other until the end of the experiment. Figure 2 illustrates one cycle of this protocol, which includes three stages: the growth stage in blue, the monitoring stage in orange, and the collection stage in green. The black and purple vertical lines at the bottom of the graph indicate the load in each stage (black for 16 kN and purple for 6 kN). The vertical axis represents the normalized duration, which is the time duration normalized by the combined time of the monitoring and collection stages. The vertical line represents the shaft speed.

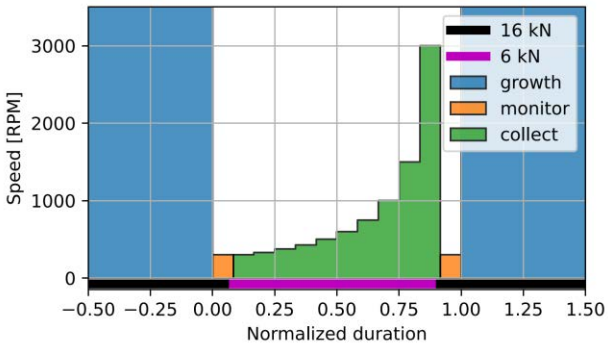

Figure 2: Example of one protocol cycle for spall growth. One cycle consists of three stages: 1: growth in blue, 2: monitor in orange, 3: collect in green.

In the growth stage, the aim is to accelerate spall growth; therefore, the bearing is subjected to a radial load of 16 kN, and the shaft rotational speed is set to 6000 RPM. One cycle of this stage lasts approximately 50 minutes.

In the monitor stage, two measurements are conducted at a high load with a speed of 300 RPM, one at the beginning of the collection stage and one at the end. In these measurements, the changes in the load cell are clearer and therefore will be used in this study for the load-based algorithm.

In the collection stage, measurements are taken from the sensors. In this phase, the load is reduced, and the speed changes to 10 different speeds spaced between 300 and 3000 RPM. The measurements at this stage will be used for future research. This stage takes around 20 minutes.

The experiment was halted approximately every 5 million revolutions for visual inspections. The test is stopped when a critical spall size, exceeding two times the distance between rolling elements, is reached. Beyond this size, two rolling elements no longer bear any load, which can lead to accelerated spall growth and, consequently, a high risk of critical failure.

3. Analysis of Load Cell Signal

In a faulted bearing, with a spall not larger than the distance between two rolling elements in the outer race, the interaction of the rolling element and the spall can be roughly divided into two stages. In one stage, none of the rolling elements interacts with the spall. The other stage is when one of the rolling elements is interacting with the spall; both stages are illustrated in Figure **3**.

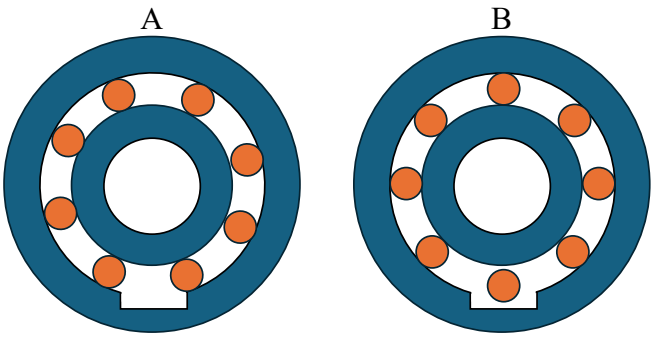

Figure 3: Illustration of REB interaction with outer race spall; (A) none of the RE interact with the spall (B) One RE enters the spall.

In stage one, the force applied to the bearing is divided among all the rolling elements in the bearing. In stage two, one of the rolling elements is inside the spall and, therefore, does not carry any load. This results in a different distribution of the load which appears to be observable on the load cell. By detecting these changes in the load cell, one can estimate the duration of the interaction with the spall, which can then be easily calculated to determine the spall length. At higher speeds, the transition between stages occurs more rapidly, meaning the system doesn't have enough time to stabilize, making it more challenging to detect in the time domain.

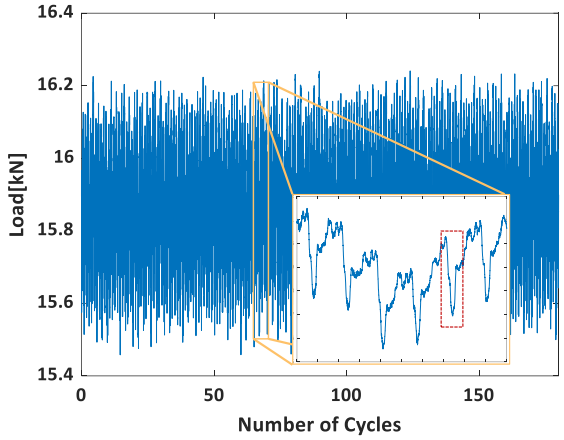

Figure 4: Raw load signal at 300 RPM with zoom on one cycle, equivalent to one shaft rotation: the area of interest marked by the red dashed rectangle indicate the area rolling element over the defect.

When examining the load signals acquired from the experiment at low speeds, it is possible to detect the interaction of the rolling element with the spall. Figure 4 shows an example of a signal with the visible interaction marked. To automate the process of identifying load distribution changes in the signal, a seven-step algorithm is proposed. The steps are described in Figure 6, with each step designed to emphasize and isolate the interaction of the rolling element with the spall. Each one of the steps is explained:

1. The load signal is detrended, by subtracting the "smoothed" signal from the original signal, making the signal centered around zero.
2. The interaction with the spall that occurs during the rotation of the shaft is periodic in the time domain when the speed is constant. However, even when setting the test rig to a constant speed, the speed is never truly constant. Therefore, angular resampling of the detrended load signal is conducted, converting the signal to the cycle domain.
3. Bearings are asynchronous components due to slippage (Sol et al., 2022). When employing Modified SA, as further explained in point 5, one can obtain a signal with isolated synchronous elements to the shaft's frequencies. By subtracting the SA signals from the original signal, the discrete shaft synchronous frequencies are removed, mitigating the interferences of other rotating components. This yields a signal containing only the asynchronous components. This algorithm is known as de-phase (Klein, 2017).
4. The cycle of interest is the interaction between the rolling element and the spall. Therefore, angular resampling is performed again based on the BPFO. Unlike the angular resampling based on the shaft's speed in step 2, the angular resampling in this step ensures a consistent number of samples in each cycle of the BPFO.
5. Modified Spectrum Analysis (MSA) (Koren, 2017) is utilized in this scenario. In MSA, the signal is segmented into N parts. The amplitudes of the Fourier Transforms (FT) for these segments are then averaged, resulting in an MSA signal with the averaged amplitude and phase information from a single segment. The fundamental steps of the MSA algorithm are outlined in Equations 1 and 2. Where N is the number of segments into which the signal is divided, and x_n represents a single segment of the signal. This technique is employed to isolate signal components asynchronous to the BPFO, including noise.

$$|\bar{X}| = \frac{1}{N}\sum_{n=1}^{N}|fft(x_n)| \quad (1)$$

$$MSA = ifft\{|\bar{X}| \cdot exp(j \cdot \angle fft(x_1))\} \quad (2)$$

6. A dynamic threshold is established by computing a percentage of the difference between the signal's highest and lowest points. Initially, a lower threshold is implemented for smaller spalls, which are more susceptible to noise interference. Once the estimated spall length reaches a predetermined value, a higher threshold is activated. This adjustment is intended to enhance accuracy. Figure 5 shows a processed signal with a set threshold indicated by a yellow dashed line.

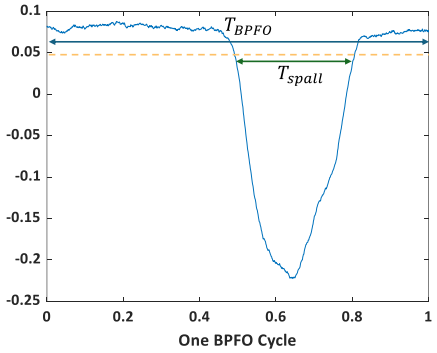

Figure 5: Processed signal with threshold indicated by a yellow dashed line; $\boldsymbol{T_{spall}}$ denotes the number of points below the threshold, and $\boldsymbol{T_{BPFO}}$ represents the total number of points in the MSA signal.

7. The determination of the pulse length involves calculating the percentage of values below the dynamic threshold. With the utilization of Equation 3, estimation of the spall size becomes feasible.

Here, RE represents the distance between two rolling elements, T_{spall} denotes the number of points in the synchronous average below the threshold, and T_{BPFO} represents the total number of points in the MSA signal.

$$S = RE \cdot \frac{T_{spall}}{T_{BPFO}} \quad (3)$$

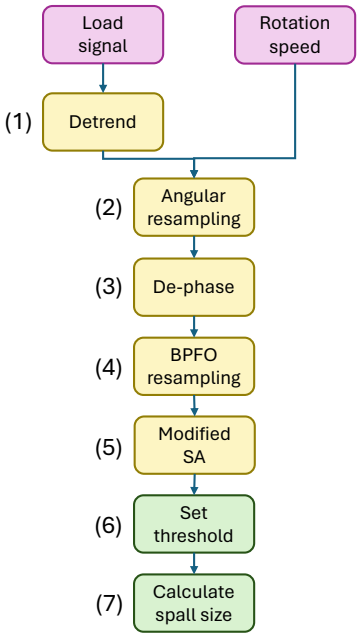

Figure 6: Block diagram of the load-based algorithm.

4. RESULTS

To validate the load algorithm, visual inspections were conducted during the endurance experiment. The tested bearing is a SKF N209 ECP cylindrical roller bearing. During each visual inspection, only the outer ring was disassembled, examined, and photographed. The spall size was measured by counting the number of pixels the spall occupies in each photo. An example from two visual inspections is shown in Figure 7. The spall lengths calculated from the proposed algorithm and the visual inspections were plotted for comparison and presented in Figure 8.

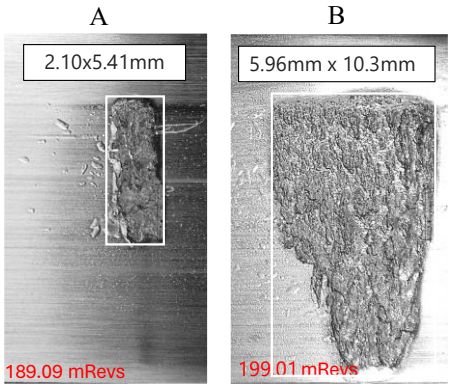

Figure 7: Visual inspections during endurance test: (A) at 189.09 million revolutions and (B) at 199.01 million revolutions. direction of the RE is from right to left.

It is evident that the estimated spall size by the load algorithm follows the trend of the measured sizes. However, in some cases, the estimated spall size deviates from that trend. These deviations sometimes occur after the visual inspections. The process of disassembling and reassembling could significantly alter the measured signals, as noted in a previous study (Heng et al., 2009). However, in the load signals, the impact is relatively small compared to acceleration and can be mitigated by using smoothing techniques. In other cases, the changes could be related to machinery malfunction, which contaminated the measurements. Despite these deviations, the suggested algorithm has shown good results and, in most cases, has been able to estimate the spall length accurately.

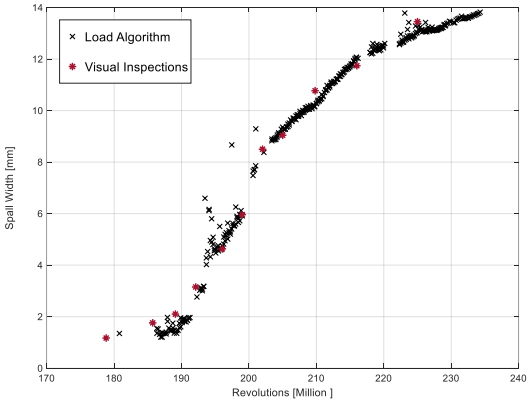

Figure 8: Comparison between the results of the load-based algorithm and the visual inspection.

In this work we present an algorithm to track spall size continuously in a robust manner in a lab environment by using existing load cells. Our proposed method can be used to validate spall size estimation algorithms. Moreover, it can be used to further study the physics of spall propagation, e.g., understanding the effects of speed and load.

5. CONCLUSION

In conclusion, bearings play a vital role in nearly all rotating machinery, highlighting the necessity of accurately estimating the severity of defects within them. As of today, there is no robust method for severity estimation in bearings, which can be used in all machinery. Endurance tests are crucial in bearing research, providing valuable insights into spall growth, and accurately labeling the data is essential for understanding this process.

Traditionally, labeling has relied on visual inspections during endurance tests, which can significantly alter vibration analysis results. This study introduces a load-based algorithm that eliminates the need for visual inspection, thus providing a more extensive dataset for labeling the severity of spalls. Although load cells are not typical components in machinery, they are common in experimental test rigs and can greatly assist with future research. The load-based algorithm was validated via visual inspection, demonstrating good agreement between the two methods. Not only does this algorithm streamline the testing process, but it also serves as a valuable tool for future studies, enabling researchers to track spall propagation and establish ground truth for developing acceleration-based algorithms. Overall, the implementation of this load-based algorithm represents a significant advancement in bearing defect analysis, offering improved labeling accuracy and opening up new avenues for further research in the field.

BIOGRAPHIES

Tal Bublil is currently a Ph.D. student in the BGU-PHM LAB at the Department of Mechanical Engineering in Ben-Gurion University of the Negev, under the supervision of Prof. Jacob Bortman. He completed his bachelor's degree with the highest honors in mechanical engineering at Ben-Gurion University of the Negev and completed his master's degree through the fast-track program.

Cees Taal has a research background with over ten years of experience in the field of sensor signal processing and machine learning. He has worked in academia (Delft University of Technology, Delft, The Netherlands, and KTH Royal Institute of Technology, Stockholm, Sweden) on audio and speech processing, after which he held various industrial positions in biomedical engineering (Philips Research, Eindhoven, Netherlands) and the energy domain (Eneco, Rotterdam, Netherlands). He is currently appointed as a Technologist of SKF, The Netherlands, where he is responsible for defining a research strategy in the field of bearing diagnostics and prognostics. Cees received the IEEE Signal Processing Society Best Paper Award in 2016.

Bert Maljaars is a researcher in SKF Research and Technology Development, working on diagnostics and prognostics in bearing condition monitoring. He received his MSc degree in Mechanical Engineering from Eindhoven University of Technology and afterwards his PhD degree (2017). His main research interests are state estimation, signal processing, physical modeling, optimization and control.

Renata Klein received her Ph.D. in the field of Signal Processing from the Technion, Israel Institute of Technology. For 17 years she managed the Vibration Analysis department in ADA-Rafael, the Israeli Armament Development Authority. Later, as the Chief Scientist in RSL- Electronics, she invented and led the development of a vibration based diagnostics and prognostics system that is used successfully in combat helicopters and UAVs of the Israeli Air Force. Renata is the CEO and owner of R.K. Diagnostics. In this role, and per invitation from Safran Aircraft Engines, she developed a full set of vibration based diagnostics and prognostics algorithms for jet engines. These algorithms are being integrated into the next generation of CFM jet engines. In recent years, Renata has focused on supervising academic research programs in the area of rotating machinery prognostics. Jointly with Prof. Jacob Bortman, she co-manages the BGU PHM Lab in Ben Gurion University of the Negev, teaches and provides supervision to MSc and PhD students.

Jacob Bortman is currently a full Professor in the department of mechanical engineering and the head of the PHM Lab in Ben-Gurion University of the Negev. Retired from the Israeli air force as brigadier general after 30 years of service with the last position of the head of material directorate. Chairman and member of several boards: director of business development of Odysight Ltd, Chairman of the board of directors, Selfly Ltd., board member of Augmentum Ltd., board member of Harel finance holdings Ltd., Chairman of the board of directors, Ilumigyn Ltd. Editorial board member of: “Journal of Mechanical Science and Technology Advances (Springer, Quarterly issue)”. Head of the Israeli organization for PHM, IACMM - Israel Association for Comp. Methods in Mechanics, ISIG - Israel Structural Integrity Group, ESIS - European Structural Integrity Society. Received the Israel National Defense prize for leading with IAI strategic development program, Outstanding lecturer in BGU, The Israeli prime minister national prize for excellency and quality in the public service - First place in Israel. Over 80 refereed articles in scientific journals and in international conference.

Landing Gear Health Assessment: Synergising Flight Data Analysis with Theoretical Prognostics in a Hybrid Assessment Approach

ABSTRACT

This study addresses a critical shortfall in aircraft landing gear (LG) maintenance: the challenge of detecting degradation that necessitates intervention between scheduled maintenance intervals, particularly in the absence of hard landings. To address this issue, we introduce a Performance Degradation Metric (PDM) utilising Flight Data Recorder (FDR) output during the touchdown and initial roll phases of landing. This metric correlates time-series accelerometer data from a Saab 340B aircraft's onboard sensors with non-linear response dynamic models that predict expected LG travel and reaction profiles across a set of ground contact cycles within a single landing. This facilitates the early detection of deviations from standard LG response behaviour, pinpointing potential performance abnormalities. The initiator of this approach is the Landing Sequence Typology, which systematically decomposes each aircraft landing into successive dynamic periods defined by their representative boundary conditions. What follows is the setting of initial parameters for the ordinary differential equations (ODE)s of motion that determine the orientation and impact responses of the most critical components of the LG assembly. Solving these ODEs with the integration of a non-linear representation of an oleo-pneumatic shock absorber model compliant with CS25 aircraft standards produces anticipated profiles of LG travel based on factors such as aircraft weight and speed at touchdown, which are subsequently cross-referenced with real accelerometer data, enhanced by video footage analysis. This footage is crucial for verifying the sequence of LG touchdowns and corresponding accelerometer outputs, thereby bolstering the precision of our analysis. Upon the conclusion of this study, by facilitating the early identification of LG performance deviations in specific landing scenarios, this diagnostic tool shall enable timely maintenance interventions. This proactive approach not only mitigates the risk of damage escalation to other components but also transitions main LG maintenance practices from reactive to proactive.

1. INTRODUCTION

Landing gear (LG) operational health is of paramount importance in ensuring aviation safety and optimising maintenance practices. Accurate assessment of LG component health can prevent catastrophic failures and reduce unscheduled downtime. Given the unique challenges posed by LG structural health monitoring (SHM)—arising from the use of high-strength, low-toughness materials in primary LG components, with relatively smaller critical crack propagation thresholds compared to the airframe—there is a compelling need for tailored monitoring approaches. A crucial constituent of LG SHM involves the monitoring of load, usage, and/or signs of crack initiation to estimate the remaining fatigue life of its monitored component/s. As a consequence, a prominent number of proposed LG health monitoring techniques rely on direct sensor placements, which can be intrusive, add weight, and increase the risk of error and maintenance requirements due to the introduction of said sensors. This study thereby addresses a prominent issue in the current LG integrity assessment approach followed by operators and MROs: the inability to detect LG degradation that requires intervention between scheduled maintenance intervals without the presence of hard landings. By inspecting touchdown and follow-up roll data at each landing cycle of the aircraft being monitored, we aim to remove the need for additional sensors. A Performance Degradation Metric (PDM) is being formulated, wherein the correlation of accelerometer time-series outputs with outputs from dynamic Ordinary Differential Equations (ODE)s of motion solved by Simulink models provides an indication of whether the LG's reaction profile was typical or deviant. This approach shifts the focus

from identifying issues like structural cracks and bearing wear to detecting abnormalities through deviations in dynamic performance from the models derived from a distinct set of conditions under which the aircraft interacts with the ground, incorporating shock absorber behaviour, aircraft mass, and impact speed. Awaiting identical conditions for comparison would necessitate an impractical volume of test data and landings. Therefore, this strategy focuses on assessing how and to what extent each of these variables impacts each of the main LG's performance during each landing.

Data for this study were collected using the Cranfield University Saab 340B aircraft, operated by the National Flying Laboratory Centre. This twin-engine turboprop, known as the National Flying Laboratory, has been customised to include specific experimental and teaching equipment to enhance its utility as a flying laboratory. The key modification vital for this study is the installation of an Ekinox-D: An INS sensor that offers orientation, heave, and centimeter-level position accuracy.

The rest of the paper is organized as follows: Section 2 delves into the traditional and contemporary methods of LG maintenance, discussing the shift from time-based strategies to real-time health monitoring, illustrated through various studies and the integration of progressive monitoring systems like fiber-optic sensors. In Section 3, we outline our methodology, emphasizing the integration of video footage, on-board sensor data, and dynamic modelling to analyse aircraft landing dynamics. Data collection techniques and the specific analytics used to extract and process this data are also detailed. Section 4 projects the future direction of our research, outlining the subsequent phases including sensor data analysis, structural dynamic response assessment, and the continuous development of our Performance Degradation Metric (PDM).

2. BACKGROUND

2.1. Traditional LG Maintenance Approaches

Traditionally, LG maintenance has leaned on time-based preventive strategies and Non-Destructive Testing (NDT) methods, including magnetic particle inspection, ultrasonic testing, and eddy current testing, as Schmidt (2008) notes. These conventional methods, applied during fixed maintenance intervals, often necessitate the disassembly of LG components for thorough inspection. In this context, the introduction of progressive monitoring marks a significant shift in maintenance paradigms. For instance, Kaplan et al. (1997) demonstrated the application of damage tolerance methods to extend the life of LG assembly subcomponents of a CASA 212 aircraft beyond their initial Safe-life design limits. By conducting loads, stress, and crack-growth analyses, they determined tailored inspection intervals. This approach underscores the potential of integrating damage tolerance principles to refine LG maintenance practices, paving the way for the adoption of landing profile-specific and load-adaptive health monitoring. Despite their intuitive approach and its success in extending the gear's service life, their methodology does not support real-time nor near-real-time assessment of LG health—a capability our current study seeks to develop. Importantly, while their approach contributes to extending the safe operational life of LG components, our project does not address direct estimations of life extension beyond set service limits, focusing instead on identifying and addressing immediate health concerns in operational conditions.

2.2. Advancements in Real-Time LG Health Monitoring

Building on these developments, recent advancements have shifted focus towards real-time LG health monitoring systems. These often involve the placement of sensors on critical LG components to monitor their condition during operation, such as that proposed by Zhang et al. (2018), who studied the placement of fiber-optic sensors on the outer tube weld of a LG assembly to capture weld crack signals. Further illustrating this trend, the EU-funded E-LISA project aims to develop an intelligent test facility for electro-mechanical LG, which will include PHM functionalities for the electrical brake system (De Martin et al., 2022). This project focuses on integrating sensors and monitoring systems into a novel LG design to enable condition-based maintenance. Similarly, Delebarre et al. (2017) contribute to the expanding landscape of sensor-based health monitoring with their development of a wireless monitoring system for lightweight aircraft LG, which uses pressure sensors and accelerometers to measure the mass distribution on each LG and monitor the shock during the landing phase. The system aims to provide real-time information to the pilot and maintenance personnel to improve safety and ease maintenance operations.

2.3. Data Analytics and Physics-Based Modelling in LG Health Monitoring

Integrating health monitoring systems into the LG architecture presents numerous challenges, such as coping with the harsh operational environment, managing the constraints on sensor placement, and ensuring the reliability of data transmission and analysis. These hurdles notwithstanding, the advancements in sensor technology and data analysis techniques offer promising pathways to surmount these obstacles, thereby enhancing the efficacy of aircraft LG health monitoring. In this vein, the work by (Bakunowicz & Rzucidło, 2020) presents an approach to detecting aircraft touchdowns using virtual sensing techniques by employing data from accelerometers mounted on structural parts of the airframe, utilising continuous wavelet transformation (CWT) to identify unique frequency signatures characteristic of LG touchdown. The CWT method, focusing on the detection of aircraft touchdowns with a high degree of precision, aligns closely with the

present paper's emphasis on optimising aircraft sensor output for LG health assessment. By extracting critical frequencies from accelerometers on-board during touchdown, our approach seeks to isolate and analyse pre-impact signatures, enhancing the precision of our health assessment metrics. Another pertinent reference in the context of virtual sensing is the work of Hsu et al. (2022) and its continuation by Chang et al. (2023), where they harness Flight Data Recorder (FDR) accelerometer outputs from a fleet of aircraft to detect early signs of exacerbated LG shimmy, thus indicating potential degradation that could require maintenance beyond scheduled intervals. Their study covers the taxiing phase before take-off and following landing, employing machine learning (ML) to link accelerometer readings with maintenance records across various LG components. They subsequently predict potential faults with almost 100% accuracy on almost all LG subcomponents used in training their ML model based on expert input and extensive data from landing cycle-based maintenance actions recorded on those specific LG components. Our study, while also utilising accelerometer data, extends the analysis to include longitudinal accelerations and converges specifically on the dynamics of landing impact and the subsequent short roll period, used in this case to include jumps and consequentially the Landing Sequence Typology approach which thereby defines non-linear response models representing their corresponding periods, for a CS25 aircraft.

The development of physics-based models for LG dynamics and health prediction has garnered significant attention in the field of LG SHM. These models aim to capture the interactions between various LG components and the forces they experience during operation (Schmidt, 2021). Recent studies have furthered this endeavour, focusing on high-fidelity dynamic modelling, synthetic dataset generation, and the advancement of prognostic algorithms for enhanced predictive accuracy. Wu, Gu, and Liu (2007) have notably developed a Nonlinear Model Predictive Control (NMPC) algorithm for semi-active LGs, utilizing Genetic Algorithms (GA). This method demonstrates an enhancement in LG performance by optimising the damping characteristics at touchdown, validated through drop tests that confirm the simulation model's accuracy. The GA-based NMPC approach effectively addresses the complex nonlinear dynamics of semi-active LGs, ensuring optimal performance despite constraints like the control valve's rate and magnitude limitations. In our approach, unlike the empirical validation possible through drop tests as utilised by Wu et al. (2007), we navigate the absence of a drop-test rig by emphasizing the integration of real-world operational data and physics-based models to refine our simulation accuracy further. This is in line with Krüger and Morandini's (2011) emphasis on the critical role of numerical simulation in LG dynamics assessment. Their research highlights the significance of modelling LG's dynamic response to various load excitations, underscoring the importance of a comprehensive understanding of LG dynamics for safety and performance. Finally, De Martin et al. (2022) present the development of the E-LISA iron bird, an innovative test facility for LG systems that includes PHM functionalities for the electrical brake system. The E-LISA project aims to reproduce the dynamic loads on the LG during landing, taxiing, and take-off, as well as the real contact between the LG wheel and runway. This approach aligns with our research objective of integrating real-world operational data and physics-based models to refine simulation accuracy and develop a hybrid approach for LG health assessment. De Martin. et al. (2022) present a high-fidelity dynamic model of the test rig, which incorporates the effects of runway-irregularities. This model serves as a foundation for generating synthetic datasets representative of various operating conditions and degradation levels, facilitating the development of prognostic algorithms. Their approach is similar to our use of physics-based models to predict the degradation of LG performance over time, and it highlights the importance of incorporating realistic operational conditions and representative component interactions in the set dynamic equations used to represent the conditions of a landing.

3. METHODOLOGY

The methodology of this research is designed to analyse aircraft landing dynamics by integrating aircraft touchdown video footage, on-board sensor data, and bookcase non-linear response dynamic models, or 'archetypes', representative of the touchdown phases of each landing analysed. This multi-faceted approach allows for a robust examination of the impact sequences and a connection to the oleo-pneumatic shock-absorber (OSA) behaviours of the LG associated with different landing types. The study focuses on the following key aspects: capturing precise landing dynamics through video and sensor data, categorising landing types, formulating and solving ODEs to simulate these events, and validating these simulations against real-world data as feasibly as possible. Details follow in the subsections below, with corresponding visualisations provided in Figure (1), where the actions and outputs are denoted in green and blue blocks, respectively.

3.1. Data Collection

3.1.1. Video Footage Acquisition

A mirrorless APS-C video camera equipped with a telephoto lens is positioned on a fluid-head-equipped tripod by the runway border to record the final approach and touchdown. Operating at a frame rate of 29.97 fps and keeping the aircraft in-frame while extending the focal length to include only the undercarriage in the frame as soon as the aircraft is critically close to the airstrip, we ensure that each phase of the LG's contact sequence with the runway is meticulously documented. To ensure clarity and precision in the footage, the camera's shutter speed is set to at least four times the frame rate. This serves two critical purposes: it counteracts the shutter roll effect noticeable during fast panning—important for preventing deformations in the objects in-video, affecting important parameters such as adding distortions to tire deformation, which would be misleading—and it minimises motion blur to capture crisp imagery (when inspecting each frame in the video) of exact moments of touchdown, spin-up, spring-back, and hop. Additionally, the ISO setting is carefully controlled to prevent excessive photo grain, which impairs the accurate identification of the wheel edges contacting the airstrip. This footage is crucial for visualizing the aircraft's attitude at approach and touchdown, and the temporal separation between all undercarriage units; the main right, main left, and nose gear contacting the runway. The video data serves two primary purposes: it provides a visual reference for validating sensor data (temporal OSA impact delivery to on-aircraft accelerometer response output) and helps in identifying any discrepancies between observed and simulated main LG assembly behaviours. In Figure (2), an example of the footage contents may be seen.

Figure 2. touchdown footage frame

3.1.2. On-board Data

The aircraft is equipped with an IMU as part of a custom fit Inertial Navigation System (INS); the Ekinox-D, operating at sampling rates of 50Hz. The onboard data acquisition takes place by the use of the Curtiss-Wright/ ACRA Control KAM-500 system, which collects analog data from the Saab 340B's on-board sensors, including the Rockwell Collins AHS-3000 Attitude Heading Reference System. This setup captures essential aircraft dynamics and engine metrics using the Commercial Standard Digital Bus (CSDB) protocol (Alam, Whidborne, and Westwood, 2024). The data from these sensors are filtered to focus specifically on the touchdown phase, where detailed information about acceleration spikes and other dynamic responses is crucial for later analysis and simulation. The parameters recorded by these instruments include data on:

- Inertial Measurement Unit (IMU) and navigation: roll, pitch, heading, heave, surge, and sway from a MEMS (Micro-Electro-Mechanical Systems) sensor.
- Aircraft dynamics and engine metrics: accelerations, aileron and elevator deflections, angle of attack, fuel flow rates, gas generator speeds, propeller speeds, and turbine pressures.
- Environmental conditions: Airspeeds (indicated, true), Mach numbers, air temperatures, and radio altitudes.

In this study of aircraft dynamics, particularly before the initiation of gas generators and propellers, it is essential to calculate the root mean square (RMS) of accelerometer readings under stationary conditions. RMS is a statistical measure used extensively in signal processing to quantify the magnitude of a varying quantity. It provides a concise metric of the vibrational and transient accelerations experienced by the aircraft when it is static, which serves as a baseline for understanding the alterations in mechanical vibrations once the aircraft's propulsion components are activated. This baseline is critical for isolating and analysing the effects of mechanical and aerodynamic forces on the aircraft's structural integrity and operational efficacy. By calculating

the RMS value of accelerometer data while the aircraft is stationary, we can establish a reference point against which deviations caused by the gas generators and propellers can be measured, thereby offering insights into the dynamic behaviour of the aircraft under different operational conditions. Below are the RMS values which show minimal deviations and reaffirm the trustworthiness of the accelerometers for our use case:

INS MEMS Sensor:

- Lateral Acceleration: 0.0199g
- Longitudinal Acceleration: 0.0049g
- Normal Acceleration: 1.026g (indicative of gravity's influence)

Aircraft's on-board accelerometers:

- Lateral Acceleration: 0.0046g
- Longitudinal Acceleration: 0.0015g
- Normal Acceleration: 1.026g

3.1.3. Parameters Monitored for Data Pruning

In this step, a subset of the original time-series data is created based on the critical time period for analysis. Here, the Gaussian kernel, synonymous with the Radial Basis Function (RBF), is pivotal in the field of kernel-based change point detection (KPD), offering a nuanced approach to analysing complex data patterns. Its efficacy proves useful as a part of our method when filtering the time-series accelerometer readings for point-of-touchdown. This algorithm was rigorously tested across numerous flights, to ensure consistent touchdown indications across all accelerometer axes. Seeking a universally applicable method across diverse flight profiles, the single-point RBF approach (dynamic programming) was used. This method, applied to the derivative of time-series accelerometer readings showed promising adaptability and accuracy. Providing start and end points close to a chosen cut-off of radio-altitude also reduces its computing requirements and is currently the chosen approach. In Figure (3), you may see a plot of accelerometer measurements, their derivatives, and a red dashed line running vertically along the plot, indicating the KPD output corresponding to point of touchdown for the landing aircraft.

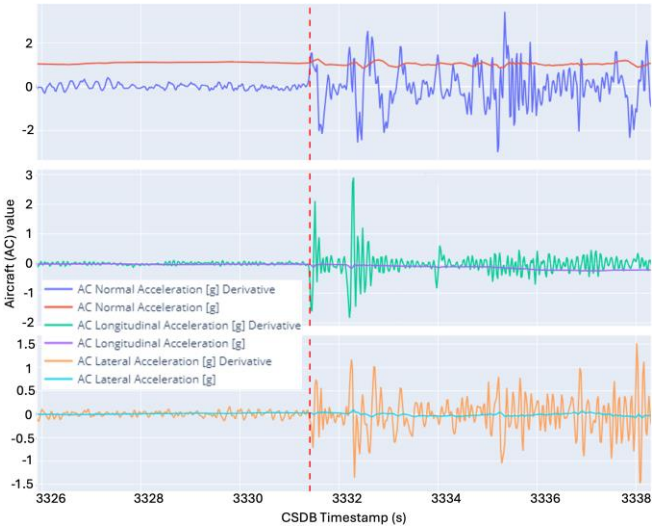

Figure 3. Accelerometer values and their derivatives w.r.t time for a level touchdown.

3.2. Landing Sequence Typology

To facilitate a structured analysis where causes and effects are recognised between landing load and landing variables, be they environmental, kinematics based, and/or temporal, each landing event is decomposed into several periods based on the amount of ground contact cycles. Each period is subsequently fitted to a category of distinct profiles based on observed dynamics and impact characteristics. The profiles are developed by analysing both video footage and sensor data to characterise each sequential landing period. This involves examining footage frames for the tyre impact timing, impact sequence, and the incidence angle, in addition to KPD-dictated touchdown indicators which serve in conjunction with the footage to dictate when the first period (linked to a profile) ends and the next begins. Each profile represents a set of initial conditions that are subsequently used to tailor the non-linear response archetypes. The profiles are categorised to be represented by, at their simplest:

- A smooth landing characterized by a negligible time difference between the touch-down of the rear right and left LG.
- High impact landings with minimal temporal separation between the rear LGs.
- Asymmetrical high impact landings affecting one side more than the other.
- Landings involving bounces, skips, or jumps.

By defining the characteristics of each period and linking it to a profile, the dynamic equations set for each profile can be adjusted to reflect the real-world dynamics observed during the data collection phase. This step ensures that they are representative of the variety of conditions the aircraft encounters in the duration of its single landing event.

3.2.1. Empirical Data Subsets Creation

Following the detailed decomposition of landing sequences as outlined in Section 3.2, and the rigorous data pruning mechanisms discussed in Section 3.1.3, the next phase focuses on compiling targeted time-series databases. These databases commence from the precisely determined touchdown point, leveraging the Gaussian kernel's efficacy in pinpointing this instant with high accuracy. The newly formed databases are confined to the parameters that are most indicative of landing dynamics and are crucial for the subsequent analysis:

- **Accelerometer Outputs**: Capturing the triaxial forces during the landing, these readings are pivotal for assessing the aircraft's response to touchdown dynamics.
- **Aircraft Attitude**: This includes the pitch, roll, and yaw of the aircraft at the point of touchdown, offering insights into the angular orientations that influence landing impacts.
- **Speed**: Ground speed and airspeed are included to correlate the velocity at touchdown with the landing impact severity.
- **Gross Weight**: The total weight of the aircraft influences the impact force and is thus critical for understanding the stress distribution on landing gears.
- **Radio Altitude**: For confirming the moment of touchdown and aids in synchronising other data streams.

Each database subset is tailored to represent a single impact cycle, which is identified based on the landing sequence typology. This approach ensures that each dataset is representative of specific landing conditions, thereby allowing for a more granular analysis of landing dynamics.

The speed, gross weight, and radio altitude are inserted into the completed landing condition archetypes for an output of the sequential response profiles that would allow for comparisons with the original subset databases containing the additional parameters representative of the period being inspected.

3.3. Landing Condition Archetypes

The preceding step, landing sequence typology, carries us closer to accurately representing the dynamics of a landing event by segmenting it into distinct sequential periods. Each period is tailored with specific boundary conditions corresponding to a respectively identified landing profile, enhancing the ground truth of our simulations, herein referred to as ‘archetypes’ which consist of non-linear dynamic ODEs combined with a model of a CS25 aircraft’s shock absorber and its interaction with the tyre and aircraft mass at level landing, which are critical for characterising the physical response of the aircraft's landing gear system under load. Given the lack of physical drop test rigs for empirical validation, it is imperative to assess the fidelity and robustness of these models.

Validation occurs in a bifurcated approach: Initially, the fidelity of the physics-based Simulink model is confirmed to ensure alignment between simulated performances with actual aircraft landing observations. This verification leverages detailed video stream analysis and FDR accelerometer data, which guide the establishment of stringent constraints and operational requirements specific to the landing gear system components in the simulation. These requirements are grounded in recognized benchmark methods, such as implementing damping strategies to mitigate resonance phenomena like shimmy and gear walk in the simulated landing gear assembly. A critical damping target, as stipulated by SAE International (2017) is reducing system oscillation to no more than a third of its original amplitude within three oscillation cycles post any perturbation.

3.3.1. Sequential Period Differential Equations

Using the data derived from the landing profiles, a set of ODEs is devised for each scenario. Free body diagrams (FBD) are utilised prior to forming these equations, ensuring that all relevant forces and interactions are accurately represented. The FBD of a level landing can be seen in Figure (4). These equations consider the mass, damping characteristics, and stiffness of the aircraft’s LG and structure. They include the non-linear characteristics of a CS-25 aircraft shock absorber, the interaction between the LG and the runway surface, and the effects of tyre dynamics on the LG system performance.

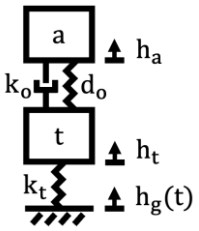

Figure 4. FBD for a level landing

The Simulink model in Figure (5) is adapted from that provided by (Jan R. Wright & E. Cooper, 2014). Simulink's environment allows for the continuous adjustment and real-time simulation of the equations, facilitating an iterative process of model refinement. The system is broken down into the aircraft rigid body mass and tyre mass, each with their own set of ODEs. The aircraft mass ODE includes terms for the spring and damper forces connecting the aircraft and tyre. The tyre mass ODE considers the forces from the OSA spring and damper, the tyre spring force, and runway height profile. A simple rigid aircraft landing system, assuming lift equals weight at touchdown, and ignoring spin-up and spring-back

and resulting LG motion due to them, is broken down as follows. Given:

- $\boldsymbol{h_a}$: Height of the aircraft mass from a reference point.
- $\boldsymbol{h_t}$: Height of the tyre mass from the same reference point.
- $\boldsymbol{h_g(t)}$: Runway height from the reference point, which is a function of time.
- $\boldsymbol{k_a}$: Spring constant connecting aircraft and tyre.
- $\boldsymbol{d_a}$: Damper constant connecting aircraft and tyre.
- $\boldsymbol{k_t}$: Spring constant connecting tyre and ground.

The resulting ODEs for the aircraft and tyre mass, respectively, are in Eq. (1) and Eq. (2) below:

$$m\ddot{h}_a = -k_a(h_a - h_t) - d_a(\dot{h}_a - \dot{h}_t) \qquad (1)$$

$$m_t\ddot{h}_t = k_a(h_a - h_t) + d_a(\dot{h}_a - \dot{h}_t) - k_t(h_t - h_g(t)) \qquad (2)$$

Additional ODEs are introduced for pitch and yaw dynamics depending on the period profile being modelled, considering the aircraft's moments of inertia, aerodynamic moments, and LG forces, and are a work-in-progress.

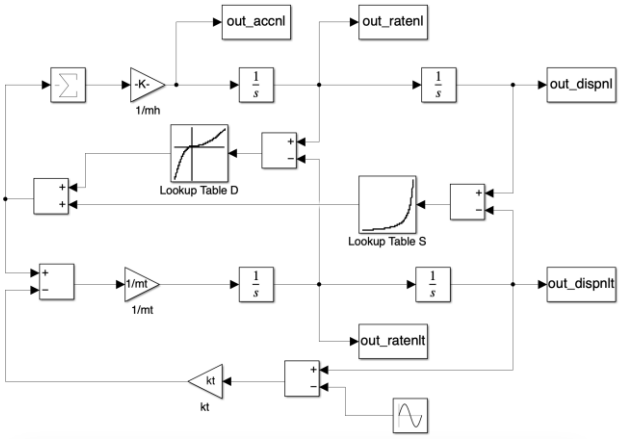

Figure 5. Simulink representation for a rigid-body level aircraft landing on main landing gear.

3.3.2. Non-linear Oleo-Pneumatic Shock Absorber

The OSA modelled employs a gas spring mechanism (the integral part affecting its dynamics), where the dynamics are significantly influenced by changes in gas volume and pressure during landing impacts. Its functionality is governed by the Ideal Gas Law, expressed as $PV^{\gamma} = C$, where P represents the absolute pressure, V the volume of the gas, γ the polytropic constant, and C a constant. The value of γ varies based on the OSA's operational conditions:

- Static Conditions (γ=1): This scenario represents steady, slow compressions such as during taxiing, where the temperature is maintained constant due to sufficient time for heat transfer.
- Dynamic Conditions (γ=1.3−1.4): During rapid compressions, such as landings, the process is adiabatic with no heat transfer, reflecting a higher γ value.

During the OSA's operation, as the LG encounters forces from the runway, the piston compresses, altering the gas volume. For a given change in volume ΔV caused by the piston stroke z, the new volume V_2 is given by $V_2 = V_1 - Az$, where A is the piston area. The corresponding pressures before and after compression, from the fully extended state V_∞ to the compressed state V_c are linked by Eq. (3):

$$P_\infty {V_\infty}^{\gamma} = P_c(V_\infty - Az)^{\gamma} \qquad (3)$$

The absolute pressure/displacement relationship can then be expressed in Eq. (4), where z_∞ is the fully bottomed distance (Jan R. Wright & E. Cooper, 2014):

$$\left(\frac{P}{P_\infty}\right) = \left(1 - \frac{z}{z_\infty}\right)^{-\gamma} \qquad (4)$$

According to Currey (1988), the typical characteristics for these calculations are as follows:

- Piston Area (A): Depends on the static pressure in the shock absorber, e.g., A=0.005m² if $P_{\text{static}} = 100$ bar.
- Pressures: $P_c = 3P_{\text{static}}$ and $P_\infty = 0.25P_{\text{static}}$.
- Volume Ratios: Assuming $V_\infty/V_c = 12$, then $V_\infty = V_c + A \cdot z_{\text{static}}$.

During landing, assuming that the lift equals the weight of the aircraft and neglecting tyre deformation to simplify the energy considerations, the kinetic energy of the aircraft equates to the work done by the OSA as in Eq. (5) (Jan R. Wright & E. Cooper, 2014):

$$\frac{1}{2}mv_y^2 = \eta_{\text{SA}}F_{\text{LGmax}}z_s = \eta_s\eta_{\text{LG}}Wz_s \qquad (5)$$

Where:

- m : Mass of half the aircraft plus part of the landing gear above the OSA.
- η_{SA} : Efficiency of the OSA, typically around 0.8.
- η_{LG} : LG load factor, ranging from 2 to 2.5 for CS-25 aircraft, representing the ratio of (static + dynamic reaction load) to (static load).
- W : Weight of the aircraft, equal to mg.

The force generated by the OSA, which is crucial for mitigating the impact during landing, is a function of the pressure differential across the piston. This force contributes to the overall dynamics of the aircraft's LG by opposing the landing load and dissipating kinetic energy. This is then translated into the Simulink environment through a series of blocks representing the aircraft's landing dynamics. The forces calculated from the OSA's pressure and volume changes are fed into the model to simulate the periods within the real-time landing event. These blocks use look-up tables generated from the aforementioned theoretical calculations.

3.3.3. Sequential Response Profiles

Sequential response profiles are derived from the outputs of the Simulink model to assess the performance of the OSA and the travel behaviour of the main LG during each sequential period. These profiles are essential for evaluating what similarities can be inferred between the archetypes and the empirical subset time-series data. The response profiles include the shock-absorber travel time-series, which tracks the displacement and normalised load absorbed over time, and the tyre reaction time-series, documenting the reaction forces of the tyre which reflect the dynamics of the unsprung mass. The analytical approach involves aligning the data starting at the moment of touchdown, identified by radio altitude and verified through accelerometer data, ensuring that the simulation phases are synchronized with the actual event timings. The Simulink solver continuously processes the differential equations representing the landing dynamics. The shock-absorber's travel and tyre reaction forces are methodically captured and plotted to provide an examination of the forces at play during the landing.

3.4. Comparison with On-board Data

In parallel, while video footage is used to validate the temporal and sequential accuracy of the archetypes in some capacity, the sequential response profiles (Simulink outputs) are compared to the time-series empirical accelerometer output corresponding to each of these periods. In our study, the primary objective of comparing Simulink model outputs to empirical accelerometer data is to establish a robust relationship in terms of observed trends and to correlate these observations with specific landing profiles, such as a hard level landing. This analysis involves comparisons of both Simulink outputs and accelerometer data collected from the aircraft during defined landing scenarios. The goal is to systematically expand this analysis across multiple flights and varying initial conditions, thereby compiling a comprehensive set of correlations between the model's predictions and the actual accelerometer responses recorded on the aircraft. For each period of each landing event analysed, the model outputs and accelerometer readings are compared to determine how closely the simulated responses (from the Simulink model) align with the real-world data under similar operational conditions. Key parameters considered during these comparisons include aircraft speed, gross weight, and radio altitude variation which would give us vertical speed at the point of touchdown. Through repeated evaluations across diverse flight conditions, this method allows us to refine our understanding of the dynamic interactions between the aircraft's LG and the runway surface.

3.5. Performance Degradation Metric Definition

As the dataset grows, encompassing a wider array of flight profiles, we progressively build a Performance Degradation Metric (PDM). This metric is designed to assess, using only the time-series output from the aircraft's accelerometers at touchdown, whether the observed accelerometer responses align with expectations derived from our simulations and previous correlations. This involves two critical analyses: first, evaluating the output of the Simulink model corresponding to the given profile (in the form of sequential response profiles for the specific period), and second, examining the established relationships between key accelerometer performance indicators, including peak-to-peak time, temporal peak separation, and time interval analysis relative to specific thresholds, and their alignment with Simulink model outputs. Based on the discrepancies identified between the simulated results and the actual data, adjustments are made to the ODEs and their parameters in the Simulink model. These adjustments may include changes in the damping coefficients, stiffness parameters, and mass distribution within the landing gear system. Each iteration aims to reduce the error margin and enhance the fidelity of the model. This approach aims to ensure as much as possible that each phase of the investigation contributes to a systematic and scalable understanding of the landing dynamics, which is crucial for advancing the predictive capabilities of our models.

Central to the separation in terms of model comparison of this analysis is the delineation of the minimal interval necessary for both main LGs to contact the runway simultaneously in a level touchdown—a scenario that equally distributes the landing load but remains exceedingly rare due to the imperative for pilots to adjust for crosswinds through controlled bank angles and the inherent inconsistencies present in airstrip surfaces. In recognising that aircraft landings may encompass a complex combination of the aforementioned scenarios, the PDM shall incorporate a nuanced measurement of the intensity and category of each phase encountered, leading to the point of analysing probability of performance degradation; assessing each LG unit's potential for operational wear (be it the right or left LG assembly). By continuously refining the correlation between simulated outcomes and actual flight data, our study aims to provide reliable predictive tools that can effectively anticipate operational degradation of the aircraft's landing systems under varied operational conditions.

This PDM is to output a relative operational health status of the main LG assemblies as shown in Figure (4). This plot displays the relative operational health status of the main LG assemblies over the course of successive landings. The initial operational health status is set at 100% at the commencement of operation (0 landings), with the Safe-life indicating the theorised lifespan, shown as a fixed endpoint in the plot at a landing life of 60k. The plot simplistically portrays the relative operational health as declining linearly; however, this does not reflect real-world conditions and is merely a simplification for illustrative purposes. The plot serves as a theoretical model, illustrating the projected outcomes we aim to achieve by the conclusion of the project. Key components include:

- **Safe Life Health Status**: The dashed red line serves as a theoretical performance threshold. Should the operational health of any LG assembly drop below this line, as predicted by the hybrid model, this would suggest potential risks at which an inspection is required.
- **Left and Right LG Hybrid Approach Health Status**: The blue and green lines show actual health status tracking for left and right LG, respectively, with maintenance actions represented by 'x' markers.
- **LG Failure at 5400 Landings**: This trend exemplifies the characteristic decline preceding a failure event.
- **LG Health in Ideal Low Wear Conditions**: A trend representing a LG assembly that has undergone extremely low-impact landing cycles.

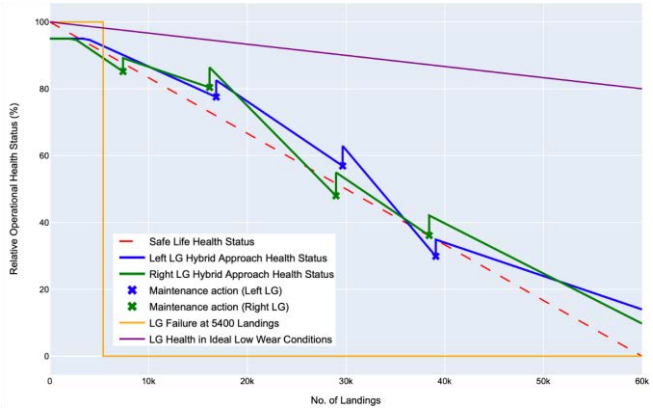

Figure 6. LG Operation Health Status

The value of the relative operational health status represents the current operational condition of the system, rather than direct LG part degradation. Its value is relative to the corresponding value of the Safe Life Health Status at that no. of landings. In Figure (7), a closer examination of the initial segment of the plot in Figure (6) reveals inherent uncertainties in the model's operation, stemming from the requisite number of landing cycles needed to establish reliability. Currently, this figure is illustrative and subject to refinement as our project evolves towards more precise and realistic estimations.

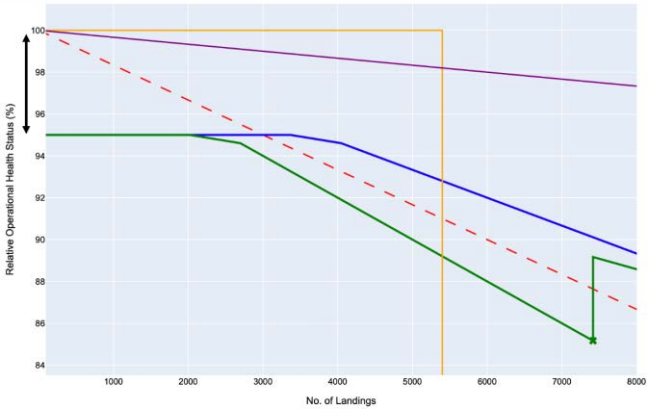

Figure 7. A close-up on no. of landings required for model validity

4. PROJECT DIRECTION AND FUTURE WORK

This paper marks the commencement of a structured approach for enhancing LG health assessments by means of virtual sensing combined with landing scenario-representative empirical models. While this paper discusses the initial stages of the first study, subsequent planned investigations will further this exploration:

Study 1 - Sensor Data Analysis and LG Dynamics: This segment focuses on extracting and analysing data from the FDR and IMU, comparing these to LG response profiles that are a result of landing condition archetypes to detect deviations in accelerometer oscillations and other critical parameters. Objectives include:

- **Operational Condition Analysis**: Examining variations in LG dynamics across different operational conditions.
- **Performance Pattern Identification**: Identifying desirable performance patterns and recognising limitations.

Study 2 - Sensor Placement and Data Precision: This study aims to compare IMU and on-aircraft accelerometer outputs during the landing's touchdown and roll phases, to identify the most effective sensor placements for LG response evaluation. This assists in pinpointing LG performance patterns during crucial phases. The focus areas are:

- **Sensor Output Comparison**: Crafting strategies for comparing sensor outputs to underline strategic placement.
- **Filtering Techniques**: Applying filtering methods to sensor outputs for improved data accuracy.

Study 3 - Structural Dynamic Response: Initiates a quantitative examination of modal frequencies and structural resonances before landing, employing high-fidelity spectral analysis to differentiate these from frequencies observed

post-touchdown. This study encompasses high-fidelity spectral analysis to separate pre-impact from post-impact frequencies.

Results and Future Directions: Following these studies, we shall present:

- **PDM Development**: A more detailed discussion on the development and validation of the PDM, including an assessment of operational degradation in the port and starboard LG relative to maintenance schedules.
- **Empirical and Theoretical Insights**: A comparative analysis offering essential insights from our empirical data and theoretical models.
- **Case Studies**: Application of our hybrid approach to real-world scenarios.

Future initiatives will broaden these methodologies to encompass more aircraft components and scenarios, aiming to reduce aircraft downtime and enhance safety across various models.

ABSTRACT

The recent advances on utilizing Generative Artificial Intelligence (GenAI) and Knowledge Graphs (KG) enforce a significant paradigm shift in data-driven maintenance management. GenAI and semantic technologies enable comprehensive analysis and exploitation of textual data sets, such as tabular data in maintenance databases, maintenance and inspection reports, and especially machine documentation. Traditional approaches to maintenance planning and execution rely primarily on static, non-adaptive simulation models. These models have inherent limitations in accounting for dynamic environmental changes and effectively responding to unanticipated, ad hoc events.

This paper introduces a *maintenance chatbot* that enhances planning and operations, offering empathetic support to technicians and engineers, boosting efficiency, decision-making, and on-the-job satisfaction. It optimizes shift scheduling and task allocation by considering technicians' skills, physical stress, and psychological state, thus reducing cognitive stress. The approach ultimately improves human performance and reliability, embodying a human-centricity in the domain of maintenance and health management.

The practical impact of the *maintenance chatbot* is illustrated through its application in maintenance of railway cooling systems. The presented use case demonstrates the chatbot's potential as a transformative tool in maintenance management. Finally, the paper discusses the theoretical and practical considerations, in particular in the light of regulative frameworks such as EU AI ACT, highlighting the future pathways for complying with responsible AI requirements.

1. INTRODUCTION

The industrial landscape is currently facing a significant challenge due to the shortage of skilled labors, exacerbated by the increasing complexity of machinery and technological systems, as well as green transition, leading to limiting production by 28% in the European Union (EU) (European Commission 2023). This shortage poses a critical threat to the operational efficiency and sustainability of maintenance operations within various sectors. The complexity of modern machines requires a high level of expertise, yet industries often find themselves compelled to hire workers who may not fully meet these competency requirements (Shin et al. 2021). The European Union estimates the investment needed to reskill and upskill in manufacturing to 4.1 billion EUR up to 2030 (European Commission 2023). This gap between the required and available skill sets leads to inefficiencies, increasing human failure, thus reducing reliability and increasing downtime, and a greater potential for errors in maintenance operations.

Simultaneously, advancements in GenAI and semantic technologies have opened new avenues for capturing and leveraging the domain knowledge of experienced professionals (Abu-Rasheed et al. 2024), and at the same time assisting them on improving their problem-solving capabilities, e.g. through query-answers with chatbots (Kohl und Ansari 2023b). These technologies, particularly Large Language Models (LLMs), demonstrate an unparalleled capacity to analyze and interpret complex datasets, including technical documentation, maintenance logs, and operational reports (Birhane et al. 2023). Their ability to generate contextually relevant, accurate responses based on vast amounts of textual information marks a significant step forward in the development of cognitive assistants for maintenance tasks.

The intersection of skilled labor shortages (as a problem space) and GenAI technologies (as a solution space) underscores a critical need for tools that can bridge the gap between the complexity of modern machinery and the competencies of the available workforce. Cognitive assistance in maintenance, facilitated by AI-driven solutions, offers a promising approach to address this challenge (Kohl und Ansari 2023a). By providing real-time, tailored information and support, such tools can enhance decision-

making, reduce cognitive load, and improve the efficiency of maintenance technicians who may not possess the full spectrum of required competencies and experiences. Furthermore, the integration of GenAI and semantic technologies in maintenance operations enables the preservation and dissemination of expert knowledge, mitigating the risk of knowledge loss due to workforce turnover or the retirement of seasoned professionals (Alavi et al. 2024). This capability is particularly valuable in light of the increasing complexity and specificity of modern industrial systems, where the loss of domain-specific knowledge can have significant operational impacts (Ansari 2019).

The need for cognitive assistance in maintenance is not only a response to the skilled labor shortage but also a strategic investment in the quality and reliability of maintenance operations. By enhancing the capabilities of maintenance technicians, engineers and planners, AI-driven tools can contribute to more resilient, efficient, and effective maintenance practices. The development and implementation of such tools, as exemplified by the LLM-based maintenance chatbot presented in this paper, represent a forward-looking approach to addressing the challenges of the contemporary industrial maintenance landscape (Romero und Stahre 2021). The following paper addresses the challenge of improving the workflow of maintenance operations and planning by leveraging LLM and semantic information.

The rest of the paper is structured as follows: In Section 2, the state-of-the-art is described, focusing on cognitive assistance system, Generative AI, especially Large Language Models. Thus, the research gap is identified. Section 3 introduces the system architecture and modular chatbot design, and Section 4 elaborates on its use case. Finally, Section 5 discusses the key findings and identifies the pathways for future research.

2. STATE OF THE ART

This section explores the capabilities and applications of cognitive assistance systems within industrial manufacturing, emphasizing their role in augmenting human capabilities. It highlights how these systems utilize advanced technologies such as LLMs and KGs to optimize task execution. Additionally, it addresses the implications of the EU AI Act, which mandates transparency and safety in the deployment of such AI-driven systems, ensuring their responsible application in industrial environments.

2.1. Cognitive assistance system

Digital assistance systems (DAS) support workers in production, assembly and logistics to carry out their tasks efficiently in line with the situation and context (Ansari et al. 2020). These systems facilitate tasks ranging from scheduling and information retrieval to more complex operations, leveraging user inputs to deliver relevant outcomes and insights (Pokorni und Constantinescu 2021). Cognitive assistance systems (CAS), particularly within the manufacturing sector, extend this concept by focusing on augmenting human capabilities in intricate tasks rather than substituting human efforts (Kernan Freire et al. 2023), which can draw conclusions from its experience on the basis of significant portions of suitably presented knowledge so that it provides more appropriate, accurate or up-to-date information in its next use. These systems are engineered to support complex activities, including lifelong learning (Freire et al. 2023), machine operation, and task execution, through advanced methods of human-machine interaction (Listl et al. 2021). Employing a broad spectrum of techniques such as natural language processing (NLP) (Ansari et al. 2021), pose estimation for ergonomic risk identification (Kostolani et al. 2022), perception, and augmented reality (Zigart und Schlund 2020), CAS are designed to foster an intuitive and efficient interface for users.

CAS, utilizing NLP for natural language understanding, generation, and dialogue management, represent the most widespread interaction modality within CAS (Kang et al. 2020). These CAS are capable of engaging users in meaningful conversations, thereby facilitating labor-intensive tasks across multiple sectors, including customer service, healthcare, education, and manufacturing, through efficient and reliable communication (Eloundou et al. 2023).

In the industrial context, the application of CAS is an evolving research domain with significant potential benefits (Mark et al. 2021). These include providing centralized access to diverse information systems, decision making (Rožanec et al. 2022), delegating tasks (Burggräf et al. 2021), and enabling hands-free and gaze-free interactions (Romero und Stahre 2021), thereby enhancing operational efficiency and safety. Additionally, CAS in manufacturing can serve as valuable tools for on-the-job training (Wang et al. 2022) and real-time machine parameter adjustments, thereby contributing to the flexibility and adaptability of manufacturing processes (Zheng et al. 2022). Such applications highlight the transformative potential of cognitive assistants in augmenting human work, optimizing task execution, and facilitating continuous learning and adaptation in complex industrial environments.

2.2. Generative AI and Large Language Models

According to the OECD, GenAI “creates new content in response to prompts, offering transformative potential across multiple sectors such as education, entertainment, healthcare and scientific research”(OECD Artificial Intelligence Papers 2024). It, therefore, significantly broadens AI's application spectrum (Gozalo-Brizuela und Garrido-Merchan 2023). At the heart of GenAI's advancements are LLMs like Generative Pre-trained Transformers (GPT), which have dramatically enhanced AI's language processing and generating

capabilities, offering applications from automating documentation to improving decision-making in industries.

Retrieval-Augmented Generation (RAG) (Jing et al. 2024) extends LLMs by integrating them with information retrieval systems, enabling real-time access to extensive databases for more precise, context-specific causal outputs (Zhou et al. 2024). This is particularly valuable in manufacturing and maintenance, where accessing up-to-date technical and diagnostic information is crucial (Kernan Freire et al. 2023).

AI agents represent a further advancement, capable of autonomous decision-making based on environmental learning and adaptation (Zhao et al. 2023). In the context of manufacturing and maintenance, these agents can autonomously monitor system health (Han und Tao 2024), predict (Saboo und Shekhawat 2024) and automate maintenance tasks (Sun et al. 2024), thereby reducing downtime and maintenance costs. It can therefore be said that current approaches can achieve relevant results through their purely probabilistic transformer architecture by using attention with classical RAG, but cannot use factual, linked knowledge.

2.3. Knowledge Graph

Knowledge Graphs (KGs) structure knowledge in graphs, connecting entities and their relationships, thereby facilitating semantic searches and data integration (Fensel et al. 2020). In GenAI applications, KGs enhance RAG (Zhu et al. 2024) by providing structured, semantically linked domain information to improve response accuracy and contextual relevance (Agarwal et al. 2020), particularly valuable in domain-specific applications like manufacturing (Yu 2022). KG therefore enhance capabilities of chatbots by providing them with structured context information on specific user requests (Li et al. 2021). By leveraging the rich semantic relationships within KGs, chatbots are able to understand and process user queries more effectively, navigating through complex information networks to retrieve or infer accurate answers (Yu 2021).

Within manufacturing, KGs encapsulate domain knowledge and causal relationships between failure modes and solutions, informed by Failure Modes and Effects Analysis (FMEA) (Razouk et al. 2023). This structured knowledge aids RAG systems in querying precise information for predictive maintenance and decision support, thereby streamlining maintenance protocols and diagnosing machinery issues through an understanding of causal links.

The synergy between KGs and RAG significantly enhances manufacturing operations' efficiency by enabling access to detailed domain knowledge, reducing downtime, and guiding accurate maintenance decisions, thus enhancing operational reliability and performance (Ansari et al. 2023).

2.4. EU AI Act

In response to the rapid developments in the field of AI in recent years, the European Union has implemented a regulatory framework for development, market introduction and deployment of AI-driven products, services, and systems. The framework is designed to guarantee transparency, accountability, and safety for both current and forthcoming AI technologies within the EU. Especially in the area of manufacturing a responsible application of AI is essential to mitigate risks and deliver business benefits (Besinger et al. 2024).

Since current pre-trained LLMs like the GPT-models (Brown et al. 2020) or Metas Llama-Series (Touvron et al. 2023) are trained outside of the European Union, the EU AI Act addresses this issue by extending its scope to include providers operating within the EU as well as those in third countries, particularly when the output of their AI systems is utilized within the Union. The EU AI Act defines different categories from no risk to high-risk. The use of AI in human interaction, emotion recognition, and content generation is categorizes as low risk (second category). Article 52 (European Commission 2024) addresses the regulatory requirements for providers and users (excluding end-users) of AI systems categorized as low risk. There are three critical areas pertinent to the case presented in this paper: Transparency in AI interactions, the Marking of synthetic content, and the Disclosure requirements for emotion recognition and biometric categorization.

Firstly, concerning Transparency in AI interactions, the legislation mandates that AI systems engaging in human interaction must inform users of their non-human nature, except in contexts where such interaction is inherently apparent. Secondly, the requirement for marking synthetic content, such as audio, images, videos, or text, created or significantly altered by AI there must be machine-readable marks signifying its artificially generated or manipulated status, except for minor edits. Lastly, concerning emotion recognition and biometric categorization, users must be informed about these processes, with data handling needing to comply with EU regulations (European Commission 2024).

2.5. Research Gap

In industrial maintenance, the accessibility and quality of critical data is a crucial issue. Despite the increasing availability of information from maintenance reports, personnel documents, and enterprise resource planning (ERP) systems, the effective use of this data remains largely untapped. Therefore, to the best of the authors' knowledge, current research has not sufficiently explored the use of LLM in chatbots in industrial applications, especially the use of linked data and documents in an agent network. This paper presents a novel way to combine LLM with RAG and KG in an intent-driven agent framework, providing a flexible,

generalizable and scalable approach for industrial maintenance.

3. METHODOLOGY

In the following the design of the system architecture, which enables an LLM-based maintenance chatbot is described. Further, we propose a modular agent layout for the chatbot. The architecture is based on by RAMI 4.0 (DIN 91345) and inspired by (Margaria und Schieweck 2019).

3.1. System Architecture

The system architecture for the application of an LLM-based maintenance chatbot, see Figure 1. is structured into three distinct tiers, namely data tier, analytics tier and presentation tier, each with specific components, capabilities and information flows designed to interact seamlessly within the broader ecosystem of the industrial application.

Data Tier: The *Event Broker* facilitates communication between the analytics components and the data sources. It manages the flow of real-time data to the Data Analytics (Stream) and routes information to and from the Prescriptive Analytics. The *Database* stores historical data, such as CAD-models, maintenance reports or technical data, which is subsequently used for trend analysis and informing predictive models. It also serves as a repository for collected data over time and connects them through semantic similarities, which leverages the suitability of natural language interaction. Vectorized data schemas in the Data Tier allow for efficient data retrieval. *Edge Devices* are directly connected to the database and serve as intermediaries between the physical sensors and the system's core data infrastructure. They perform preliminary data processing, filtering, and aggregation tasks.

Sensors, either attached to machines or environmental sensors, collect data about the operational status, health, and performance of the machinery and environmental status. This data is crucial for monitoring and maintenance purposes. It incorporates different database structures. For processing natural language, the core components are a vector database and a KG, which serve as the foundation for an efficient RAG pipeline. While vector databases enable efficient data retrieval through vectorized representation of domain specific data (Jing et al. 2024), KGs provide structured representation of the data (Pan et al. 2024). A combination of these components is leveraged to reduce hallucination and utilize information which is not inherent to the LLM. The KG, see Figure 1, enables the connection of ERP data with task and competence relevant information. This data model allows a holistic view on the maintenance process as well as the possibility for downstream agents for interconnected reasoning. *Machines* are the physical hardware being monitored and maintained. Connected to sensors, they are the source of the operational data fed into the system for analysis. *Assistance Systems*, such as smart tools and tablets, are connected to sensors. They serve as an interface for workers

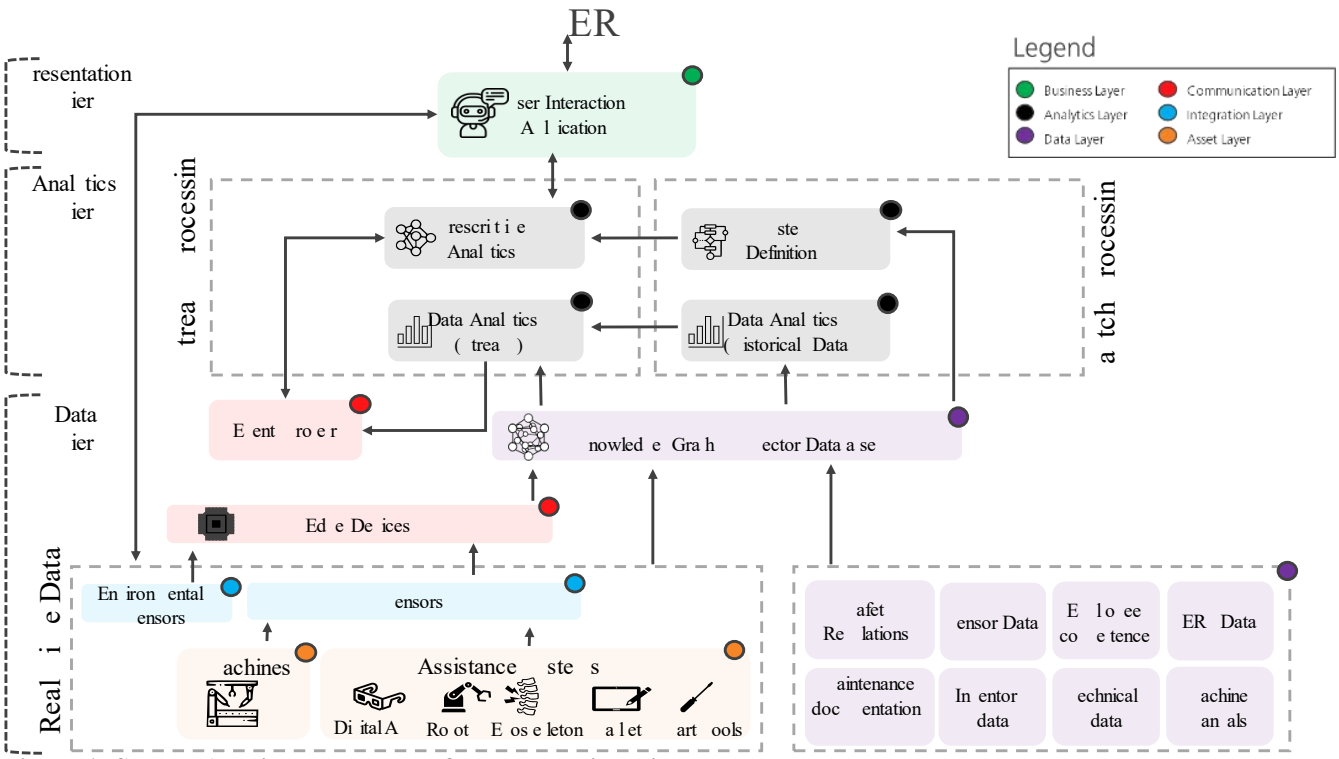

Figure 1: System Architecture Layout for empathetic assistance systems

on the ground, providing them with real-time guidance deri ed f ro t he s s te 's anal sis.

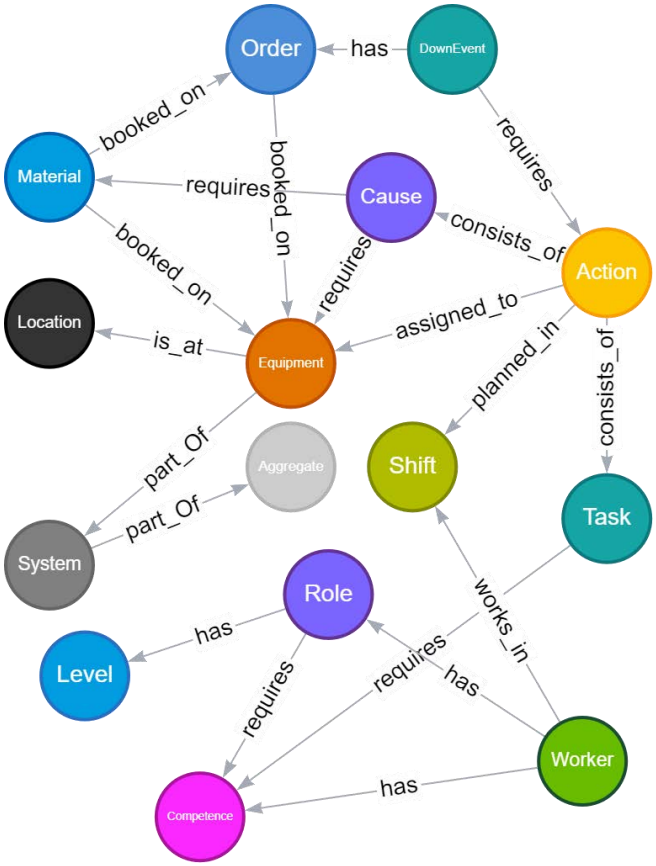

Figure 2: Data model of the KG based extended from (Kohl und Ansari 2023a)

Analytics Tier: The *Prescriptive Analytics* component is directly linked to the User Interaction Application. It processes the user's input, utilizing the Rasa conversational AI framework (Introduction to Rasa Open Source & Rasa Pro 2024), to generate actionable advice or maintenance recommendations. It uses advanced algorithms such as anomaly detection to suggest specific actions based on the analyzed data. The *System Definition* , powered by the Llama-2-70b-model (Touvron et al. 2023), functions as a reasoning framework that defines and orchestrates data analytic processes. It incorporates a multi-agent layer structure to process user input and determine the most appropriate action to take (Jiang et al. 2023). Therefore, necessary parameters and fitting data sources are determined to resemble the scope for aspired data analytics. The *Data Analytics (Historical Data)* component uses batch processing to analyze historical data to identify trends, patterns and potential issues based on past events. In contrast to the historical data analytics, the *Data Analytics (Stream)* component processes simulated real-time sensor data to offer immediate insights and detect current or impending issues, which is essential for real-time decision-making and alerts. The Data Analytics component utilizes multiple regression to forecast outcomes and incorporates K-means clustering to discover trends in historical data, as well as an Isolation Forest algorithm for anomaly detection. The foundational understanding of the Data Analytics (Historical Data) additionally augments the predictive real-time models to ensure a maximum of information for analysis.

Presentation Tier: The *User Interaction Application* component serves as the interface between the end-user and the chatbot system. It is where users interact with the chatbot, inputting queries and receiving responses. In this context, a simplistic User Interface featuring a Chatbot window was implemented, as illustrated in Figure 4.

Each tier in this architecture is intricately connected, allowing data to flow from the machines up through the system to enable real-time and predictive maintenance decision-making. The architecture is designed to maximize efficiency, reduce mean time to repair, and provide actionable insights through a user-friendly interface.

3.2. Modular Chatbot Layout

This chatbot layout is aligned with existing frameworks for developing multi-agent dialogue systems (Engelmann et al. 2023; Xi et al. 2023). It is depicted in Figure 3 and features a central User Agent linked to three specialized agents (Scheduling, Competency, Analyzer), all interfacing with an

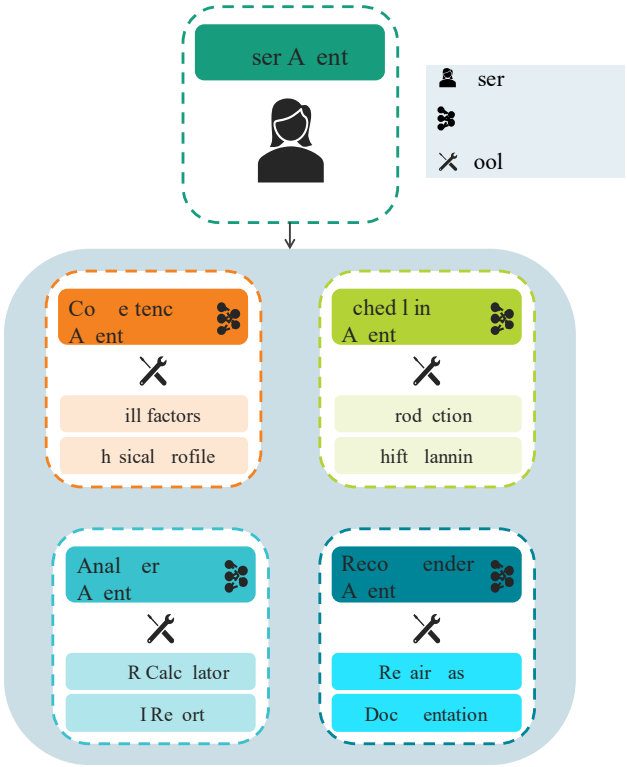

Figure 3: Interconnected Agent Layout for a modular maintenance chatbot architecture

LLM acting as a classification engine to determine which agent is triggered for a certain query. This User Agent represents the System Definition within the System Architecture, see Figure 1 and therefore determines which specialized agent is triggered subsequently. These specialized agents comprise of several tools and determine the correct tool usage for task-specific challenges. Moreover, the agents can interface with each other if the task requires agent collaboration. The proposed modular design allows for seamless integration of further agents and tools within agents to encounter novel challenges over time.

- **User Agent:** Channels user inputs to the appropriate specialized agents and consolidates their outputs for user communication. It is the link between Presentation and Analytics Tier.
- **Scheduling Agent:** Selects the production planning and shift planning tools based on user agent task instructions and operational needs. The optimization algorithm leverages provided data sources within the Data Tier and interacts with the Competency and Analyzer Agent to ensure fairness and efficiency while allocating shifts and schedule production.
- **Competency Agent:** Decides whether to analyze skill factors or physical profiles, aligning workforce tasks with individual skills and physical capabilities for optimal job assignment. Through its empathetic capability it continuously checks for physical and ethical alignment of worker tasks.
- **Analyzer Agent**: Chooses between MTTR calculation and KPI report analysis tools to assess maintenance effectiveness and identify areas for operational improvement. It provides recommendations such as prioritization or suggestions for automations.
- **Recommender Agent:** Has access to both historical and real-time data. When an anomaly is detected, it becomes operational. It offers similar historical failures, spare parts, and can store documentation in the KG.

Contrary to the User Agent the specialized agents interact with the Data Tier and leverage aforementioned RAG pipelines with KGs and vector databases to process dynamic and real-time information (Huang et al. 2024). This layout serves as an illustration of how agents can be utilized to allow dynamic maintenance strategies. The system architecture, see Figure 1, provides a high-level reference structure for the integration of new agents, such as a failure mode and effects analysis (FMEA) agent using the cause entity from the KG.

The architecture of this modular system integrates prompts as follows: The overarching system prompt guides the Chatbot, setting its function within a maintenance environment. This structure includes more specific prompts at subordinate levels. The User-Agent prompt functions analogously to a supervisory agent, tasked with identifying the most appropriate agent response to a user query. Each specialized agent operates under its own prompt; for example, the Analyzer Agent is responsible for generating reports based on historical or real-time data. This necessitates determining whether to initiate tools such as MTTR or KPI reports. Subsequently, this agent classifies the tool required for the task, parsing input parameters – such as the specific machine and time span – from the LLM. These parameters, where descriptions are also provided, are then employed within Python functions, with the resulting outputs fed back to the LLM, which then crafts responses based on these function outputs.

3.3. Regulative Considerations

In the context of implementing a maintenance chatbot, aligning with the EU AI Act's transparency obligations is essential for fostering trust and ensuring responsible use. The EU AI Act mandates that users are explicitly informed when they are interacting with AI systems, like chatbots. This requirement is critical in maintenance environments, where decisions can impact operational safety and efficiency. By disclosing the chatbot's AI nature, users are empowered to make informed choices about their engagement, understanding that they are consulting a machine for assistance. This transparency not only builds trust in the technology's capabilities and limitations but also reinforces the importance of human oversight in decision-making processes. Ensuring users are aware they are interacting with

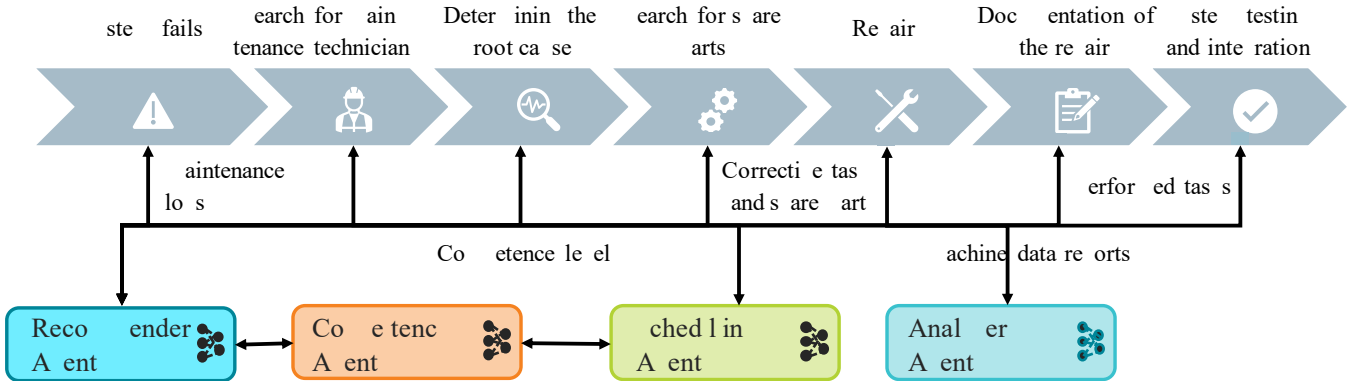

Figure 4: Maintenance process and its triggered agents as well as information flow

an AI helps maintain a balance between leveraging technological advancements and preserving human judgement and accountability in maintenance operations.

4. USE-CASE

The use case discusses a maintenance workflow in the railway industry, utilizing a chatbot for maintaining a cooling system., see Figure 4. The used cooling system provides sensor data about machine states as well as extensive manufacturer information. As it is one of the most frequently installed systems in Vienna's tramways and subways, extensive data on maintenance incidents in form of logs and spare parts is available. The data tier and the used maintenance data set consists of text-based, tabular industrial maintenance logs (Ansari 2020). The dataset was transformed in order to fit the structure of the Sequential QA (SQA) format by Microsoft (Iyyer et al. 2016) in order the be ideally processed by LLMs. In the use case scenario, the KG is constructed from maintenance logs exported from an ERP system, detailing machine failures and corrective actions, also integrates information on the equipment and spare parts used for repairs. The association of actions with required competence and the frequency of these actions by maintenance technicians serve to depict their competence levels (Ansari et al. 2023). Further, a vector database houses segments, specifically text excerpts, from work instructions and machinery documentation. For real-time data, the system monitors the current production schedule along with a simulated data stream of sensor readings from the machines. Additional stress levels of maintenance technicians are recorded for evaluation purpose.

Figure 5: Maintenance of a railway cooling system using a chatbot

4.1. Application of the Chatbot

The chatbot's supportive capability is discussed based on the standard end-to-end maintenance process see Figure 4. It consists of equipment failure, search for maintainer, identification of fault cause, search for spare parts, repair action, documentation of the maintenance process, reintegration of the machine. The following shows points of human interaction as well as autonomous chatbot within this process.

1. **Equipment failure**: The recommender agent is activated by an error notification, triggered by an anomaly in the real time data flow of the machine. Based on the error notification similar historical failures and corresponding actions are determined by semantic search of the task recommendation agent (Ansari et al. 2021).
2. **Search for maintainer**: The scheduling agent, competency agent and task recommendation agent exchange information about the production schedule, available maintenance personnel, their corresponding competencies, and the necessary tasks for failure resolution. According to that an allocation of the most fitting maintainer for the task is deducted.
3. **Identification of fault cause**: This stage marks the initial interaction between the maintainer and the chatbot. Utilizing the chatbot's knowledge, sourced from documents within the vector database, it can pose inquiries related to specific domains or machinery. Throughout this process, the human evaluates the tasks recommended by the chatbot for accuracy and corroborates them based on personal experience and the information furnished by the chatbot.
4. **Search for spare parts**: Once the tasks required for resolving the failure are identified, the task recommendation agent traverses through historical data in the KG to propose necessary spare parts.
5. **Repair action**: During the physical repair, the chatbot acts as an accessible source of pertinent information, offering guidance through machine documents or other necessary data from the vector database. Additionally, it can process requests for more detailed machine information, which are then thoroughly examined by the analyzer agent, e.g. asking for the mean time of repair.
6. **Documentation of maintenance process**: Building on prior interactions, the chatbot can autonomously create new connections within the KG and carry out the documentation process upon request from the maintenance personnel.
7. **Reintegration of the machine**: Finally, the chatbot guides through standard tasks to reintegrate the machine levering information from diverse work instructions.

The proposed integration of a chatbot within the standard end-to-end maintenance process, see Figure 4, represents a significant advancement in operational efficiency and precision. By embedding intelligent, autonomous capabilities at critical junctures of the maintenance workflow, from initial equipment failure detection to the reintegration of repaired

machinery, this model showcases a transformative shift towards more resilient and adaptive maintenance operations. The synergy between human expertise and artificial intelligence not only enhances the decision-making process but also optimizes resource allocation, reduces downtime, and enables empathic human-machine collaboration (Sorin et al. 2023).

4.2. Example: Analyzer Agent

To illustrate a potential maintenance workflow, we present an example of a chat where a user activates the Analyzer Agent. The dialogue demonstrates the triggered process chains, including the reasoning (highlighted in italics) and the tools employed. Due to space constraints, a detailed description of the various prompts is largely omitted. The chat ot is referred to as "AI." se rs can also follow the thought process through a collapsible dropdown segment in the interface, see Figure 6.

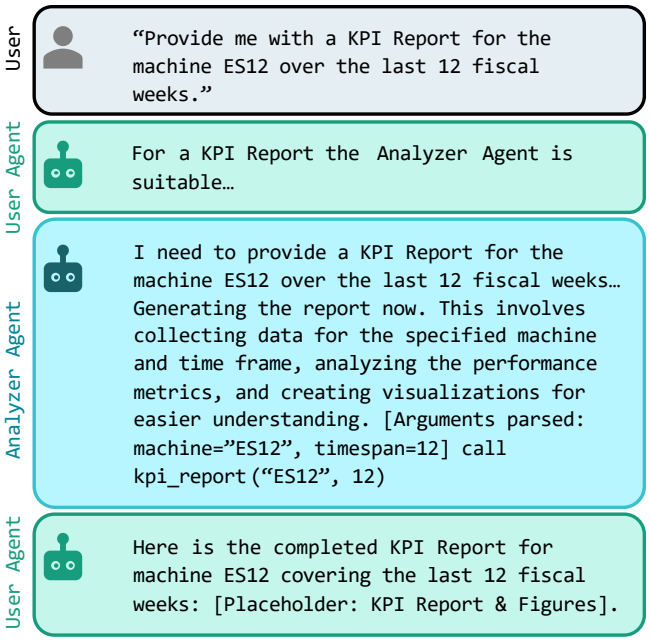

Figure 6: Example prompt of the Analyzer Agent

This example highlights how the chatbot, in its current state, bases its decisions, extending to the collaboration of multiple agents to optimize outcomes, such as in production planning.

4.3. Evaluation of the maintenance-chatbot

The evaluation is based on two types of maintenance tasks performed in Wien's pilot factory: a simple task for changing and cleaning a filter and a more complex task for changing the rotor, where the root cause is not clear. The depicted tasks require different competence levels in different areas. In the test scenarios, the maintenance chatbot demonstrated promising results for guiding the maintenance technicians through the root cause identification and for offering more detailed answers when needed, thereby reducing MTTR by 25% in comparison to the control group. In the case of the more challenging problem setting, the possibility of creating KPIs in natural language for deeper analysis reduced the MTTR by approximately 30% leading to an even higher impact. Furthermore, the dialogues are tailored to the individual competence levels, which permit queries and elucidations of (partial) steps, diminish the stress level and cognitive load, and facilitate a more empathetic conversational style. In addition, a ground truth dataset was constructed. Based on the logs, the appropriate agent or tool was triggered, and that the response was satisfactory in 83% of all cases. Specific tools, such as LangSmith (Ito et al. 2020), are currently under evaluation concerning integration for even better agent handling. Given the implementation of the LLaMA2 model within this chatbot, the Do-Not-Answer dataset (Wang et al. 2023) establishes a framework for safeguarding LLMs against potential risks. The efficacy of this dataset in mitigating harms will be further assessed in forthcoming studies through an adapted version tailored to evaluate the specific vulnerabilities and challenges posed by this chatbot.

5. Conclusion and Outlook

In summary, this investigation highlights a maintenance chatbot's significant efficiency over traditional systems in minimizing Mean Time to Repair (MTTR), thereby boosting operational efficiency and equipment effectiveness in manufacturing. Traditional NLP based systems show an improvement in MTTR of at least 20% in production environments, which is confirmed by preliminary investigations by (Ansari et al. 2023). Additionally independent studies on LLM based assistance systems (Noy und Zhang 2023) show even higher potentials in operational efficiency, well in line with the first tests of the detailed maintenance chatbot in the pilot factory use cases. Leveraging advanced NLP and machine learning, the chatbot surpasses conventional systems by integrating ERP data and identifying relationships for enhanced maintenance insights, significantly reducing cognitive load and stress.

Looking ahead, the scalability and generalizability of the maintenance chatbot are poised for improvement with the multi-agent systems, and causal AI. AutoGen frameworks (Wu et al. 2023) are anticipated to refine the chatbot's content generation and adaptation capabilities, enabling reciprocal learning. Multi-agent systems promise to distribute problem-solving tasks effectively, improving maintenance operations' efficiency. Meanwhile, causal AI could provide a deeper understanding of the complex causal relationships within maintenance data systems, offering more accurate step-by-step solutions.

Future directions indicate that maintenance chatbots could overcome current limitations and adapt across various manufacturing settings. This flexibility is key to meeting the

sector's varied needs, marking a significant advancement in CAS for maintenance. Driven by improvements in data integration, natural language processing, and causality understanding, this represents a crucial step in manufacturing's digital transformation.

ACKNOWLEDGEMENT

The authors would like to acknowledge the financial support of this research work by the Fraunhofer-Gesellschaft as part of the Fraunhofer flagship project EMOTION.

BIOGRAPHIES

L. Kohl, Dipl.-Ing., has been a research assistant at the Institute of Management Sciences at TU Wien and at Fraunhofer Austria Research GmbH in factory planning and production management since September 2019. At Fraunhofer Austria, Linus Kohl leads the group for production optimization and maintenance management. Mr. Kohl studied industrial engineering - mechanical engineering at TU Wien. His work focuses on maintenance - the data-driven analysis and optimization of machines and systems using AI-based assistance systems. Linus Kohl is largely responsible for establishing the areas of retrofitting, maintenance as a service and industrial cognitive system at Fraunhofer Austria.

P. Besinger joined Fraunhofer Austria Research GmbH in 2021 in the role of research assistant, working on the development, integration and operation of AI-based software at companies and the associated requirements engineering. He completed his aste r's de r ee in ind strial en ineerin - Machine Engineering at TU Wien in 2021. Mr. Besinger received three TU Wien merit-based scholarships from 2018 - 2021 for outstanding performance. He is particularly interested in the application as well as implementation of Responsible AI in an industrial context to strengthen trust in AI-models and minimize socially harmful impacts of AI-systems.

S. Eschenbacher S. Eschenbacher is currently pursuing a aster's de r ee in AI En i neerin at the n i er sit of Applied Sciences Technikum Wien. She joined Fraunhofer Austria GmbH in 2022. Her research interest lies in the application of LLM and multi agent frameworks and on how these technologies can be deployed in real-world production environments to drive innovation and support the digital transformation in the industry.

F. Ansari is full professor at TU Wien and chair of Production and Maintenance Management and at the same time he serves as the head of strategic projects at Fraunhofer Austria. He conducts interdisciplinary research at the intersection of AI, Industrial Engineering and Production Management, where maintenance plays a central role. His interdisciplinary background is underlined by a degree in mechatronics and a dissertation in computer science (summa cum laude) at the University of Siegen. With his international involvement in various scientific associations (IEEE, IFAC, IALF), as well as his habilitation in Industrial Engineering, entitled "Management of Knowledge Intelligence in Human-centered Cyber Physical Production Systems", Dr. Ansari has established his role as an important part of the international research community.

Leveraging Generative and Probabilistic Models for Diagnostics of Cyber-Physical Systems

ABSTRACT

A critical task for system operators is the precise identification of the root causes underlying an error situation. This identification is fundamental in deciding optimal maintenance actions, such as replacing a component versus calibrating it. However, the actual causes of an error are often neither measured nor unique. The measured quantities are the result of complex interactions between different error causes and system variables. Root cause identification in this context becomes a matter of inferring hidden causes from their measurable effects. This challenge is notably pronounced in cyber-physical systems comprising control loops. Control mechanisms, integral to maintaining system performance, introduce a layer of complexity in diagnostics and ultimately complicate the isolation of the underlying causes of errors. To address this challenge, we introduce a two-step approach to derive the hidden causes as a statistical inference task. First, we develop a generative model leveraging existing control software and expert-based insights into the mechanisms of errors, i.e., a simulator of synthetic data given some hidden error causes. Then, we transform the generative model into a probabilistic program on which statistical inference can be executed within a probabilistic programming language framework. This inference effectively estimates the hidden causes given some measured data from the system. Being intrinsically a statistical approach, these inferences come with a confidence interval. We applied this methodology to an industrial printer's sheet transport belt, operating in a closed-loop configuration. Our approach successfully discerned the contributions of three distinct hidden causes to the belt's deviation from its intended position. This paper highlights the efficacy of generative modeling followed by a probabilistic programming approach in unraveling complex interactions within cyber-physical systems for optimal maintenance.

1. INTRODUCTION

In order to match the increasing market demands on overall equipment effectiveness, industrial manufacturers of cyber-physical systems need efficient methods to diagnose system malfunctions. In practice, finding the root cause of such malfunctions is challenging for several reasons, ranging from technological to human and organizational ones.

On the technological side, the high demands on performance lead to increasingly complex systems with many intertwined control mechanisms that obscure the path from a root cause to its measurable effects (Borth & Barbini, 2019). The lack of direct observability for each cause of malfunctions forces the diagnostic to infer the many root causes from their effects on the few measured observables. Moreover, these observables are often not measured for diagnostic purposes but rather for control and performance ones, i.e. are indirect.

On the human and organizational side, the knowledge needed to solve difficult diagnostic cases is within the design and engineering departments, while the responsibility of offering diagnostic support lies on the service department (van Gerwen, Barbini, & Nägele, 2022). The transfer of the necessary knowledge is thus a difficult process that relies on expensive escalation-based approaches, i.e. design and engineering departments are called in by service to support the diagnostic reasoning. Finally, the struggle to timely train the service personnel capable of executing the needed diagnostic reasoning is a growing concern in the face of relentlessly increasing system complexity.

To tackle the points above we propose a method that focuses on two pillars. First, capture in models the knowledge of the system behavior, e.g. control loops, together with its failures. This should be done iteratively within the design and engineering departments, by incrementally incorporating knowledge on failures occurring in the field. Second, support the diagnostic reasoning process by performing statistical inference on the above models together with data from an error situation in the field, inferring the hidden causes of errors in

a Bayesian way. This is the contribution of this methodology to the service department.

The rationale behind the proposed approach is that humans have the knowledge and the inclination to reason *forward*, i.e. in a simulation-like manner from the causes of a failure towards the resulting effects. Many such simulation models are readily available in industrial companies. Conversely, it is more challenging for humans to perform *inverse* diagnostic reasoning from the effects towards the causes: they need computational support to do so. In this paper we leverage the available system expertise and modeling capabilities of humans, with statistical inference tools to achieve diagnostic reasoning support.

The remainder of the paper is organized as follows: below we give an overview of the relevant literature. In Section 3 we introduce the details of our approach. In Section 4 we first apply our methodology to synthetic data and then to real data from an industrial system, finally we conclude our paper and give directions for future research in Section 5.

2. Literature review

The proposed method has its foundations in model-based diagnostics (De Kleer & Kurien, 2003) and specifically in its probabilistic implementation with Bayesian networks (Lucas, 2001; Srinivas, 1995). In this context, Bayesian networks, a type of probabilistic graphical model, are used to infer the likelihood of causes based on observed data via Bayes' theorem. The quantity of interest for the diagnosis is the posterior probability of cause C given observations O, computed as $P(C|O) = P(O|C) \cdot P(C)/P(O)$.

The present paper extends the previous work in two directions. First, we model and reason with continuous random variables, rather than discrete. This is fundamental when tackling performance issues, i.e. scenarios where the system's components are not described by a neat dichotomy of states, such as *normal* or *abnormal*, but rather sit in a continuous spectrum of states. Second, we model and reason on dynamic processes rather than on static ones. This is needed when diagnosing systems with feedback control loops and when the cause of failures shows a time-dependent behavior. In the literature, such systems are often modeled with dynamic Bayesian networks (Bartram & Mahadevan, 2015), but this is cumbersome and very quickly results in very large models, so we propose a different approach.

In this paper, we perform statistical inference on dynamic models with continuous random variables by using a probabilistic programming paradigm (van de Meent, Paige, Yang, & Wood, 2018). The proposed probabilistic programming approach can be seen as a generalization of Bayesian filtering and smoothing methods (Särkkä & Svensson, 2023) such as Kalman filters and particle filters. Several methods have been introduced in the probabilistic programming literature to perform such statistical inference, sampling-based methods like Markov chain Monte Carlo (van de Meent et al., 2018), gradient based methods (Kucukelbir, Tran, Ranganath, Gelman, & Blei, 2017) and analytic methods like message passing (Cox, van de Laar, & de Vries, 2019), or combinations thereof (Cox et al., 2019). In this paper we rely on Markov chain Monte Carlo using the Python library Numpyro (Phan, Pradhan, & Jankowiak, 2019). The proposed methodology makes use of simulation models to generate synthetic data for validation and fine-tuning of the inference models. The use of synthetic data has been explored before in other fields, see (Tremblay et al., 2018) on the use of synthetic data in deep learning, and (Cranmer, Brehmer, & Louppe, 2020) for a discussion on the use of simulation for inference.

3. Methodology

Our methodology is schematically represented in Figure 1. It uses two models, *simulation* and *inference*, and develops in three phases, *creation, validation* and *usage* phases. These are represented with different colors in the figure; orange, blue and green, respectively.

In the *creation* phase, we first compile a *simulation* model using knowledge of the system, thus re-using already available control models, and augmenting these with (conjectured) models of failure mechanisms. The latter heavily relies on expert knowledge based on historical failures. The *simulation model* outputs synthetic data given a single or a combination of failure mechanisms. The *simulation model* is then transformed into an *inference model*. This transformation is not computational, i.e. it requires additional modeling. For example, some aspects of the simulation might be deemed irrelevant or negligible and dropped from the inference. Further, one could decide to decompose a single *simulation model* into multiple *inference models*. We will return to this in Section 4.2.

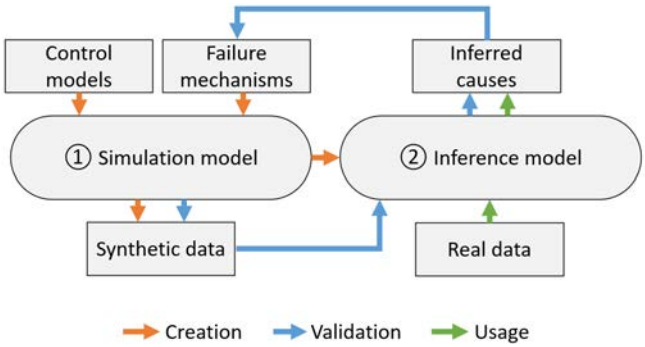

Figure 1. Schematic representation of the proposed methodology

In the *validation* phase, the goal is to verify that the constructed inference model indeed provides an inverse to the

data generation process. We do so by testing whether the model can correctly infer the hidden causes of failures in synthetic data generated in simulation models. We repeat this for different types and combinations of failures.

Finally, in the *usage* phase, we use the *inference model* on the real data coming from a system in the field to infer the hidden causes of failures. The optimal service action, e.g. part replacement versus cleaning, is then decided based on these inferred causes.

4. APPLICATION

We apply the proposed methodology to a subsystem of a Canon Production Printing (CPP) industrial printer. This subsystem contains a conveyor belt that rests horizontally on two cylinders. The cylinders rotate at a variable speed and transmit this movement to the belt. For this subsystem, it is required that the belt is at the center of both cylinders, perpendicular to the directions of its movement. To fulfill this requirement, one of the cylinders can be tilted by raising or lowering it. The mechanism responsible for this tilting is driven by a motor. In the remainder of this paper, we will refer to it as the Z-position motor. This tilting causes the belt to slide up or down the cylinder each revolution by an amount proportional to the Z-motor position. Every few revolutions the position of the belt is measured and a correction is computed by a Proportional Integral (PI) controller, resulting in an adjustment of the Z-motor position. This steering action is necessary to counter the various causes that make the belt drift away from its intended position.

Our goal here is to discern the unknown causes of this drift and to infer their strength, given the available data on the belt and motor positions over time. This is crucial from a maintenance perspective, to define the best service action in those cases in which, despite the control mechanism, the belt goes out of its intended position. Following our methodology, we first make a model relating the known, i.e. measured, and the unknown variables of this system. Then we conjecture the functional form of the unknown variables to create a complete simulation model. In the next Section, we use the equations of the PI-controller for the former and expert knowledge for the latter.

4.1. Simulation model

Every step of the PI-controller begins with a measurement of the belt position. This belt position must be a function of the previous belt position, the previous motor correction, and the drift incurred between the current measurement and the previous one. Based on the current positions of both the belt and Z-motor, the position of the latter is updated by a PI controller with the goal of returning the belt to its intended position. The equations modeling this behavior are:

$$\begin{cases} \mathsf{belt}_k = & \mathsf{belt}_{k-1} - \alpha \cdot \mathsf{motor}_{k-1} + \mathsf{drift}_k \\ \mathsf{integral}_k = & c_{int}(\mathsf{belt}_k + \mathsf{belt}_{k-1}) + \mathsf{integral}_{k-1} \\ \mathsf{motor}_k = & c_{prop}\mathsf{belt}_k + \mathsf{integral}_k \end{cases} \quad (1)$$

Where α, c_{int}, and c_{prop} are known proportionality constants and subscripts $(\cdot)_k$ corresponds to the value at sample k. All three quantities are measured. Notice that in Equation (1) the last 2 equations are taken directly from the implementation of the controller.

Not contained in these equations is the condition that the steering motor stays within a bounded range. If the necessary correction is outside these bounds, the motor will stay at the limit of its range, causing the belt to drift outside of its desired position. Throughout this paper, we assume that the motor and the belt position sensor never fail. This assumption can be relaxed, if necessary, and the proposed methodology can still be applied.

In Equation (1) the drift can be computed at all times since it is a function of the belt and motor positions, both measured. What remains unknown are the different error mechanisms and how they add up to the total drift. For this, we use expert knowledge.

We conjecture that the drift results from the linear combination of five causes:

- Calibration: the belt might not be completely horizontal when the Z-motor is at position 0. This results in a constant calibration error c.
- Misalignment: the belt might not be well aligned with the previous component of the printer, which results in pages coming into the belt with a lateral velocity relative to the direction of motion of the belt, causing drag to one side. This results in a constant misalignment error m that is present only when the machine is printing.
- Degradation: the belt material might wear out and deform over time, resulting in a time-dependent drift D_k. We conjecture this degradation to be exponential and with an unknown deformation direction.
- Sheets: when the pages make contact with the belt, they might cause a perturbation to its position, depending on the properties of the pages. This would result in a train of pulses P_k with varying amplitude and width, present only when the machine is printing.
- Noise: we finally conjecture that all other sources of error add up to a Gaussian term $\varepsilon_k \sim \mathcal{N}(0, \sigma)$ with unknown variance and zero mean.

These causes are described by the following equations:

$$\mathsf{drift}_k = c + \mathsf{print}_k(m + P_k) + D_k + \varepsilon_k \quad (2)$$

$$D_k = s(4^{\delta k} - 1) \quad (3)$$

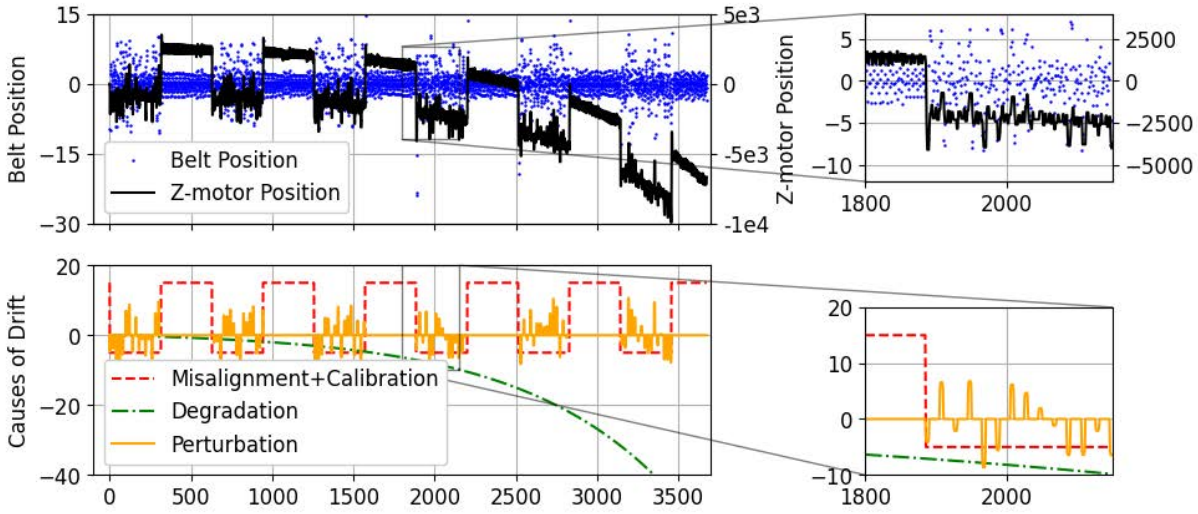

Figure 2. Example synthetic data produced with the simulation model. Observe how the motor displacement follows the sum of the three hidden contributors to the belt drift. See main text for a detailed explanation.

In equations (2,3) we can see the decomposition of the drift into its different terms, with the conjectured form of the degradation as being an exponential with exponent parameter $\delta \geq 0$ and sign $s \in \{-1, 1\}$. print_k is the variable that represents whether the machine is printing and takes values in $\{0, 1\}$. The variables c, m, D_k and P_k in Equation (2) are unknown, while print_k and drift_k are known quantities. In the interest of brevity, we have not included here the detailed equations of the perturbation term P_k.

Considered together, equations (1,2,3) describe a model of the system. The model has been implemented in Python, allowing us to compute simulations such as the one shown in Figure 2. The first author can provide the code if needed to an interested reader.

In the top plot of the figure, we represent the observable time series belt_k and motor_k from Equation (1) in a double-axis, left for the belt and right for the Z-motor. Observe the different units for each time series. We can see that the (simulated) PI-controller is capable of keeping the system controlled in the presence of the Drift causes, shown in the plot below, as evidenced by the belt position remaining stable around 0. It does this by adjusting the Z-motor position. Eventually, the Z-motor will hit its limit, after which the position of the belt quickly drifts away from its intended position (not shown in the plot). In the bottom plot, we show the different contributors to the drift of the belt, for simplicity of visualization we have combined calibration and misalignment in a single one.

4.2. Inference model

The next step in our methodology is to translate the simulation model into a probabilistic model suitable for inference. In such a model, one describes the unknown variables of the simulation as hidden, i.e. unobserved, random variables. Then one describes the known, i.e. observable, variables as functions of the unknown variables, therefore random variables themselves, but which are observed. These functions relating observable and hidden variables can be: probabilistic (e.g. perturbation), or deterministic (e.g. degradation as a function of s and δ), and need not be invertible. The task of these models is to infer the probability distributions of the hidden random variables that best *explain* the observations. We use the framework of probabilistic programming to instantiate these models and perform inference. Numpyro, see (Phan et al., 2019), is the probabilistic programming language of choice for this work.

Considering the temporal nature of our data and the controlled step-wise nature of the system, we propose a Bayesian state-space model as the probabilistic description. A Bayesian state-space model is a dynamical system of equations relating random variables. The system is determined by the observability and update equations. The observability equation (4) connects the vector of observed variables $\vec{y}_k$ at time k to the vector of hidden variables $\vec{\theta}_k$, external observable variables $\vec{x}_k$ and noise term $\vec{\varepsilon}_k$. The update equation (5) connects the vector of hidden variables at time k with the vector of hidden variables at time $k-1$ and the update noise $\vec{\eta}_k$. Together, they define the system:

$$\vec{y}_k = \mathbf{A}_k\vec{\theta}_k + \mathbf{B}_k \cdot \vec{x}_k + \vec{\varepsilon}_k. \quad (4)$$

$$\vec{\theta}_k = \mathbf{G}_k \cdot \vec{\theta}_{k-1} + \vec{\eta}_k, \quad (5)$$

Where $\mathbf{A_k}$ and $\mathbf{B_k}$ are matrices, $\vec{\varepsilon}_k$ is the observation noise vector at time t, $\mathbf{G_k}$ is often called the innovation or transition matrix at time k and $\vec{\eta}_k$ is the update noise. For this system to be fully Bayesian, we can treat the matrices $\mathbf{A_k}$, $\mathbf{B_k}$,

and $\mathbf{G_k}$, or their coefficients, as random variables themselves and give them Bayesian priors. The equations of a Bayesian state space model describe the evolution of the hidden and observed variables, but not the evolution of their probability distributions. That is the task that the probabilistic program computes in the background.

The translation from a simulation model like that described by equations (1,2,3) into a Bayesian state-space model is not unique and need not be 1-to-1. For instance, the modeler is free to leave elements of the simulation model out of the inference model, implicitly leaving them as contributions to the noise term. They are also free to choose which unknown variables in the simulation model should be mapped to hidden variables in the Bayesian state space model and which should be expressed as coefficients of the matrices $\mathbf{A_k}$, $\mathbf{B_k}$, and $\mathbf{G_k}$, which are treated as static random variables.

For our conveyor belt, we have only one observed variable, $y_k := \mathsf{drift}_k$. The parameters of the model are defined as

$$\mathbf{A} := [1, 0], \quad \mathbf{B} := [c, m], \tag{6}$$

$$\mathbf{G}_k := \begin{bmatrix} 4^\delta & s \cdot 4^\delta - 1 \\ 0 & 1 \end{bmatrix}. \tag{7}$$

The external variables are $\vec{x}_k = [1, \mathsf{print}_k]$, the hidden variables are $\vec{\theta}_k = [D_k, 1]$ and the noise terms are $\varepsilon_k \sim \mathcal{N}(0, \sigma)$ and $\eta_k := 0$.

For simplicity, we choose not to model perturbation P_k explicitly and let it be absorbed by the noise term ε_k. To make this model fully Bayesian, we assign prior distributions to the random variables c, m, δ, s, and σ. We choose uninformative uniform distributions in the interval $[-80, 80]$ for c, m (the whole range of the belt), a wide uniform distributions in $[0, 0.5]$ for δ, uniform 50% prior for each value of s, and a half-normal distribution with width 1 for σ. The ranges of these priors are chosen by domain experts to encompass all plausible failure configurations.

Once we have expressed the model in this form, the probabilistic programming language performs inference by approximating the joint probability distribution of the hidden and observable variables given a particular observation, and applying Bayes rule. Table 1 shows the result of performing inference on the synthetic dataset from Figure 2. Observe how the inferred values for degradation, calibration and misalignment match their real values.

We conclude that the different causes of drift can be inferred from the synthetic data. This gives us reason to believe that, as long as the data from the real system is sufficiently approximated by the simulation model, the inference can also be performed on the real data. This will be shown in the next section.

Table 1. Inferred values for the different sources of drift considered. Errors express a 2-σ confidence interval.

Parameter	Real value	Inferred value
c	15.00	15.02 ± 0.18
m	-20.00	-20.02 ± 0.20
δ	$8.00\,e^{-4}$	$8.00e^{-4} \pm 7e^{-6}$
s	1.00	1.00 ± 0.00

4.3. Results

Given the long service life of the belts, we adapted the inference procedure to better fit the diagnostic needs in the field by inferring the state of the belt at regular intervals. This allows us to track the state of the machine over time. Algorithm 1 outlines the procedure for this periodic computation of degradation, calibration and misalignment given a stream of field data that is split into periods. For each period, the inference engine takes as input the estimated degradation at the beginning of the period, infers the calibration, misalignment and decay exponent, then computes the additional degradation corresponding to that period, and passes the latter to the next iteration.

Algorithm 1 Iterative belt drift inference

```
Data ← [period_1, ..., period_n]
params ← []
prev_D ← 0
for period in Data do
    (c, m, δ, s) ← InferParams(period, prev_D)
    D ← CompDegradation(period, δ, s, prev_D)
    prev_D ← D
    params.append([c, m, δ, s, D])
end for
return params
```

The probabilistic programming comes into play in this algorithm when $params[i] = [c^{(i)}, m^{(i)}, \delta^{(i)}, D^{(i)}]$, the inferred parameters for period i, are treated as probability distributions, rather than point estimates. Inferring these distributions is done through the use of Markov Chain Monte Carlo methods for approximating a total probability distribution. The posterior probability conditioned on the observed data is computed via the Bayes-Laplace rule, rather than a standard parameter fitting technique like minimum square error. This is all handled in the background by the probabilistic programming library and implemented via the function $InferParams$ in the algorithm.

To compute the additional degradation in a given period we modify our hypothesis for the degradation (see eq. (3)) to allow for varying decay exponents over the different periods.

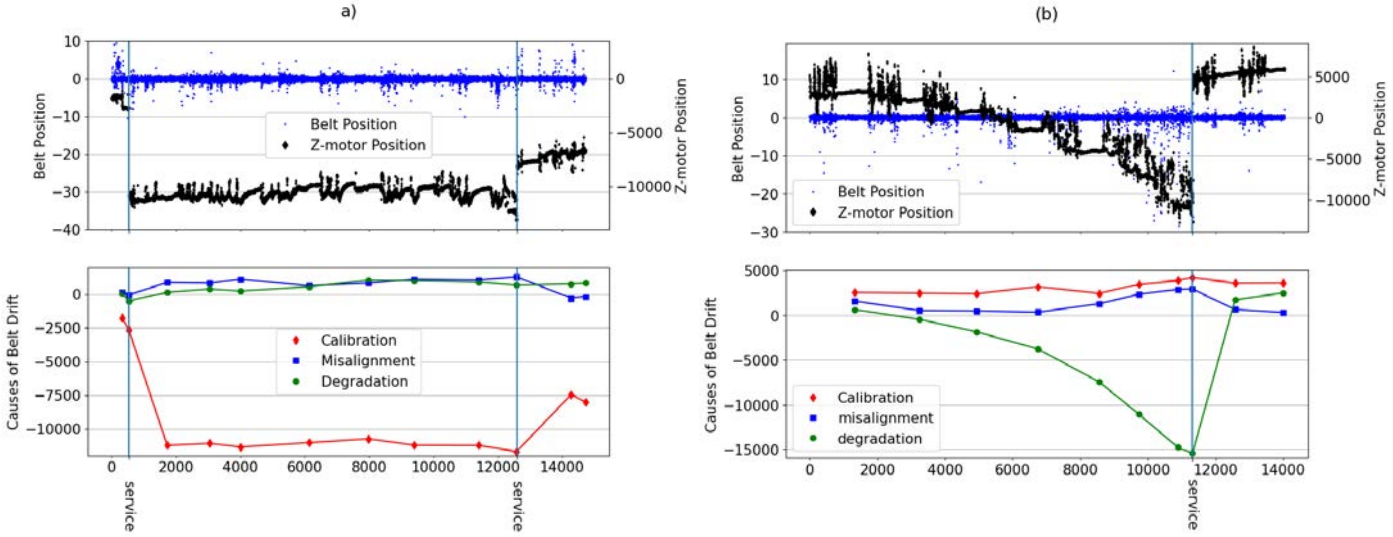

Figure 3. Example of measured data where miscalibration (a), and degradation (b) are the main causes of a belt position error. The Belt and Z-motor positions are measured, while the causes of belt drift in the bottom plots are inferred. The sources of drift are shown here in the units of the Z-position motor rather than the belt for comparison with the former.

We assume that degradation in period i follows the equations:

$$D_k^{(i)} = s \cdot 4^{\delta^{(i)} k} + \mathcal{C}^{(i)}, \quad (8)$$

$$\mathcal{C}^{(i)} = prev_D - s \cdot 4^{\delta^{(i)} k_{i-1}}, \quad (9)$$

where $prev_D = D^{(i-1)} = D_{k_{i-1}}^{(i-1)}$ is the computed degradation at the end of period $i-1$, k_{i-1} is the step that marks the end of period $i-1$, and $\delta^{(i)}$ is the computed decay exponent in period i output by $InferParams$. This condition ensures that degradation grows exponentially and that degradation at the beginning of one period is equal to degradation at the end of the previous period, i.e. it ensures continuity. The computed degradation at the end of period i is then $D^{(i)} := D_{k_i}^{(i)}$.

In Figure 3 we apply the procedure to two typical examples from the field of belts where excessive degradation or miscalibration are the cause of a service action by a service engineer.

Although Figure 3 shows the average degradation, misalignment and miscalibration for each period, we also compute posterior distributions for each parameter, alongside a noise parameter for each period, not shown in the plot. Observe how the three different causes of drift are correctly discriminated and tracked over time. Equipped with these results, a service engineer would perform a replacement of the belt in Figure 3-(b) and a re-calibration of the belt in Figure 3-(a), a much less material and time-consuming action.

5. Conclusions

In this paper, we proposed a methodology for model-based diagnostics of cyber-physical systems leveraging generative and inference models. The generative model is compiled using already available knowledge on failure mechanisms, together with control models, and serves a dual function. On the one hand, it helps validate the expert knowledge on failures, by comparing the results of simulations to data from incidents in the field. On the other hand, it is used to validate the inference models by providing us with a controlled test bench in which to test the ability of the inference model to distinguish the different causes of errors. The inference model is derived from the generative model and is used with field data from real incidents to perform root-cause diagnosis.

We then applied our methodology to the case of an industrial conveyor belt in a closed control loop configuration, with several hidden mechanisms driving the belt out of its desired position. With the proposed methodology we correctly identify the different causes of drift of the belt, thus offering valuable advice for the optimal maintenance action.

To the authors' knowledge, this is the first time probabilistic programming has been used for diagnostics of cyber-physical systems. We believe the present paper proves its utility as a tool for probabilistic modeling and inference in the prognostic and health management domain, opening the door to model-driven and physics-inspired diagnostics. In applying the proposed methodology to the case of an industrial conveyor belt we have identified several aspects for future research. The probabilistic programming framework has a prediction functionality that could be used to make prognostic forecasts of remaining useful life. In future research, we plan on adding this aspect to our methodology. Further, the translation of generative models into inference models is a manual process requiring a certain degree of familiarity with inference and statistical modeling. How to automate, fully or

partially, the translation from simulation to inference models remains an open question. Finally, the proposed methodology has been scoped and tested at a subsystem level, comprising a belt, motor, and control mechanism. How to make such models composable and much larger for system-level diagnosis remains a challenge to be addressed in future research.

ACKNOWLEDGMENT

The research is carried out as part of the Carefree program under the responsibility of TNO-ESI in cooperation with Canon Production Printing. The research activities are supported by the Netherlands Ministry of Economic Affairs and Climate, and TKI-HTSM.

The authors would like to thank Robert Passmann and Peter Kruizinga for providing valuable discussions and comments.

ABSTRACT

Predictive maintenance deals with the timely replacement of industrial components relatively to their failure. It allows to prevent shutdowns as in reactive maintenance and reduces the costs compared to preventive maintenance. As a consequence, Remaining Useful Life (RUL) prediction of industrial components has become a key challenge for condition based monitoring. In many applications, in particular those for which preventive maintenance is the general rule, the prediction problem is made harder by the rarity of failing instances. Indeed, the interruption of data acquisition before the occurrence of the event of interest leads to right censored data. There are few articles in the literature that take that phenomenon into account for RUL prediction, even though it is common in the industrial environment to have a high rate of censored data.

The present article proposes a deep-learning approach based on multi-sensor time series which allows to consider censored data during the training of the neural networks. Two methods are proposed, respectively based on the Dual Aspect Self-Attention based on Transformer proposed by (Z. Zhang, Song, & Li, 2022) for non-censored data and on a recurrent neural network. Their evaluation on the C-MAPSS benchmark dataset shows, compared to the state-of-the-art RUL prediction methods, no loss in the absence of censoring, and outperformance on censored data.

1. INTRODUCTION

Technology and electronic developments of sensors nowadays allow the collection of huge amounts of data on mechanical and industrial equipment, in particular time series measuring their evolution over time. The definition of the maintenance schedule, which is crucial for the industry, therefore shifts to predictive, or condition-based maintenance (CBM). The latter is defined by opposition to the historical preventive maintenance, for which the maintenance schedule is pre-defined, each component being replaced at fixed time intervals. CBM avoids replacement of healthy components, and therefore reduces costs, by determining a dynamic schedule depending on the real-time monitoring of the system. A crucial step is therefore the estimation, given the actual status of the system, of the Remaining Useful Lifetime (RUL) of a component, that is the time before its failure.

Several approaches exist to create CBM models for RUL estimation (Arena, Collotta, Luca, Ruggieri, & Termine, 2021), most of them being model-based methods, data-driven methods or hybridisation of those approaches.

Model-based methods consider the physical phenomenon, for instance corrosion or fatigue, that leads to the failure. A mathematical model is used to simulate the studied mechanism and to get a RUL prediction (Tinga & Loendersloot, 2019). A precise physical and mechanical knowledge is however needed to build physical-based models. Moreover, this approach results in highly complex models when applied to large scale industrial systems composed with a lot of subsystems.

Data-driven methods regroup approaches that rely on stochas-

tic models or statistical analysis to create fault detection models not directly mimicking the underlying physics. It may consist in statistical algorithms to diagnose battery fault (Y. Zhao, Liu, Wang, & Hong, 2017), stochastic processes to mimic the degradation processes (Garay & Diedrich, 2019) or evolving fuzzy models for semiconductor health management (Boutrous, Bessa, Puig, Nejjari, & Palhares, 2022).

Data-driven methods include machine learning algorithms, which have been extensively used by the Prediction and Health Management community to establish predictive maintenance rules. Multiple linear regression durability models were for instance used to predict the fatigue life of automotive coil (Kong, Abdullah, Schramm, Omar, & Haris, 2019), or SVM classifiers for fault detection in vehicle suspensions (Jeong & Choi, 2019). In (Vasavi, Aswarth, Pavan, & Gokhale, 2021), a kNN classifier is used to detect fault by predicting vehicle health using real time data, while (Patil et al., 2018) relies on decision trees and gradient boosting regressor for RUL prediction.

Deep learning, like machine learning methods, allow to have no physical or mechanical knowledge of the studied system. In recent years, numerous articles have demonstrated the effectiveness of those methods for RUL prediction. The data at hand being mainly time series, the developed methods focus on architectures widely used to treat sequential data. Recurrent neural networks like Long-short-time-memory (LSTM) (Zheng, Ristovski, Farahat, & Gupta, 2017), or Convolutional neural network (CNN) (Sateesh Babu, Zhao, & Li, 2016) and recently Transformers (Z. Zhang et al., 2022), which were adapted from the original Transformer architecture (Vaswani et al., 2017) to deal with time series are popular method used to perform RUL predictions.

The presence of right-censored data is an important issue in many real-life industrial applications, which is not taken into account by most methods. Indeed, when the current policy on the field application is predictive maintenance, equipment's are renewed before failure, leading to numerous time-series in the dataset for which the RUL is unknown. One way to deal with such data is to use the survival approach based on Cox models that has been successfully transposed from medical analysis to maintenance analysis (Chen et al., 2020; Yang, Kanniainen, Krogerus, & Emmert-Streib, 2022). An alternative is the ordinal regression (OR) approach where the RUL prediction is replaced by a vector of predictions encoding the failure time (Vishnu, Malhotra, Vig, & Shroff, 2019).

The present paper deals with a new deep-learning method based on ordinal regression to predict RUL on censored data. It relies on two main contributions regarding the state of the art. Firstly, the DAST model (Z. Zhang et al., 2022) based on Transformers is adapted to an ordinal regression framework. Secondly, it is put onto competition with an improved of the LSTM-OR model (Vishnu et al., 2019) to obtain the final prediction rule.

To illustrate its performance, the proposed method is run on the C-MAPSS Turbofan NASA benchmark dataset, and compared to state-of-the-art methods, able to consider censored data or not. The benchmark dataset is being characterized by the absence of censor, the latter is artificially introduced at various levels. The proposed method is comparable to the best methods on non-censored data and better when a significant amount of data is censored.

2. Related Work

As stated in the introduction, the aim of this study is to consider the RUL prediction problem when the learning dataset is right-censored. That situation is common in applications, as such a censoring corresponds to components changed before the failure. This section introduces the main ideas of the DAST (Z. Zhang et al., 2022) and LSTM-OR (Vishnu et al., 2019) architectures, and then builds upon those ideas to propose a novel method for RUL estimation on censored data.

Beforehand, let us introduce the notations which will be used throughout the paper.

For a given unit, we denote by:

- $\mathrm{T}^\star$ the time of failure,
- C the censoring time if relevant, that is if the unit is replaced before failure,
- $\mathrm{T} = \min(\mathrm{C}, \mathrm{T}^\star)$ the observed time of replacement,
- X the time series of the p sensors data, $x_{k,t}$ being the measure of sensor k at time t,
- Z the optional of vector covariates, that is characteristics of the unit which are not varying with time.

Let us fix a maximum value R_{max} for the RUL estimation, which is standard procedure (Heimes, 2008; H. Li, Zhao, Zhang, & Zio, 2020) and is relevant for the applications, as it focuses on the precision of the method on the period preceding the failure. At a given time point t, we then define the lifetime to predict by

$$\mathrm{R}_t = \min(\mathrm{T}^\star - t, \mathrm{R}_{max})$$

Note that this lifetime is observed in the training set only when $\mathrm{T}^\star = \mathrm{T}$. If not, the only available information is that $\mathrm{R}_t \geq \min(\mathrm{C} - t, \mathrm{R}_{max})$.

All the variables in that section are in fact indexed by the number i of the considered unit, for instance when computing a loss. That index is omitted unless necessary for reading purposes.

2.1. Dual Aspect Self-Attention based on Transformer (DA-ST)

The DAST model is an encoder-decoder, with the specificity of a double encoding, using a time step encoder and the sensor encoder.

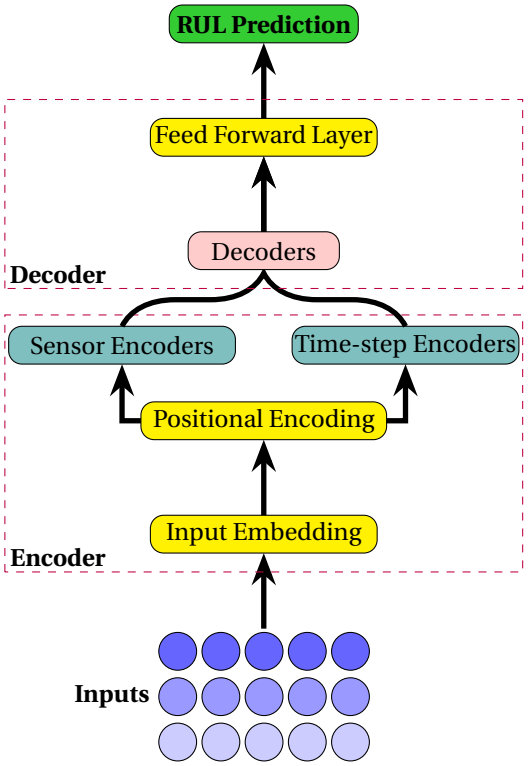

Figure 1. Original DAST architecture (Z. Zhang et al., 2022)

The input data of the DAST architecture consists in a decomposition of the times series X by a sliding window processing of width W, as shown in Figure 2. The input is thus a list of matrices (X_t), each of size (p, W):

$$X_t = \begin{pmatrix} x_{1,t} & \cdots & x_{1,t+W} \\ \vdots & \ldots & \vdots \\ x_{p,t} & \cdots & x_{p,t+W} \end{pmatrix} \quad (1)$$

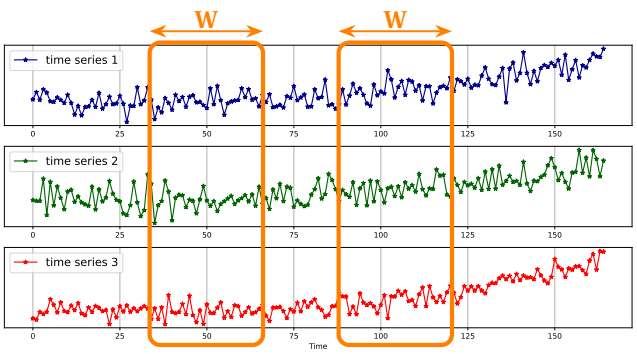

Figure 2. Example of sliding window of size W for time-series on 3 sensors

The data of each window are normalized to equalize the amplitude for each sensor and completed with positional encoding to keep track of the relative time positions of the columns as well as constant lines corresponding to the covariates Z. It is also enriched for each sensor by the mean value and the slope of the linear regression as a function of time, as proposed in (Song et al., 2020).

The originality of DAST is to consider these inputs in two dimensions. On the one hand, the enriched matrix X_t is given as input of the time step encoder, which encodes through self-attention scores per time point the dependency between the vectors of data at different time points. On the other hand, its transpose X_t^T is given as input to the sensor encoder which uses the same architecture to encode and capture the dependency information between the sensors. A final fusion layer finally allows to mix both encodings into a final one, which contains the importance of different combinations of sensors and time steps at the same time. That information is valuable in the context of RUL estimation and is processed by the decoder part of the architecture to obtain a prediction.

As the prediction is a scalar corresponding to $\hat{R}_t$, the model is trained using a RMSE loss, that is the square root of the mean squared prediction error when summing over all units i and time points t.

2.2. Ordinal Regression for RUL Estimation with censored data

In various applications, the complete lifetime of the units is not systematically available as the components may be changed before failure, leading to right-censored lifetime. Direct RUL estimation requires the complete lifetime of the components in the learning data set and thus discards such data, which may represent most of the available data. One possible method to integrate both right-censored and uncensored lifetime data, is the ordinal regression approach developed in (Vishnu et al., 2019).

The key idea is to discretize the object to be estimated, by replacing the RUL $R_t^\star$ by a binary vector of the component status in the future. To do so, two integers L and K are fixed and the status of the unit is checked one time every L cycles (or time points in the time series). The new target is then a vector Y_t of length K where

$$y_{t,k} = \begin{cases} 0 & \text{if} \quad T > t + kL, \\ & \text{i.e. the unit is healthy after } k * L \text{ cycles}, \\ 1 & \text{if} \quad T \leq t + kL \quad \text{and} \quad T = T^\star, \\ & \text{i.e. the unit has failed before } k * L \text{ cycles}, \\ - & \text{if} \quad T \leq t + kL \quad \text{and} \quad T = C, \\ & \text{i.e. the unit status is unknown after } k * L \text{ cycles} \end{cases}$$

t is the time of the current time step and k is the index of Y_t.

Let us for example consider L = 10 and K = 10:

- if the component fails after 75 cycles, $Y_t = (0,0,0,0,0,0,0,0,1,1,1)$,
- if the component is replaced after 75 cycles but before failure $Y_t = (0,0,0,0,0,0,0,0,-,-,-)$. The last three elements are masked as no status appropriate for learning is available.

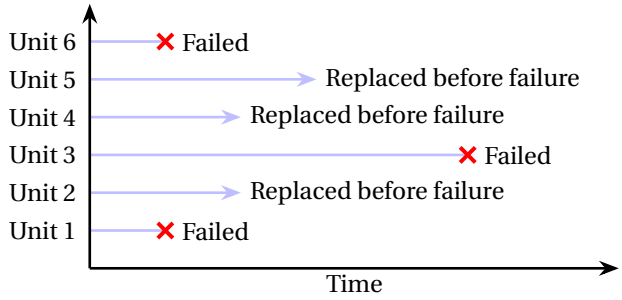

Figure 3. Right-censored data: unit 2, 4 and 5 are censored to the right, they were still healthy when replaced

A learning phase applied on the binary vectors of the training set allows then to obtain a prediction rule, as initially proposed using an LSTM architecture (Vishnu et al., 2019). The prediction for a given unit at time t, denoted by $\hat{Y}_t$, is a vector of K probabilities indicating the probability of failure before the corresponding time steps.

As the problem has become a binary classification problem, the learning is done using the binary cross-entropy (BCELoss). It is however adjusted for right-censored data by discarding all coordinates equal to - in the Y vectors. For example, if $Y_t = (0,0,0,0,0,0,0,0,-,-,-)$, its contribution to the loss is only computed on the seven first coordinates. In other terms, the loss is the sum over all units i and times t of

$$\mathrm{BCE}(Y_t, \hat{Y}_t) = -\sum_{k=1}^{K} \left(y_{t,k} log(\hat{y}_{t,k}) + (1 - y_{t,k}) log(1 - \hat{y}_{t,k}) \right) \tag{2}$$

where the term in the sum is set to 0 whenever $y_{t,k}$ is masked.

2.3. The proposed method

We consider a framework to deal with censored data using the OR encoding with the following step:

1. Adapt the DAST architecture to the OR framework by adding a sigmoid layer, leading to the **DAST-OR** architecture. After training, it outputs a vector $(\hat{Y}_t)$ of length K for every time point in a time series.
2. Following (Chaoub, Voisin, Cerisara, & Iung, 2021) which studies LSTM for RUL prediction, a feed-forward-layer is added in the LSTM-OR architecture, between the LSTM and the sigmoid output layer.This model is denoted as **LSTM-MLP-OR**. It outputs an alternative vector $(\hat{Y}_t)$ of length K for every time point in a time series.
3. Map every vector $\hat{Y}_t$ into a predicted RUL $\hat{R}_t$, following (Vishnu et al., 2019):

$$\hat{R}_t = R_{max}(1 - \frac{1}{K}\sum_{k=1}^{K} \hat{y}_{t,k}) \tag{3}$$

with $R_{max} = KL$ being chosen as the length of the time interval covered by $\hat{Y}_t$.

4. Select the best model in terms of RMSE loss of this RUL prediction on the validation data.

Note that the RUL estimation introduced step 3 is of practical use, but also allows comparison with methods in the literature estimating directly the RUL.

Moreover, to reduce randomness, 10 train of each model are performed, leading to two options:

1. **The simple model:** The model with the best loss on the validation dataset is chosen.
2. **The ensemble model:** We consider an ensemble of models, the final prediction corresponding to the average prediction of the 6 best models among the 10 models trained.

3. Experimental Evaluation

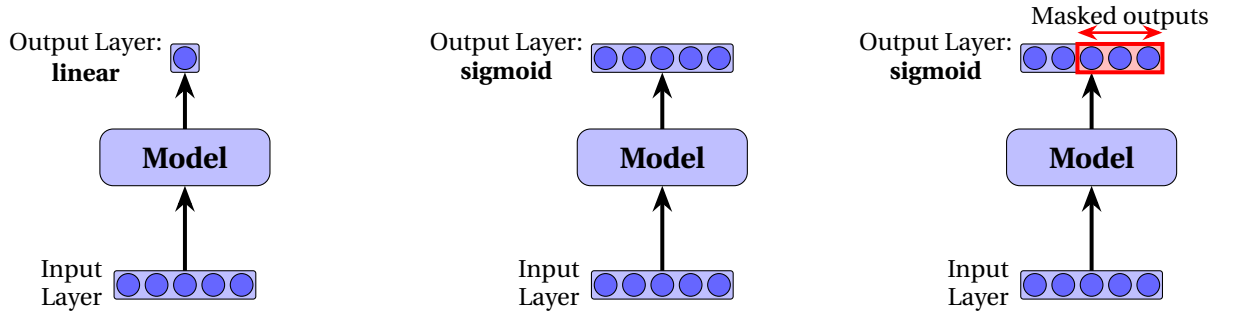
3.1. The CMAPSS dataset

The performance of the proposed method is evaluated on the **C-MAPSS** (Commercial Modular Aero Propulsion System Simulation) dataset, which is used as a benchmark for RUL estimation methods. It simulates run-to-failure trajectories of turbofan engines (Saxena, Goebel, Simon, & Eklund, 2008) in two different operating conditions and two failure modes, leading to four sub-datasets FD001, FD002, FD003 and FD004. The characteristics of the four sets are summarized in Table 1. Each trajectory contains the following variables:

1. a unit number corresponding to the component identifier,
2. a time variable corresponding to the number of cycles performed,
3. the simulation parameters (operating condition and failure modes),
4. the simulated data from 21 sensors.

Table 1. Summary of C-MAPSS dataset

C-MAPSS sub-datasets	FD001	FD002	FD003	FD004
Train trajectories	100	260	100	249
Test trajectories	100	259	100	248
Operating condition	1	6	1	6
Fault modes	1	1	2	2



(a) Metric regression (b) Ordinal regression (c) Ordinal regression with censored data

Figure 4. Metric regression compared to ordinal regression

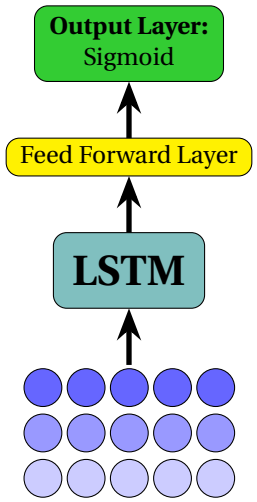


Figure 5. LSTM-MLP-OR architecture

3.2. Data preprocessing and censoring

Sensors having a constant value during the experiment are removed, leaving 14 sensors for datasets FD001 and FD003, and 21 for datasets FD002 and FD004. Data standardization is processed on the remaining sensors by removing the mean and scaling by standard deviation.

Right-censoring is artificially added to the data, with rates $p_c \in [0\%, 20\%, 50\%, 70\%, 90\%]$. More precisely, for every censor rate p_c, the corresponding fraction of the units are randomly chosen, and, for each selected unit, the time series are truncated prior to failure at a random moment. When $p_c = 90\%$, it leads to a train set where only 10% of the units have a known RUL, and approximately 45% of the initial data is kept.

Finally, to be able to chose the best models during the training, each sub-dataset is divided into a training set and a validation set, 20% of randomly chosen units joining the validation set.

3.3. Trained models

Three architectures are trained on the four datasets of the CMAPSS data:

1. **DAST for RUL** (Z. Zhang et al., 2022),
2. **LSTM-MLP-OR**,
3. **DAST-OR**.

Moreover, each of them are trained ten times, and those results are used to derive a single and an ensemble model for each architecture. Ensemble models are denoted with the addition of a final E, for instance DAST-ORE for the ensemble version of DAST-OR.

We also consider the model **BEST-ORE** which is chosen between DAST-ORE and LSTM-MLP-ORE based on the RMSE on the validation dataset.

Seven different models are thus obtained, which can be fairly compared, on exactly the same preprocessing, censoring, as well as training, validation and test sets.

For all models, we use $R_{max} = 130$, and for the methods relying on ordinal regression, we consider Y vectors consisting on K = 13 coordinates corresponding to the status every L = 10 cycles.

3.4. Hyperparameters of the models

The hyperparameters employed for the DAST are those described in the original article (Z. Zhang et al., 2022), except for number of epochs that is set to 250 with early stopping. They are summarized table 2.

The hyperparameters for DAST-OR are essentially identical. Table 3 presents those which are specific to DAST-OR (sigmoid output layer and loss) or are chosen different (a manual tuning on the window size gave better results). The number of epochs is set to 500 with early stopping.

The hyperparameters of the LSTM-MLP-OR model mainly correspond to the article introducing LSTM-OR (Vishnu et al., 2019). However, not all parameters being explicitly de-

Table 2. Hyperparameters of DAST

Hyperparameter	Value
Input embedding	1 MLP layer with 64 neurons, activation: Linear
Sensor encoder	N = 2 Sensor encoder blocks with H = 4 heads
Time step encoder	N = 2 Timestep encoder blocks with H = 4 heads
Decoder	N = 1 Decoder block with H = 4 heads
Output layer	1 MLP layer with 64 neurons, activation: ReLU
Final output layer	1 MLP layer with 1 neurons, activation: Linear
Learning Rate	0.001
Batch Size	256
Dropout	0.2
Window Size	40 for FD001 and FD003, 60 for FD002 and FD004
Optimizer	Rectified Adam
Loss	RMSE

Table 3. Hyperparameters of DAST-OR

Hyperparameter	Value
Final output layer	1 MLP layer with 13 neurons, activation: Sigmoid
Window Size	60 for FD001 and FD003, 80 for FD002 and FD004
Loss	BCELoss

tailed in the original article, manual tuning has been applied to the LSTM-MLP-OR model with a few trials on the validation set.

3.5. Results on uncensored data

This part focuses on the comparison of the results obtained on data without censoring. Table 4 shows the results for the seven trained models on each of the four datasets, with various state-of-the-art methods. Note that the seven methods are trained with the same preprocessing and separation into training and validation sets, whereas the reported values for other methods correspond those indicated in the corresponding publications. Small variations may therefore not be significant.

On FD001, results of DAST-ORE are equivalent to the results of DAST and F+T. On FD002 results of LSTM-MLP-OR and LSTM-MLP-ORE are significantly better than the results obtain with DAST, and equivalent to results obtain with MLP+LSTM and F+T. On FD003 DAST-ORE perform better than other models of the state of the art. The results of LSTM-MLP-ORE are equivalent to the result of MLP+LSTM and F+T. On FD004 LSTM-MLP-ORE perform significantly better than other models. All the OR method proposed are significantly better than the LSTM-ORCE.

Two main conclusions can be drawn from those results. The first is that, even if OR models were designed to handle right-censored data, the obtained results on uncensored data are equivalent to those found in the literature with models specifically made for direct RUL estimation. The second interesting fact to note is the dependence on the number of operating conditions in the dataset (cf Table 1). Differences between sets FD001 and FD003, with a unique operating condition, and sets FD002 and FD004, with six different ones, are commonly found in the state of the art (C. Zhao, Huang, Li, & Yousaf Iqbal, 2020) (Sateesh Babu et al., 2016) (C. Zhang, Lim, Qin, & Tan, 2016) (Zheng et al., 2017) (X. Li, Ding, & Sun, 2018). Furthermore, the number of inputs used between is different. In this study, it appears that DAST-based methods are more powerful when the operating condition is unique, while LSTM-based outperform them when there are 6 operating conditions. Learning both architectures and keeping the best on the validation set, as does BEST-ORE, is therefore useful.

3.6. Results on censored data

The results on the C-MAPSS dataset for each right-censored rate are detailed in Tables 6 and 5. The former compares the proposed ensemble methods to the ensemble LSTM-ORCE method (Vishnu et al., 2019) for the data subsets (FD001 and FD004) and censoring rates studied in that article. The train and validation sets being different, small variations should not be interpreted. However, it clearly indicates a better performance of DAST-ORE on FD001 and a significant improvement with LSTM-MLP-ORE due to the supplementary MLP layer on FD004.

Table 6 shows the results for the models listed in section 3.3 trained on the same training and validation data. For readability, BEST-ORE is not indicated, but the associated RMSE is always the lowest among the RMSEs of LSTM-MLP-ORE and DAST-ORE.

The FD001 dataset has more simple operating conditions and more simple failure modes than the other C-MAPSS sub-datasets. On FD001 the DAST-ORE model has the best RMSE for each percentage of right-censored value. With the increase of p_c, the RMSE is slowly deteriorating and reach it's worst value at $p_c = 90\%$, which is not a surprise as the learning data becomes less informative. Other models, especially LSTM-based ones, show a bigger deterioration with increasing censoring.

The results are similar on FD003, which has also only one operating condition but two failure modes. The best overall results are obtained with DAST-ORE. Moreover, the increasing of the RMSE for highly censored data is milder for DAST-ORE than for competing methods.

FD002 and FD004 are considered more complex than FD001

Table 4. RMSE results on the C-MAPSS dataset without censoring

Model	**FD001**	**FD002**	**FD003**	**FD004**	Average RMSE

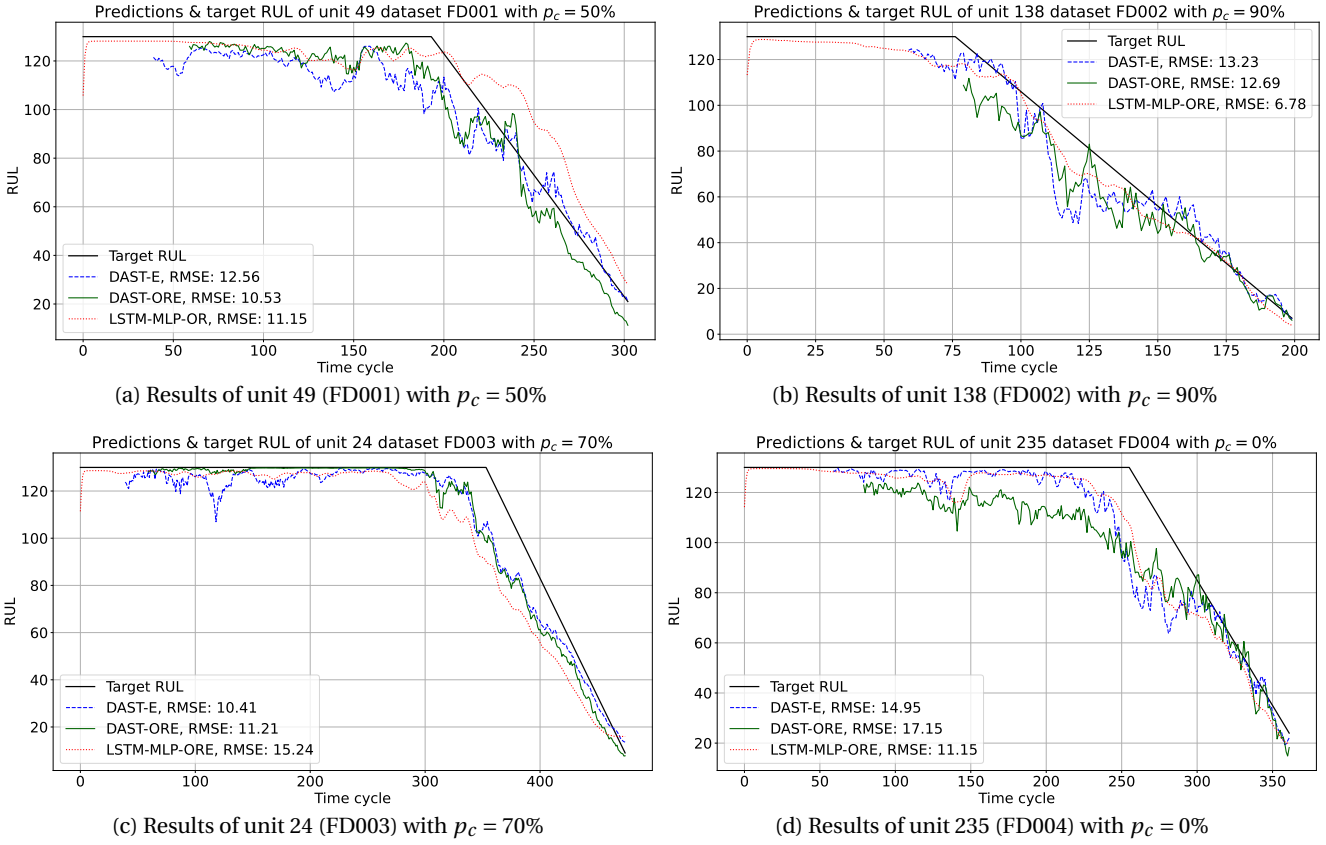
90%	**15.47**	22.14	38.41

and FD003, because they mix several operating conditions. In both cases, the LSTM-based models outperform the DAST-based ones, as for uncensored data, with a small advantage for the LSTM-MLP-ORE ensemble method. In those two cases, the decrease of performance with growing censoring is remarkably low.

The conclusion of this study is therefore two-fold. First, the competition between LSTM and DAST-based architectures remains relevant with censored data, as different conditions may lead to different rankings of those methods. Second, OR-based methods allow to obtain a reasonable loss of performance when the real time of failure is missing for most of the learning data.

As prescribed in (Saxena et al., 2008), the results were evalu-



(a) Results of unit 49 (FD001) with $p_c = 50\%$

(b) Results of unit 138 (FD002) with $p_c = 90\%$

(c) Results of unit 24 (FD003) with $p_c = 70\%$

(d) Results of unit 235 (FD004) with $p_c = 0\%$

Figure 6. Example of results on one units of each sub-dataset

ated by the RMSE on the predictions of the last time-point of the time-series in the test set. To illustrate more visually the results of the different methods, Figure 6 provides some plots of the predictions of the ensemble methods for randomly picked time series on different datasets and censoring rates.

3.7. Asymmetric score evaluation

Prediction on C-MAPSS should also be evaluated by the asymetric score (Saxena et al., 2008) defined by

$$\text{Score} = \begin{cases} e^{\frac{\hat{\text{R}}_t - \text{R}_t}{13}} - 1 & \text{if } \hat{\text{R}}_t - \text{R}_t \geq 0 \\ e^{-\frac{\hat{\text{R}}_t - \text{R}_t}{13}} - 1 & \text{if } \hat{\text{R}}_t - \text{R}_t < 0 \end{cases}$$

That score corresponds to a higher penalty for overestimation rather underestimation of the RUL.

Table 7 shows the scores for the ensemble methods DAST-E, DAST-ORE and LSTM-ORE. If the results are rather coherent with the RMSE comparisons for FD001 and FD003, the advantage of LSTM-based methods compared to DAST-E is less clear for FD002 and FD004.

However, it has to be noted that the OR-based methods were trained with a symmetric BCELoss which does not take into consideration a different penalty for over and under-estimations. In terms of binary vectors, it means a higher penalty for a close to 0 coordinate in $\hat{\text{Y}}_t$ when the truth is 1 (the fan is predicted running when it actually failed, which is an over-estimation of the RUL) than for a prediction close to 1 when the truth is 0.

A possibility to introduce this asymmetry would be to consider a modified loss by replacing Equation 2 by

$$\text{BCE}(\text{Y}_t, \hat{\text{Y}}_t) = -\sum_{k=1}^{\text{K}} \left(\alpha y_{t,k} log(\hat{y}_{t,k}) + (1 - y_{t,k}) log(1 - \hat{y}_{t,k})\right) \tag{4}$$

where $\alpha > 1$ is a hyperparameter to be optimized.

4. Conclusion

This work addresses the challenge of estimating the Remaining Useful Life (RUL) of industrial components from time series data with no prior physical model of the system and a high rate of censored data. It does so by considering two data-driven deep-learning architectures relying on the ordi-

nal regression approach introduced in (Vishnu et al., 2019) for RUL estimation. One of them is an improved version of the LSTM-OR method by (Vishnu et al., 2019), the second is an adaptation to censored data of the DAST model introduced in (Z. Zhang et al., 2022).

These approaches are shown to perform as well on the C-MAPSS data as the existing direct RUL estimation methods found in the literature on uncensored data, and better on censored data.

Furthermore, the two proposed architectures are shown to be complementary, as they outperform each other depending on the complexity of the dataset. Therefore, in the context of estimating the lifespan of components, it is interesting to put them in competition, considering that this approach should yield favorable results regardless of the complexity of the data and the rate of right-censored data.

ABSTRACT

When designing gas turbine engine components, the inspection and maintenance (I&M) plan is prepared using the safe life. However, the I&M plan determined using safe life may be costly since all components are replaced at designated life. Therefore, it is important to make maintenance decisions considering the time-dependent deterioration process of gas turbine engine components for a cost-saving I&M plan. In this study, we proposed a maintenance decision-making model for gas turbine engine components based on a partially observed Markov decision process (POMDP). Using dynamic Bayesian networks, a decision-making model integrating a reliability analysis model, and a decision model for I&M planning was constructed. The signal amplitude data resulting from non-destructive inspection according to operation hour was used as partially observed data. The total cost obtained from the proposed model were compared with the results using a fixed I&M plan. The proposed model resulted in more cost-effectiveness I&M planning within affordable risk levels by considering the interaction between risk cost and I&M cost.

1. INTRODUCTION

Ensuring the safety of the gas turbine engine is very important in aircraft operation. There are two traditional inspection & maintenance (I&M) strategies to operate aircraft safely; safe life and damage tolerance design. The safe life method (C. H. Cook et al., 1982) replaces all components after the design allowable life, and time-based maintenance (TBM) (Bousdekis et al., 2015) inspects and repairs all parts at predetermined intervals. However, traditional I&M methods require high costs since I&M actions are planned without the consideration of the components' condition. For this reason, a condition-based maintenance method that emphasizes combining data-driven reliability models with condition-monitored data was developed (Alaswad & Xiang, 2017).

Markov decision process (MDP) is one of the widely used methodologies for decision-making models with the condition-based maintenance (CBM) method. MDP takes actions at each stage to maximize the reward under perfect observation of components state. However, there are limitations for MDP that perfect observation of the components state is unrealistic (Papakonstantinou & Shinozuka, 2014b). Partially observable MDP (POMDP) quantified the uncertainty of imperfect observation by estimating the belief of state from the information obtained with the probability of observation. (Papakonstantinou & Shinozuka, 2014b, 2014a) determined the optimal life-cycle policy of concrete structures by implementing the POMDP. (Memarzadeh et al., 2014) proposed the algorithm for approximate learning and planning the Bayes-adaptive POMDP (BA-POMDP) framework to find the optimal maintenance plan of wind farms.

Morato et al. (Morato et al., 2020) incorporated the dynamic Bayesian networks (DBNs) and POMDP to obtain optimal I&M strategy for deteriorating structure. They modeled the deterioration model based on time-invariant parametric DBNs, and an optimal I&M plan was generated by minimizing the total cost of inspection, maintenance, and reliability. Hlaing et al. (Hlaing et al., 2022) presented the non-stationary policy for offshore wind tubular joints by integrating the Bayesian networks and POMDP. They estimated the probability of failure (POF) using the DBNs and obtained optimal I&M policy via POMDP.

In this work, we proposed the maintenance decision-making model for gas turbine engine components. DBNs and POMDP were integrated to get optimal I&M policy. The fatigue crack growth model was implemented for the

deterioration of gas turbine engine components, probability of detection (POD) curve which is a function of the crack size was used for the inspection model. The remainder of this paper is organized as follows. The decision-making model for gas turbine engine components is described in "Methodology" section. In "Numerical results", the optimal I&M policy obtained using the proposed POMDP model is presented. In the final section, the conclusions of this study are summarized.

2. METHODOLOGY

2.1. PARTIALLY OBSERVABLE MARKOV DECISION PROCESS

MDP provides the framework that finds the optimal policy for sequential decision-making problems, as represented in Fig. 1. In Fig. 1, the circles are random state nodes, the rectangular are decision nodes, and the polygons are reward nodes. MDP determines the optimal policy that maximizes the expected reward value by using the Bellman equation as follows:

$$V^*(s) = \max_{a \in A}[R(s,a) + \gamma \sum_{s' \in S} T(s,a,s')V^*(s')] \quad (1)$$

where s is states of the system, a is the set of possible actions, and $T(s, a, s')$ is transition matrix which is the probability of transit from current state s_t to next state s_{t+1}, $R(s, a)$ is the reward when doing action a with current state s_t, and γ is discount factor employed when the problem is infinite horizon planning case (Morato et al., 2019). However, since MDP has the limitation of perfect observation, POMDP determines the optimal policy according to the belief state estimated from imperfect observation. In Fig. 2, the belief state s_t is updated from the information of component state obtained at the inspection node z_t, The optimal policy is determined at POMDP as:

$$V^*(s) = \max_{a \in A}\left[b(s)R(s,a) + \gamma \sum_{z \in Z} P(z|b,a)V^*(b')\right] \quad (2)$$

where z is observation, and b is belief state of the component. The belief state b with action m at stage n is ${}^m b^n = b^n \times A_m$, the belief state b^{n+1} at the stage n+1 is updated with degradation model D; $b^{n+1} = {}^m b^n \times D$ (Faddoul et al., 2013).

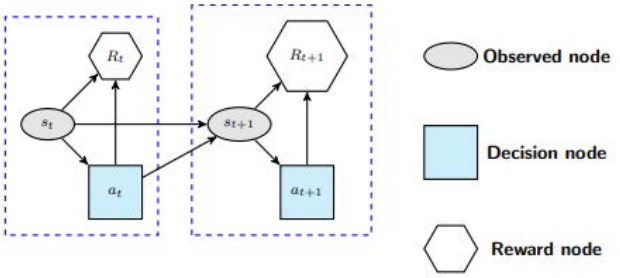

Figure 1. Graphical model for Markov decision process

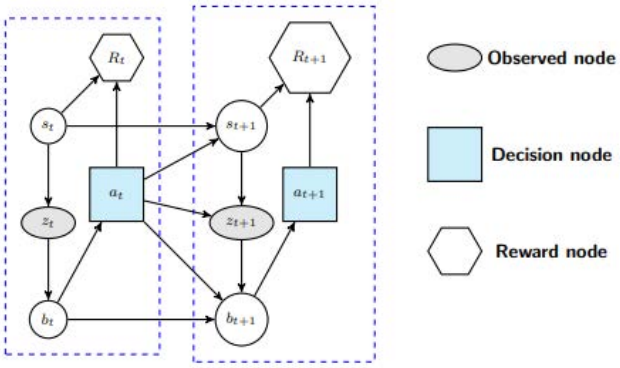

Figure 2. Graphical model for Partially observable MDP

2.2. DETERIORATION AND INSPECTION MODEL

Paris' law was used for fatigue crack deterioration model of gas turbine engine component as:

$$\frac{da}{dN} = C(\Delta K)^m \quad (3)$$

where a is the size of crack, N is the cycles of loads, ΔK is the stress intensity factor range which is function of crack size, shape, and stress range $\Delta\sigma$, and C and m are the constants related to material property.

Eddy current inspection (ECI), one of the non-destructive inspection (NDI) methods, was used as partial observation model to update the belief state of the gas turbine engine component. The POD of ECI depends on the crack size and the detection threshold (Hlaing et al., 2022). The size of the crack is estimated from the ECI signal amplitude in Eq. (4), and the POD is calculated from Eq. (5). Figure 3 presents the relation curve between the signal amplitude and the crack length, and Fig. 4 is the probability of detection (POD) estimated from the detection result data of NDI personnel (D. Lee & Kwon, 2023). The $a_{50/95}$ = 1.123 in Fig. 4 means that the detectable crack size at a 50% probability with 95% confidence is 1.123mm. The size of the crack is estimated

from the ECI signal amplitude in Eq. (4), and the POD is calculated from Eq. (5).

$$\hat{a} = \beta_0 + \beta_1 a + \varepsilon \quad (4)$$

$$POD(a) = \frac{a a^{\gamma}}{1 + a a^{\gamma}} \quad (5)$$

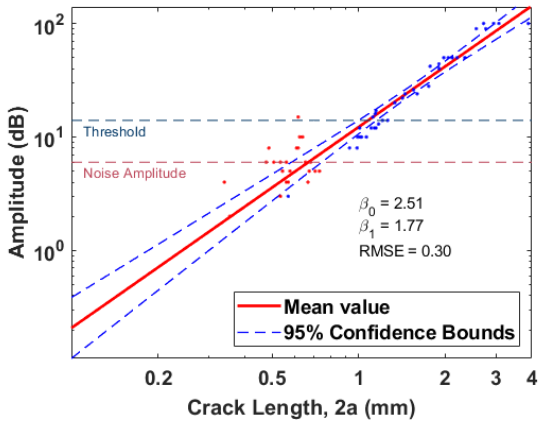

Figure 3. Relation between ECI signal and crack size

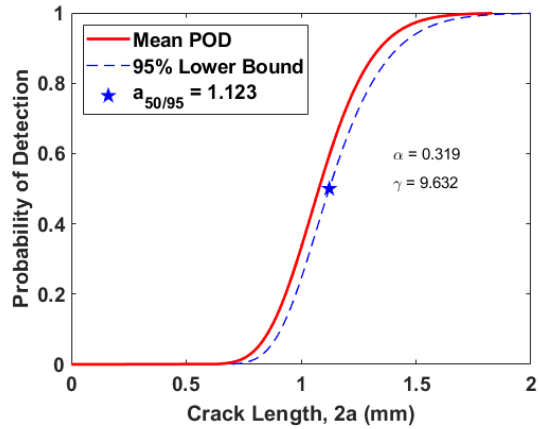

Figure 4. Probability of detection curve

2.3. DECISION-MAKING MODEL BASED ON DYNAMIC BAYESIAN NETWORKS

The maintenance decision-making model based on Dynamic Bayesian Networks (DBNs), depicted in Fig. 5 was developed by incorporating the deterioration, inspection model, and POMDP described above. In Fig. 5, the initial nodes have no parent nodes, the static nodes are time-independently invariant nodes, the observed node obtains evidence, the functional nodes formulate the crack length distribution and reliability, the decision nodes decide for actions, and the cost of the decision incurred in the utility nodes. The continuous operation time is discretized into time slices with uniform intervals.

Table 1. Prior probability distributions of initial nodes

Var	Distribution	Mean	SD	Corr.
m, $\ln(C)$	Binormal	(2.5, $\log(5.2\times10^{-12})$)	(0.3, 0.47)	-0.9
$\Delta\sigma$ (MPa)	Normal	40	5	-
a_0 (mm)	Lognormal	-1.0	0.001	-
a_r (mm)	Lognormal	-1.0	0.001	-
Y_n (%)	Normal	3.29	2.86	-

First, the crack length distribution at time slice t-1 (a_{t-1}) is estimated in the deterioration model using $\Delta\sigma$, m, initial crack length at time slice t-1 (a^0_{t-1}). Next, a_{t-1} is updated to a^*_{t-1} based on the actions determined by the signal amplitude node Y_{t-1}, noise amplitude Y_n, decision nodes for inspection DZ, the threshold of inspection D_{th}, and maintenance DM. The updated crack length distribution at time slice t-1 a^*_{t-1} is used as initial crack length distribution a^0_t at time slice t. The prior distributions of initial nodes are presented in Table 1.

The actions determined in each decision node are as follows: The inspection decision determines whether to perform an inspection or not. The cost of the inspection is obtained in inspection utility node UZ depending on the result of the inspection decision.

- No-inspection: the crack length states transit according to the deterioration model.
- Inspection: binary inspection result is obtained at node Z as 'detected' or 'not detected'. When the inspection result is 'detected', the probability of failure increases as the belief state of crack length larger than the inspection threshold increase. On the other hand, the probability of failure decreases since the crack length distribution smaller than the inspection threshold rise in the case of 'not detected'.

The quality of NDI is determined in the threshold decision node. The inspection quality is high as the threshold is lower. If the signal amplitude obtained at the cracks is larger than the inspection threshold, those cracks are detected at inspection result node Z. There is no cost for threshold decision.

There are binary options in the maintenance decision node; repair or do-nothing. The maintenance utility node UM calculates the cost of maintenance.

- Do-nothing: there is no maintenance action planned in this case, the crack length state evolves according to the stochastic deterioration process.
- Repair: perfect maintenance action is performed. The crack length distribution a^*_{t-1} is replaced by the belief state of repair crack a_r.

The total cost at time t is calculated by summing the cost of the failure, inspection, and maintenance determined according to the results of each decision node as follows:

$$C_T(h) = \sum_{t=t_0}^{t_n} \left[C_I(t)\gamma + C_M(t)\gamma + P_f(t)C_f(t)\gamma \right] \qquad (6)$$

where C_T is total cost, h is pre-defined heuristic schedule, t_n is total time horizon, C_I is inspection cost, C_M is maintenance cost, P_f is probability of failure estimated at node R, and C_f is failure cost determined in utility node UR. The C_I and C_M is not incurred in the case of no-inspection and do-nothing, respectively. The optimal actions were determined by minimizing the total cost.

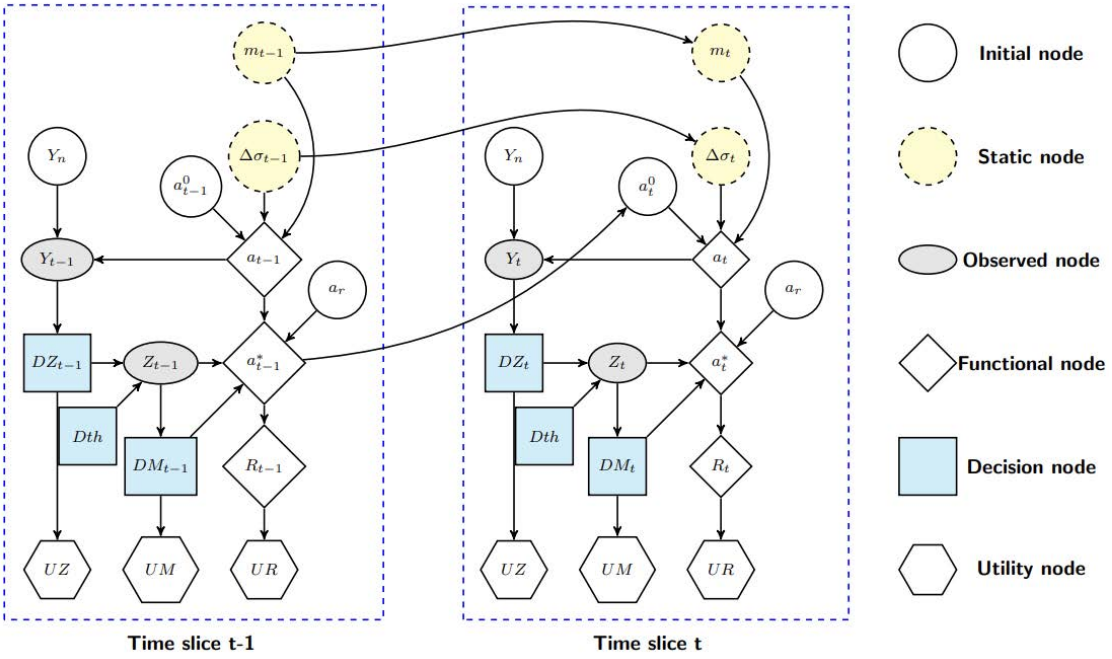

Figure 5. Maintenance decision-making model for gas turbine components

3. NUMERICAL RESULT

A maintenance decision-making model based on POMDP was constructed for the J85 gas turbine engine compressor first-stage rotor blade for the F-5 aircraft. The J85 gas turbine engine compressor first-stage rotor blade is mounted with a disc using tangs. The stress concentration at the center tang occurred due to contact force between the retainer pin and an inner surface of the tang (B. W. Lee et al., 2011). Since the fracture at the center tang may occur due to the fatigue crack initiated from fretting damages by contact stress, it is important to optimize the I&M planning of the blade center tang.

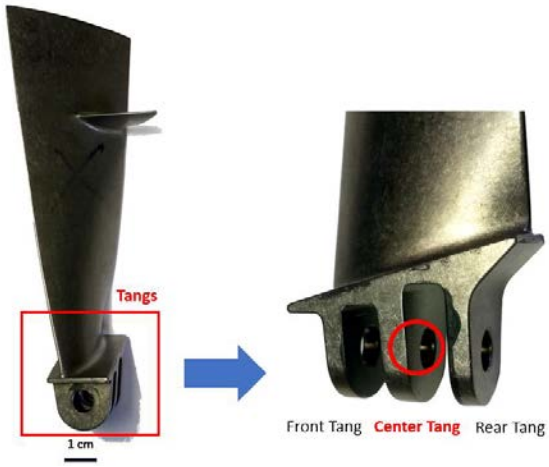

Figure 6. J85 engine compressor first-stage blade

3.1. DISCRETIZATION SCHEMES FOR MODEL PARAMETERS

Discretization of each random variable is necessary in POMDP since the probability of partial observation is discretized (Morato et al., 2020). The accuracy of POF and computational efficiency are affected by the discretization scheme. The discretization schemes for each variable in Fig. 5 are presented in Table 2. The random variables were discretized with a small number of discretization states for computational costs.

Table 2. Discretization schemes

Var	Interval Boundaries
a, a_r	0, exp(log(0.01):(log(3)-log(0.01))/4:log(3)), inf
m	0, log(exp(1):(exp(3.9)-exp(1))/4:exp(3.9)), inf
$\Delta\sigma$	1:60/4:60, inf
Y_n, Y	0:6:100

3.2. OPTIMAL POLICY BASED ON DECISION-MAKING MODEL

The overall cost of utilizing the proposed decision-making model was compared with that of time-based maintenance (TBM), a traditional I&M strategy. In TBM, NDI is conducted for every time slice, and when a crack is detected, a perfect repair action is performed. On the other hand, the decision to execute NDI and repair is made for each time slice in the most cost-effective way in the decision-making model. The parametric study for the costs of inspection, maintenance, and failure was conducted to specify the effects of actions. The state of the measured signal amplitude Y was imported from the actual measured data at each time slice (D. Lee & Achenbach, 2016). If the inspection threshold is smaller than the measured signal amplitude, it is observed that a crack is detected, and a perfect repair action is performed in the TBM strategy. Otherwise, in the POMDP strategy, it is determined whether to perform inspection and maintenance actions for each time slice depending on the total cost.

The ratio of total cost between TBM and POMDP depending on the NDI threshold over 5 time slices is shown in Fig. 7. The evidence indicated the crack state progressed from state 2 to state 5 in each time slice, with failure occurring at state 6. After repair action, the crack state returned to state 2. R_{MI} is the ratio of cost between inspection and maintenance, R_{FM} is the ratio of cost between failure and maintenance, and R_C is the total cost ratio between TBM and POMD as:

$$R_{MI} = \frac{C_M}{C_I}, R_{FM} = \frac{C_F}{C_M} \tag{7}$$

$$R_C = 100\frac{C_{POMDP} - C_{TBM}}{C_{TBM}}(\%) \tag{8}$$

Where C_M is the cost of maintenance, C_I is the cost of inspection, C_F is the cost of failure, C_{POMDP} is total cost for POMDP, and C_{TBM} is that of TBM. The R_{MI} = [10, 20, 30, 40, 50], and R_{FM} = [100, 50, 25, 20] were used to estimate the total cost. The C_{POMDP} is more cost-effective than C_{TBM} when the total cost ratio is a negative value; conversely, if this ratio is a positive value, the C_{TBM} is less expensive than C_{POMDP}.

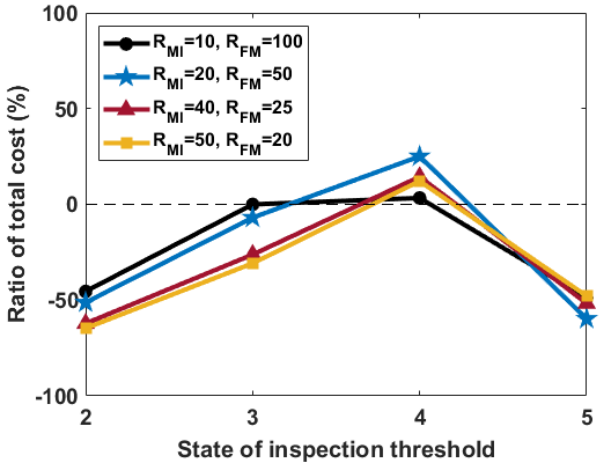

Figure 7. Ratio of total cost between TBM and POMDP

The cost of the POMDP strategy is cheaper than TBM in all R_{MI} and R_{FM} when the threshold of inspection is lower than 4. This implies that a high-quality inspection is crucial for an I&M strategy based on POMDP. When the inspection quality is high (D_{th} = 2, 3), the crack state is identified early. This enables decisions on whether to perform inspections and repairs based on the state of crack growth. Consequently, the POMDP strategy conducts fewer inspections and repairs compared to the TBM strategy, and no preventative repairs, resulting in lower total costs as illustrated in Fig. 8.

When D_{th} = 4, the crack state is detected before it grows near the limit state. In the TBM strategy, after detecting the crack, repairs are performed to maintain a low probability of failure. The inspections following repair prevent the crack from propagating toward the limit state, resulting in a low cost of failure. On the other hand, in the POMDP strategy, when the R_{MI} is low, more repairs are carried out than TBM due to lower inspection quality. When R_{MI} is high, the probability of failure increases because inspections are not performed after repairs, leading to a higher total cost.

Also, the ratio of total cost R_c increases as the inspection threshold decreases. Exceptionally, when using the TBM strategy with D_{th}=5, R_c increases. This occurs as the crack is detected in state 5, which is proximate to the failure state, as depicted in Figure 8(a). Consequently, the estimated probability of failure is relatively high, leading to an increased total cost. On the other hand, when using the POMDP strategy, repairs were carried out preventatively

even if the inspection result indicated 'No-detected' as shown in Fig. 8(b), owing to the limited inspection quality. Therefore, when the inspection threshold is 5, the total cost of the POMDP strategy was relatively lower than that of TBM since the failure cost of the POMDP strategy was low through preventive repairs.

Fig. 8 presents the optimal actions determined by using TBM and POMDP strategy depending on each R_{MI} and R_{FM} during 5 time slices. There are two color blocks to describe the results of the decision at each time slice; the left is inspection, and the right is maintenance. The action types of inspection are 'No-inspection' (gray colors), 'No-detected' (sky colors), and 'Detected' (blue colors). The red colors mean the case of a 'Repair' action, and the orange colors indicate a 'Do-nothing' action.

In the context of inspection and maintenance, Fig. 8 illustrates how the cost ratio impact the frequency of inspection and maintenance. Specifically, when the cost ratio of inspection and maintenance R_{MI} is relatively small compared to the cost of failure and maintenance R_{FM} (Fig. 8(b), (c)), more frequent inspection were performed. Since the cost of the failure is expensive compare to inspection and maintenance, it is more cost-effective to identify the state of the crack length early by inspecting frequently. For example, the optimal decision for inspection of R_{MI}=10, and R_F=100 was to inspect every time slice, similar to the TBM strategy.

In the case of high R_{FM}, and high D_{th}, repair action was performed even in the case of 'No-detected'. Since the cost of maintenance is cheaper than that of failure, and the result of inspection is uncertain, this policy is optimal to reduce the POF. On the other hand, when the information quality of inspection was high ($D_{\text{th}}\leq 3$), repair action was not performed immediately, even though the result of the inspection was 'Detected'. In this case, the decision to repair or not can be determined by the condition of the crack, not preventatively.

When R_{MI} is larger than R_{FM} (Fig. 8(d), (e)), the cost of maintenance becomes expensive. The preventive inspections and maintenance were reduced due to high-cost maintenance. Therefore, the inspection was not performed at the first time slice for all inspection thresholds. The total cost ratio R_c was highest when R_{MI}=50, R_{FM}=20, and D_{th} =2, as presented in Fig. 7. The findings from Figures 7 and 8 indicate that an increase in inspection quality and a decrease in the cost ratio between maintenance and repair enhance the effectiveness of the maintenance decision-making model based on POMDP.

4. CONCLUSION

In this work, we proposed a maintenance decision-making model for gas turbine components based on POMDP. DBNs and POMDP were integrated to construct the maintenance decision-making model. The fatigue crack growth model was implemented for deterioration of gas turbine engine components, POD curve was used for the inspection model. The total cost of POMDP was lower than that of TBM when inspection quality was high. Also, it was proven that the maintenance decision-making model is more effective than TBM as the cost ratio between maintenance and repair is smaller by parametric study of cost ratio.

Our future work will focus on complicate inspection and maintenance actions. The various options for inspection and maintenance actions will improve the decision-making model more elaborately.

ABSTRACT

Large-scale infrastructure systems are crucial for societal welfare, and their effective management requires strategic forecasting and intervention methods that account for various complexities. Our study addresses two challenges within the Prognostics and Health Management (PHM) framework applied to sewer assets: modeling pipe degradation across severity levels and developing effective maintenance policies. We employ Multi-State Degradation Models (MSDM) to represent the stochastic degradation process in sewer pipes and use Deep Reinforcement Learning (DRL) to devise maintenance strategies. A case study of a Dutch sewer network exemplifies our methodology. Our findings demonstrate the model's effectiveness in generating intelligent, cost-saving maintenance strategies that surpass heuristics. It adapts its management strategy based on the pipe's age, opting for a passive approach for newer pipes and transitioning to active strategies for older ones to prevent failures and reduce costs. This research highlights DRL's potential in optimizing maintenance policies. Future research will aim improve the model by incorporating partial observability, exploring various reinforcement learning algorithms, and extending this methodology to comprehensive infrastructure management.

1. INTRODUCTION

Sewer network systems, crucial for public health, population well-being, and environmental protection, require maintenance to ensure their reliability and availability (Cardoso et al., 2016). This maintenance is challenged by limited budgets, environmental changes, aging infrastructure, and hard-to-predict system deterioration (Tscheikner-Gratl et al., 2019).

Optimizing maintenance policies for sewer networks requires methodologies that can efficiently explore a broad solution space while adapting to the system's dynamic constraints and complexities. Maintenance Policy Optmization (MPO) addresses these needs by developing and analyzing mathematical models to derive maintenance strategies (De Jonge & Scarf, 2020) that reduce maintenance costs, extend asset life, maximize availability, and ensure workplace safety (Ogunfowora & Najjaran, 2023).

This research explores the potential of Deep Reinforcement Learning (DRL) for MPO of sewer networks, first focusing on a component-level (i.e., pipe-level) analysis. DRL is a framework that merges neural network representation learning capabilities with Reinforcement Learning (RL), a branch of machine learning known for its effectiveness in sequential decision-making problems. RL is increasingly recognized for its role in developing cost-effective policies in MPO across diverse domains such as transportation, manufacturing, civil infrastructure and energy systems. It is emerging as a prominent paradigm in the search for optimal maintenance policies (Marugán, 2023).

This paper aims to achieve two primary objectives: first, to present a comprehensive model for pipe-level MPO analysis facilitated by DRL, considering degradation over the pipe length and employing inhomogeneous-time Markov chain models to simulate the nonlinear stochastic behavior associated with sewer pipe degradation; second, to assess the efficacy of the model's policy through a case study of a large-scale sewer

network in the Netherlands, comparing it with heuristics, including condition-based, scheduled, and reactive maintenance.

We acknowledge as limitations in our approach the focus on *fully observable* state spaces, which means that inspection actions are not necessary, and our analysis is at the *component-level*. Future research will aim to broaden this scope to include partially observable state spaces and system-level analysis.

Contributions. This work's primary contributions include:

(i) We propose a framework to carry out maintenance policy optimization for sewer pipes considering the deterioration along the pipe length. This framework integrates Multi-State Degradation Models (MSDMs) and Deep Reinforcement Learning (DRL).
(ii) Our framework introduces a novel approach by encoding the prediction of the MSDM into the state space, aiming to harness prognostics that describe the degradation pattern of sewer pipes.
(iii) We demonstrate that DRL has the potential to devise intelligent strategic maintenance strategies adaptable to various conditions, such as pipe age.
(iv) We provide our framework in Python and all data used in this study at zenodo.org/records/11258904.

Paper outline. Section 2 presents the technical background. Section 3 outlines our research methodology. Section 4 formulates the MSDM. Section 5 details the framework for maintenance policy optimization via DRL. Section 6 presents our experimental setup. Section 7 analyzes the results. Section 8 discusses findings, concludes, and suggests future research.

Related work. In the past two decades, the need for integral sewer asset management has become evident (Abraham et al., 1998), emphasizing the necessity to understand the mechanisms of deterioration and develop predictive models for proactive and strategic sewer maintenance (Fenner, 2000). Sewer asset management encompasses maintenance, rehabilitation, and inspection and has been investigated through various methodologies, including risk-based strategies (Lee et al., 2021), multi-objective optimization (Elmasry et al., 2019), Markov Decision Processes (Wirahadikusumah & Abraham, 2003), considering the structure of the sewer network (Qasem & Jamil, 2021), machine learning applications (Montserrat et al., 2015; Caradot et al., 2018; Laakso et al., 2019; Hernández et al., 2021), and decision support frameworks (Taillandier et al., 2020; Khurelbaatar et al., 2021; Ramos-Salgado et al., 2022; Assaf & Assaad, 2023).

The integration of RL into sewer asset management is largely unexplored, with existing research mainly concentrating on *real-time control* for smart infrastructure, adapting to environmental changes such as storms. Mullapudi et al. (2020) uses DRL for controlling storm water system valves through simulation of varied storm scenarios. Yin et al. (2023) employ RL for *near real-time* control to minimize sewer overflows. Meanwhile, Zhang et al. (2023) and Tian et al. (2022) both examine improving the robustness of urban drainage systems, the former through decentralized *multi-agent RL* and the latter through *Multi-RL*, with Tian et al. (2024) further improving the model *interpretability* using DRL. Furthermore, Kerkkamp et al. (2022) investigates the sewer network MPO by combining DRL with Graphical Neural Networks to optimize maintenance actions grouping. Jeung et al. (2023) proposes a DRL-based *data assimilation* methodology to enhance storm water and water quality simulation accuracy by integrating observational data with simulation outcomes.

2. TECHNICAL BACKGROUND

2.1. Multi-state degradation model for sewer pipes

The modeling of sewer pipe network degradation has been explored through various methodologies, including physics-based, machine learning, and probabilistic models. For comprehensive discussions on this topic, the reader is directed to Ana & Bauwens (2010); Hawari et al. (2017); Malek Mohammadi et al. (2019); Saddiqi et al. (2023); Zeng et al. (2023).

We adopt a probabilistic approach employing Inhomogeneous Time Markov Chains (IHTMCs) to model the multi-state degradation of sewer pipes. This choice is motivated by the IHTMC's capability to better capture the degradation of long-lived assets such as sewer systems as a non-linear stochastic process, characterized by age-dependent transition probabilities between degradation states (Jimenez-Roa et al., 2024).

Inhomogeneous Time Markov Chains (IHTMCs). An IHTMC is a stochastic process $\{(X_t)\}_{t\geq 0}$, where $t \in [0, \infty)$ is continues and models *time*. The IHTMC is defined as a tuple $M = \langle \Omega, S^0, Q(t) \rangle$, where Ω is a set of K finite states indicating the *state space*, S_k^0 is an *initial-state distribution* on Ω where $\sum_{k\in\Omega} S_k^0 = 1$, and $Q(t) : \Omega \times \Omega \to \mathbb{R}$ is a *time-dependent transition rate matrix*, with entries $q_{ij}(t)$ for $i, j \in \Omega$ and $i \neq j$, representing the rate of transitioning from state i to state j at time t. The diagonal entries $q_{ii}(t)$ are defined such that the sum of each row in $Q(t)$ is zero, ensuring that the *outflow* from any state is equal to the sum of the *inflows* into other states. $Q(t)$ may be parameterized by hazard rates $\lambda(t|\theta)$ derived from the ratio $f(t|\theta)$ and $S(t|\theta)$, being respectively a *probability density function* and a *survival function*, where θ corresponds to the function hyper-parameters. The evolution over time of the IHTMC is governed by the *Forward Kolmogorov* equation:

$$\frac{\partial P_{ij}(t,\tau)}{\partial t} = \sum_{k\in S} P_{ik}(t,\tau) Q_{kj}(t) \tag{1}$$

Here, $P_{ij}(t,\tau) : \Omega \times \Omega \to [0,1]$ is a continuous and differentiable function known as the *transition probability matrix*, indicating the probability of transitioning from state i to state j in the time interval t to τ, where $\tau > t$. From Eq. (1) one can obtain the *master equation of the Markov chain*, which models the flow of probabilities between states by including inflow and outflow terms:

$$\frac{\partial S_k(t)}{\partial t} = \sum_{i\in\Omega, i\neq k} S_i(t) Q_{ik}(t) - S_k(t)\Big(\sum_{j\in\Omega, j\neq k} Q_{kj}(t)\Big) \tag{2}$$

Here, $S_k(t)$ is the probability of being in state $k \in \Omega$ at time t, the term $\sum_{j\in\Omega, j\neq k} Q_{kj}(t)$ represents the rates of transition from state k to all the other states j (excluding self-transitions).

Pipe-element degradation model. We define a pipe element by K sequentially arranged states $S = [S_1, S_2, ..., S_k]$, where S_1 signifies the *pristine* condition and S_k represents the *worst condition*. This categorization is based on sewer network inspection data, which documents types of damage and their severities on a scale from 1 to 5, along with occasional instances of functional failures ($K = 6$). The transitions within our IHTMC, illustrated in Figure 1, permit only progression from a better to a worse state, prohibiting direct improvements without repairs, while allowing any severity level to escalate to functional failure.

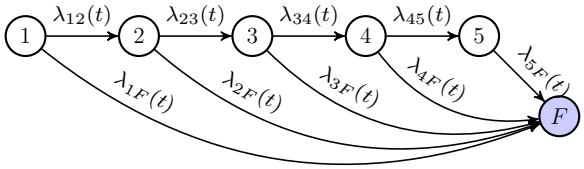

Figure 1. Markov chain structure for IHTMC.

Parametrization of IHTMC. We employed a parameterized approach for IHTMC, involving an assumption on the hazard function. In Section 4.2, we detail the parametrization used in our experimental setup. Several aspects related to the multi-state degradation model, including hyper-parameter tuning and interval-censoring, are beyond the scope of this paper. For further information, we recommend referring to (Jimenez-Roa et al., 2024).

2.2. Markov Decision Process

A Markov Decision Process (MDP) models a stochastic sequential decision process, where both costs and transition functions are dependent solely on the current state and action (Puterman, 1990). Formally, an MDP is described by the tuple $\langle \mathcal{S}, \mathcal{A}, P(s_{t+1}|s_t, a_t), \mathcal{R}(s_t, a_t, s_{t+1}), \pi_0, \gamma \rangle$, with $\mathcal{S}$ as *state space*, $\mathcal{A}$ as the *action space*, $P(s_{t+1}|s_t, a_t)$ as the *transition probability function* indicating the probability of transitioning from state s_t to s_{t+1} given action a_t, where $s_t, s_{t+1} \in \mathcal{S}$ and $a_t \in \mathcal{A}$. The *reward function* $\mathcal{R}(s_t, a_t, s_{t+1})$ specifies the reward for moving from s_t to s_{t+1} by action a_t. The *initial state* π_0 represents the distribution across $\mathcal{S}$, and $\gamma \in [0, 1]$ is the *discount factor* that balances immediate versus future rewards.

2.3. Deep Reinforcement Learning

Deep Reinforcement Learning (DRL) produces virtual agents that interact with environments to learn optimal behaviors through trial and error, as indicated by a reward signal (Arulkumaran et al., 2017). DRL has found applications in robotics, video games, and navigation systems.

We utilize DRL to train agents in virtual environments exhibiting degradation following the MSDM pattern, as detailed in Section 5. Specifically, we apply Proximal Policy Optimization (PPO) (Schulman et al., 2017), a policy gradient method in RL.

PPO aims to optimize the policy an agent uses for action selection, maximizing expected returns. It addresses stability and efficiency issues encountered in previous algorithms like *Trust Region Policy Optimization* by offering a simpler and less computationally expensive method to ensure minor policy updates.

This is achieved through an innovative objective function that penalizes significant deviations from the previous policy, fostering stable and consistent learning. The term "proximal" denotes maintaining proximity between the new and old policies, facilitating a stable training process and rendering PPO popular across various RL applications.

3. Methodology

Our methodology, illustrated in Figure 2, comprises six steps, detailed below.

Step 1. Perform data handling of historical inspection records, selecting subsets (cohorts) of interest, and calibrating the MSDM on this data. This step is beyond the scope of this paper; for details, see Jimenez-Roa et al. (2022, 2024). The results of this step are given in Section 4.

Step 2. After calibrating the MSDM, integrate these models into an environment suitable for RL applications. We present the details of our environment integrating MSDM in Section 5. In addition, we define environments for training RL agents. This is to test different MSDM hypotheses; details on this can be found in Section 6.

Step 3. Train DRL agents with PPO. Use `optuna` for hyperparameter tuning and `Stable Baselines3` for RL implementation. Details are in Section 7.1.

Step 4. Train and select the RL agents with the optimal hyperparameters on the *training* environments. In essence, these agents learn the dynamics described by the MSDM encoded in the environment.

Step 5. Compare the maintenance policies advised by the RL agents using the *test* environment against the heuristics: Condition-Based Maintenance (CBM), Scheduled Maintenance (SchM), and Reactive Maintenance (RM). Find the definition of these heuristics in Section 6.2.

Step 6. Analyze and compare the behavior of the maintenance strategies for the different RL models and heuristics. Reflect on the policies advantages and disadvantages. Find in Section 7.2 the overview of this comparison, and in Section 7.3 are the details along episodes.

4. Multi-state degradation models

4.1. Case study

Our case study conducts a detailed examination of the sewer pipe network in Breda, the Netherlands, which comprises 25,727 sewer pipes covering 1,052 km, mostly built after 1950. The network is primarily made of concrete (72%) and PVC (27%), with the shapes of the pipes being predominantly round (95%) and ovoid (5.4%). These pipes are designed for transportation (98.2%), with 88% being up to 60 meters in length. Additionally, 98.3% have a diameter of up to 1 meter, with the most common diameter being 0.2 meters, and they carry mixed (63%), rain (21%), and waste (16%) contents. The condition of the pipes is evaluated through visual inspections according to the European standard EN 13508 (EN13508, 2012; EN13508-2, 2011), focusing on identifying and classifying damage with specific codes. This study specifically addresses the damage code *BAF*, which signifies *surface damage* and was observed in 35.3% of the inspections.

4.2. Parametrization

We consider three distributions for hazard rate functions: Exponential, Gompertz, and Weibull. The hazard rates $\lambda(t|\cdot)$ for these distributions are specified as follows:

$$\textit{Exponential} \text{ function:} \quad \lambda^E(t|\epsilon) = \epsilon, \tag{3a}$$

$$\textit{Gompertz} \text{ function:} \quad \lambda^G(t|\alpha, \beta) = \alpha\beta e^{\beta t} \tag{3b}$$

$$\textit{Weibull} \text{ function:} \quad \lambda^W(t|\eta, \rho) = \frac{\rho}{\eta}\left(\frac{t}{\eta}\right)^{\rho-1} \tag{3c}$$

In Eq. (3a), a constant hazard rate indicates that the degradation model assumes a *homogeneous* time, exhibiting *memoryless* properties. Eq. (3b) and Eq. (3c) present varying hazard rates, which indicates *inhomogeneous* time.

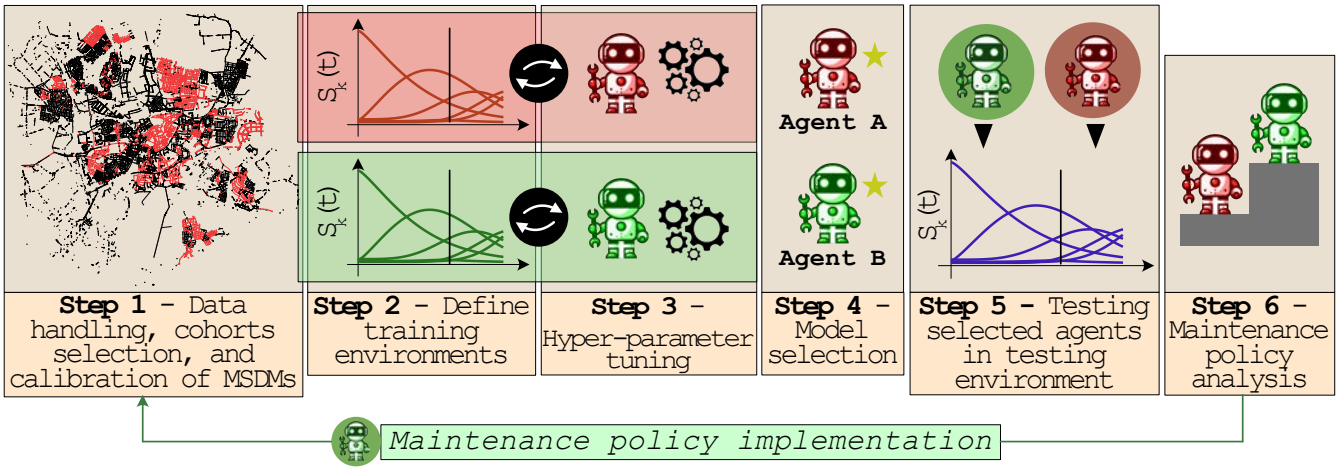

Figure 2. Methodology overview for sewer pipe maintenance policy optimization using Deep Reinforcement Learning and Multi-State Degradation models.

4.3. Solving the Multi-State Degradation Model

In Figure 1, we defined the structure of the Markov chain to model degradation in a sewer pipe, and in Section 4.2 we introduced the hazard rate functions. In the following, we present the corresponding system of differential equations.

$$\frac{\partial S_1(t)}{dt} = -\big(\lambda_{12}(t|\cdot) + \lambda_{1F}(t|\cdot)\big)S_1(t) \tag{4a}$$

$$\frac{\partial S_2(t)}{dt} = \lambda_{12}(t|\cdot)S_1(t) - \big(\lambda_{23}(t|\cdot) + \lambda_{2F}(t|\cdot)\big)S_2(t) \tag{4b}$$

$$\frac{\partial S_3(t)}{dt} = \lambda_{23}(t|\cdot)S_2(t) - \big(\lambda_{34}(t|\cdot) + \lambda_{3F}(t|\cdot)\big)S_3(t) \tag{4c}$$

$$\frac{\partial S_4(t)}{dt} = \lambda_{34}(t|\cdot)S_3(t) + \big(-\lambda_{45}(t|\cdot) - \lambda_{4F}(t|\cdot)\big)S_4(t) \tag{4d}$$

$$\frac{\partial S_5(t)}{dt} = \lambda_{45}(t|\cdot)S_4(t) - \lambda_{5F}(t|\cdot)S_5(t) \tag{4e}$$

$$\frac{\partial S_F(t)}{dt} = \lambda_{1F}(t|\cdot)S_1(t) + \lambda_{2F}(t|\cdot)S_2(t) + \lambda_{3F}(t|\cdot)S_3(t) + \lambda_{4F}(t|\cdot)S_4(t) + \lambda_{5F}(t|\cdot)S_5(t) \tag{4f}$$

Eq. 4 is solved using numerical methods, specifically the `LSODA` algorithm from the FORTRAN `odepack` library implemented in SciPy (Jones et al., 2001–). This algorithm solves systems of ordinary differential equations by employing the `Adams/BDF` method with automatic stiffness detection.

4.4. Parametric Multi-State Degradation Models

We extract a subset from our case study data set to construct a cohort with concrete sewer pipes carrying *mixed and waste content* (cohort `CMW`), representing 37.1% of the sewer network. The model parameters for this cohort are detailed in Appendix A in Tables 7 and 8.

Figure 3 illustrates the MSDMs predictions, detailing the stochastic dynamics of sewer pipe degradation for pipes in cohort `CMW`. As Figure 1 describes, this degradation is segmented into five sequentially ordered severity levels ($k = 1$ to $k = 5$), plus a functional failure state ($k = F$). Differences in the y-axis scales are intentional, to emphasize details and behaviors that various degradation models express across severity levels.

Gray circles represent the frequency per severity level from the inspection dataset. Jimenez-Roa et al. (2022) details how these frequencies are computed. Vertical black lines in Figure 3 mark the last available data point for each severity level.

Additionally, Figure 3 presents the *Turnbull* non-parametric estimator, which assumes no specific distribution for survival times (Turnbull, 1976). In our context, this estimator represents the ground truth of stochastic degradation behavior in sewer pipes.

Tables 1 presents the Root Mean Square Error (RMSE) computed with respect to the Turnbull estimator, for each MSDM assumption, for cohorts `CMW`. These results show that models employing Gompertz and Weibull distributions yield smaller RMSEs compared to the one using the Exponential distribution.

Table 1. RMSE with respect Turnbull estimator, per severity level k and total RMSE, cohort: `CMW`.

	Exponential	Gompertz	Weibull
$S_{k=1}(t)$	3.38E-02	3.27E-02	3.34E-02
$S_{k=2}(t)$	7.04E-02	3.70E-02	3.57E-02
$S_{k=3}(t)$	6.27E-02	2.81E-02	4.38E-02
$S_{k=4}(t)$	4.28E-03	1.13E-02	5.06E-03
$S_{k=5}(t)$	8.33E-03	1.09E-02	3.04E-02
$S_{k=F}(t)$	9.19E-03	1.17E-02	3.62E-03
Total	4.13E-02	2.45E-02	2.96E-02

These MSDMs serve two crucial roles within our environment: first, they drive the degradation behavior of sewer pipes, effectively emulating how sewer pipes degrade over time. Second, the output from the MSDMs is incorporated as prognostic information, available to the agent to support decisions at any

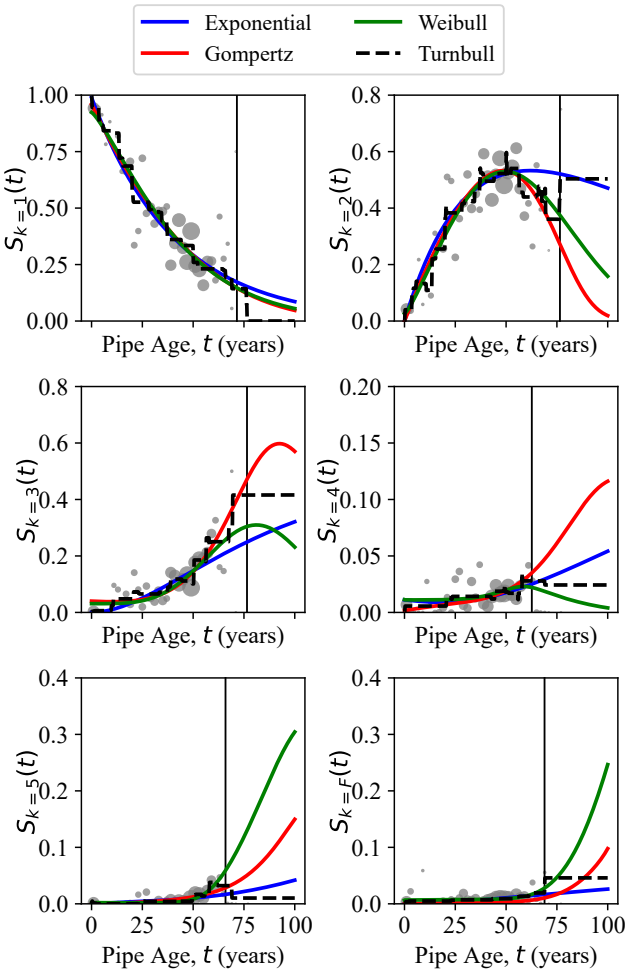

Figure 3. Probability of being in state $k \in \Omega$ at pipe age t $S_k(t)$, using three hazard functions modeled via Exponential, Gompertz, and Weibull probability density functions. The Turnbull non-parametric estimator indicates the ground truth. The gray circles indicate the frequency based on the inspection data set.

time point. This latter aspect is considered a novel feature of our framework. Details on the MDP are provided in the section below.

5. Definition of Markov Decision Process for Maintenance Policy Optimization of a Sewer Pipe considering pipe length degradation

Figure 4 provides the workflow that the RL agent uses to learn maintenance policies for sewer pipes, considering degradation along the pipe length. In the following sections, we provide the details of the environment, namely the state and action spaces, as well as the transition probability and reward functions.

5.1. State space ($\mathcal{S}$)

Our approach focuses on developing age-based maintenance policies, incorporating the sewer pipe's age into the state representation. Our state space is *continuous* and it is structured to include three key components: (i) the age of the pipe, (ii) the *health vector*, and (iii) the stochastic prediction of severity levels. We next describe the last two components.

5.1.1. Health vector (h)

In modeling the degradation of linear structures like sewer pipes, it is essential to represent changes accurately along their length. For this purpose, we define a *health vector* (**h**), which quantitatively measures the degradation at various points along the pipe. The vector is crucial in our framework, particularly influencing the reward function as described in Section 5.4.

Construction of h: We discretize the pipe into segments of equal length ΔL, with $\Delta L < L$, where L is the total length of the pipe. The number of segments, n_d, is calculated using the ceiling function to ensure it remains an integer even if L is not perfectly divisible by ΔL:

$$n_d = \left\lceil \frac{L}{\Delta L} \right\rceil \tag{5}$$

Each segment's degradation level is initially assessed and categorized into *severity levels* according to the MSDM. As the degradation progresses, the state of each segment changes following the transition probabilities described by the matrix $P_{i,j}$, where i is the current severity level, and j is the subsequent severity level, as described by the forward Kolmogorov equation (Eq. 1).

Notice that by doing this, we assume there is no statistical dependency between segments, which is a strong assumption that needs further research. However, for simplicity, we maintain this assumption in our degradation model.

Quantifying Degradation: The distribution of severity levels across the pipe is captured in vector **d**, with each element indicating the severity level of a segment. To quantify this distribution in the health vector **h**, we first count the number of segments at each severity level k using the following expression:

$$n_{d_k} = \sum_{i=1}^{n_d} \mathbf{1}_{\{\mathbf{d}_i = k\}} \tag{6}$$

where $\mathbf{1}$ is the indicator function that is 1 if the condition is true and 0 otherwise. The health vector **h** is then determined by normalizing these counts to reflect the proportion of segments at each severity level:

$$\mathbf{h}_k = \frac{n_{d_k}}{n_d} \tag{7}$$

Here, n_{d_k} is the number of segments at severity level k. Thus, $\mathbf{h}_k$ becomes part of the state space indicating the *level of degradation* present in the pipe.

5.1.2. Stochastic prediction of severity levels

To enable the agent to access information provided by the MSDM, we incorporate the prediction of severity levels into the state space. This is accomplished by solving Eq. 2, yielding a distribution $S_k(t)$.

Finally, our state space is defined as a tuple with 13 elements:

$$\mathcal{S} = \langle \text{Pipe Age}, \mathbf{h}_1, \mathbf{h}_2, \mathbf{h}_3, \mathbf{h}_4, \mathbf{h}_5, \mathbf{h}_F, S_1, S_2, S_3, S_4, S_5, S_F \rangle$$

5.2. Action space ($\mathcal{A}$)

Our action space $\mathcal{A}$ is *discrete* with dimensionality $|\mathcal{A}| = 3$. At each time step t, the agent selects an action a_t. If the decision at time t is *do nothing*, a_t is set to 0. To perform *maintenance*, a_t is set to 1, and to *replace* the pipe, a_t is set to 2. The outcomes of these actions are discussed in Section 5.3.

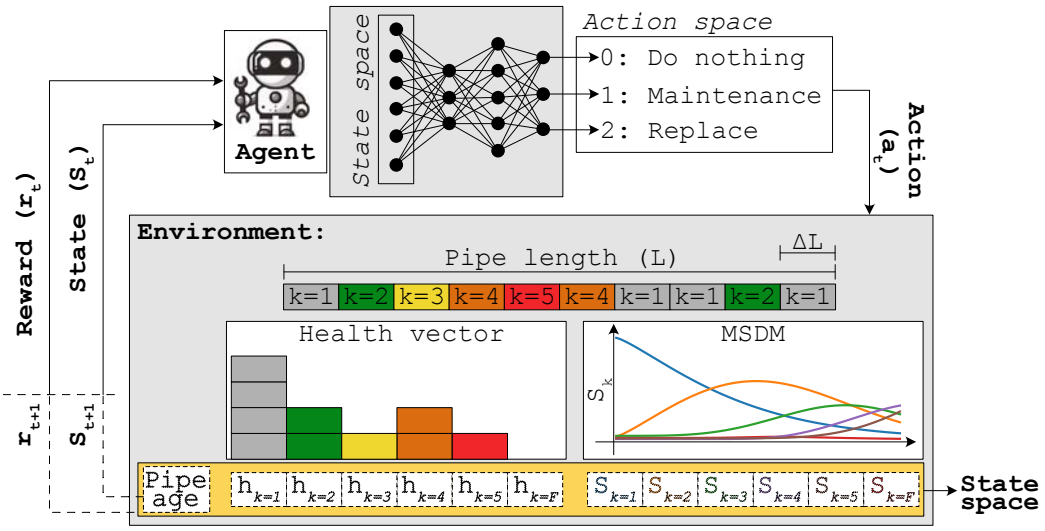

Figure 4. Environment for maintenance policy optimization of a sewer pipe via Deep Reinforcement Learning, considering degradation along the pipe length.

5.3. Transition function (P)

Our transition function $P(s_{t+1}|s_t, a_t)$ is *stochastic*, dependent on time t, and considers both the actions $a \in \mathcal{A}$ and the current s_t and next state s_{t+1} dynamics described by the MSDM. We illustrate the behavior of P with the following example.

For a 30-year-old pipe with length $L = 40$ meters and discretized in segments of length $\Delta L = 1$, let the current state space be $s_{t=30} \in \mathcal{S}$:

$$s_{t=30} = \langle 30, 0.60, 0.35, 0.025, 0.025, 0.0, 0.0, 0.475, 0.436, 0.069, 0.010, 0.005, 0.005 \rangle .$$

$s_{t=30}$ indicates the age of the pipe is 30 years. From Eq. 7, the number of segments at severity k is determined by multiplying the health vector ($\mathbf{h}_k$):

$$\mathbf{h}_k = [0.60, 0.35, 0.025, 0.025, 0.0, 0.0]$$

by 40 meters, yielding $n_{d_k} = [24, 14, 1, 1, 0, 0]$, indicating that, out of the 40 meters of pipe length, 24 segments of 1 meter are at severity $k = 1$, 14 at severity $k = 2$, and so forth.

The distribution $S_k(t = 30.0)$ predicts the probability of being in a severity level k at age $t = 30$. This is achieved by evaluating $t = 30.0$ in the corresponding MSDM.

$$S_k(t = 30.0) = [0.475, 0.436, 0.069, 0.010, 0.005, 0.005]$$

Assuming the agent takes an action every half year, we illustrate the effect of each action in $\mathcal{A}$ below.

- If $a_t = 0$: the agent decides to "do nothing", the pipe's degradation evolves in line with the MSDM progression. Here the new state space becomes $s^{a=0}_{t=30.5}$.

$$s^{a=0}_{t=30.5} = \langle 30.5, 0.575, 0.35, 0.05, 0.025, 0.0, 0.0, 0.470, 0.439, 0.071, 0.010, 0.05, 0.05 \rangle$$

  Notice that the pipe age increased to 30.5, and $n_{d_k} = [23, 14, 2, 1, 0, 0]$, where a segment with severity $k = 1$ progressed to $k = 2$, and one segment with $k = 2$ advanced to $k = 3$. Additionally, $S_k(t)$ is updated by evaluating $t = 30.5$.
- If $a_t = 1$: the agent decides to "perform maintenance," all damage points with severity levels $k \in \{3, 4, 5\}$ are moved to $k = 2$. Consequently, this action does not affect damage points with severity levels $k \in \{1, 2, F\}$. The new state space becomes $s^{a=1}_{t=30.5}$.

$$s^{a=1}_{t=30.5} = \langle 30.5, 0.60, 0.40, 0.0, 0.0, 0.0, 0.0, 0.47, 0.439, 0.071, 0.010, 0.05, 0.05 \rangle$$

  Notice that the pipe age increased to 30.5, and $n_{d_k} = [24, 16, 0, 0, 0, 0]$. However, $S_k(t)$ is updated by evaluating $t = 30.5$, same as when $a_t = 0$.
- If $a_t = 2$: the agent decides to "replace" the pipe, resetting its condition to as good-as-new. The new state space is $s^{a=2}_{t=0.0}$:

$$s^{a=2}_{t=0.0} = \langle 0.0, 1.0, 0.0, 0.0, 0.0, 0.0, 0.0, 0.986, 0.014, 0.0, 0.0, 0.0, 0.0 \rangle .$$

  The pipe age is reset to 0.0, with $n_{d_k} = [40, 0, 0, 0, 0, 0]$, and $S_k(t)$ is updated for $t = 0.0$.

5.4. Reward function ($\mathcal{R}$)

Our reward function $\mathcal{R}(s_t, a_t, s_{t+1})$ assigns a reward r_t at every decision point t, determined by the current state s_t and action a_t. This function integrates the costs of maintenance (C_M), replacement (C_R), and failures (C_F). $\mathcal{R}$ is *sparse* because it issues a non-zero value only when failures occur or interventions are undertaken.

Maintenance cost C_M is calculated as per Eq. 8, where it combines a variable cost based on severity k with a fixed logistic cost of €500, covering the expenses related to maintenance.

These costs vary with the severity level k, as detailed in Table 2. Note that no maintenance costs are associated with $k = F$ because maintenance cannot be performed on a segment that has already failed. In this case, the agent must replace.

$$C_M = -(\mathbf{h}_k \cdot c_M^k + 500) \tag{8}$$

Table 2. Maintenance costs per severity k per segment (c_M^k)

	$k=1$	$k=2$	$k=3$	$k=4$	$k=5$	$k=F$
$c_M^k =$	0	0	-€500	-€700	-€900	N.A.

Replacement costs (C_R) is computed with Eq. 9:

$$C_R = -(450 + 0.66D + 0.0008D^2)L \tag{9}$$

Here, L and D denote the pipe's length in meters and diameter in millimetres, respectively. C_R is in Euros (€).

The cost of failure, denoted by C_F, entails assigning a substantial penalty when the agent allows a segment of the pipe to achieve a failure state ($k = F$). This penalty cost is established at €-100,000. Our reward function is then:

$$r_t = \frac{C_M + C_R + C_F}{100'000 + 900 \times 40} = \frac{C_M + C_R + C_F}{136'000} \tag{10}$$

where r_t represents the reward obtained at time t, the normalization constant $136'000$ corresponds to the most expensive penalty possible at time t. Thus, r_t is defined within the interval $[-1, 0]$. This reward function aims for the agent to balance maintenance actions with the prevention of undesirable pipe conditions.

6. Experimental Setup

6.1. Setup

We will evaluate our framework with a single pipe of constant length (40 meters) and diameter (200 mm) from the cohort `CMW`, which carries mixed and waste content. Given the constant dimensions, the replacement cost C_R, as defined in Eq. 9, is €24,560. The pipe age, when initializing the episode, is randomly sampled from the uniform distribution $U \sim [0, 50]$, allowing the agent to learn the behavior of pipes within this age range. Additionally, we evaluate the policy in steps of half a year and $\Delta L = 1$ meter.

In the methodology section, we describe the training of two agents: **Agent-E** and **Agent-G**. **Agent-E** is trained in an environment where sewer pipe degradation follows the MSDM parameterised with an *Exponential* probability density function, while **Agent-G** is trained in an environment where degradation follows the MSDM parameterised with a *Gompertz* probability density function.

Both agents are tested in an environment where sewer pipe degradation follows the MSDM parameterized with the *Weibull* probability density function.

During training, each agent follows a specific state space, defined as follows:

$$\mathcal{S}^{\text{Agent-E}}_{\text{Training}} = \langle \text{Pipe Age}, \mathbf{h}_k^E, S_k^E(t) \rangle \tag{11a}$$

$$\mathcal{S}^{\text{Agent-G}}_{\text{Training}} = \langle \text{Pipe Age}, \mathbf{h}_k^G, S_k^G(t) \rangle \tag{11b}$$

Here, $\mathcal{S}$ represents the state space for each agent during training. The subscripts E and G denote the *Exponential* and *Gompertz* probability density functions, respectively. Each agent's objective is to learn an optimal maintenance strategy based on their environment's dynamics.

For testing, both agents are evaluated in the same environment, with the state space defined as follows:

$$\mathcal{S}^{\text{Agent-E}}_{\text{Testing}} = \langle \text{Pipe Age}, \mathbf{h}_k^W, S_k^E(t) \rangle \tag{12a}$$

$$\mathcal{S}^{\text{Agent-G}}_{\text{Testing}} = \langle \text{Pipe Age}, \mathbf{h}_k^W, S_k^G(t) \rangle \tag{12b}$$

In both cases, $S_k^E(t)$ and $S_k^G(t)$ remain consistent with the training phase, reflecting the MSDM predictions. However, the health vector $\mathbf{h}_k$ follows the degradation behavior described by the *Weibull* probability density function, indicated by the subscript W.

6.2. Comparison of maintenance strategies

We compare the RL agent's performance against maintenance policies based on heuristics. For this, we define the following:

- **Condition-Based Maintenance (CBM)**: Maintenance actions are based on the sewer pipe's condition. Specifically, replacement ($a_t = 2$) is performed if `pipe_age` ≥ 70 or $\mathbf{h}_{k=F} \geq 0.0$; maintenance ($a_t = 1$) is conducted if $\mathbf{h}_{k=4} \geq 0.1$ or $\mathbf{h}_{k=5} \geq 0.05$; otherwise, no action ($a_t = 0$) is taken.
- **Scheduled Maintenance (SchM)**: Actions are time-based. Replacement ($a_t = 2$) is executed if $\mathbf{h}_{k=F} \geq 0.0$; maintenance ($a_t = 1$) occurs every 10 years; otherwise, no action ($a_t = 0$) is taken.
- **Reactive Maintenance (RM)**: Replacement is undertaken only upon pipe failure, i.e., replacement ($a_t = 2$) is performed if $\mathbf{h}_{k=F} \geq 0.0$; otherwise, no action ($a_t = 0$) is taken.

Note that CBM and SchM are defined based on plausible values. However, these heuristics can be further calibrated for enhanced performance, which is beyond the scope of this paper.

7. Results

7.1. Implementation and hyper-parameter tuning

Our framework uses `Stable Baselines3` (Raffin et al., 2021), comprising robust implementations of RL algorithms in PyTorch (Ansel et al., 2024). Specifically, we utilize the PPO algorithm. Hyper-parameter optimization is performed using `optuna` (Akiba et al., 2019), a framework dedicated to automating the optimization of hyper-parameters.

The search space encompasses: exponentially-decaying learning rate with a decay rate of 0.05, with an initial learning rate ranging from 10^{-5} to 10^{-2}, discount factor (γ) from 0.8 to 0.9999, entropy coefficient from 0.0001 to 0.01, steps per update (`n_steps`) from 250 to 3000, batch sizes from 16 to 256, activation functions ('tanh', 'relu', 'sigmoid'), policy network architectures ([16, 16], [32, 32], [64, 64], [32, 32, 32]), and training epochs (`n_epochs`) from 5 to 100.

We set up `optuna` to conduct 500 trials, aiming to maximise cumulative reward in 100 episodes. Table 3 details the optimal

hyper-parameters identified. These parameters are used to obtain the results discussed in Sections 7.2 and 7.3, where our agents are trained over a total of 5 million time steps.

Table 3. Optimal hyper-parameters found using `optuna`.

Hyper-parameter	Value
Learning rate	0.0003
Discount factor	0.995
Entropy coefficient	0.008
Steps per update (`n_steps`)	2080
Batch size	104
Activation function	Sigmoid
Policy network architecture	[32, 32, 32]
Training epochs (`n_epochs`)	50

7.2. Policy analysis: overview

This section offers a broad evaluation of the policies, with a detailed analysis over episodes presented in Section 7.3. We compare the agents' performances with the heuristics detailed in Section 6.2 across 100 simulations in the **test** environment (Eq. 12), considering pipe ages of 0, 25, and 50 years, aiming to evaluate policy efficacy concerning degradation over varying pipe ages.

Table 4 presents the *mean policy cost* for Agent-E, Agent-G, CBM, SchM, and RM, highlighting the best and second-best policies in blue and red, with corresponding means and standard deviations from the simulations.

Table 4. Policy cost comparison: Mean and standard deviation (Std.) of costs for Agent-E, Agent-G, CBM, SchM, and RM, evaluated over 100 episodes in the test environment. Costs, in thousands of Euros (€), for pipe ages of 0, 25, and 50 years.

	Pipe age: 0		Pipe age: 25		Pipe age: 50	
Policy	Mean	Std.	Mean	Std.	Mean	Std.
Agent-E	51.3	80.8	116.5	97.7	156.8	121.2
Agent-G	**39.7**	66.2	**78.7**	96.6	**127.1**	128.3
CBM	51.3	107.2	112.3	88.5	**110.7**	86.6
SchM	**42.5**	70.9	**78.9**	96.4	159.8	95.9
RM	48.6	76.6	135.8	86.5	165.7	80.8

From these results, we observe that Agent-G's policy generally outperforms others for pipe ages of 0 and 25 years, securing a second-best position for pipes aged 50 years. It is noted that the cost of all policies increases with pipe age, which aligns with expectations as older pipes require more interventions.

After reviewing the mean policy costs, our focus shifts to the specific actions involved in each policy. Table 5 provides a summary of the actions executed by each policy across simulations for different pipe ages. For new pipes, the SchM policy leads in maintenance activities ($a_t = 1$), with Agent-G following. In terms of replacements ($a_t = 2$), Agent-E is the foremost in implementing this action, with CMB in second place. Both Agent-G and SchM exhibit lower replacement frequencies, explaining the mean policy costs since maintenance actions incur lower expenses compared to the penalties and replacement costs resulting from pipe failures.

For pipes aged 25 years, Agent-G executes more maintenance actions ($a_t = 1$), similar to SchM. Agent-E opts for no maintenance, aligning more with RM's strategy. Although CBM carries out some maintenance actions, replacement actions predominate, indicating a greater tendency to permit pipe failures, which explains the observed differences in mean policy costs.

Table 5. Percentage of actions per policy obtained with Agent-E, Agent-G, CBM, SchM, and RM, evaluated over 100 episodes in the test environment, for different pipe ages.

Pipe age	Action	Agent-E	Agent-G	CBM	SchM	RM
0	$a_t = 0$	99.5	97.51	99.54	94.76	99.61
	$a_t = 1$	0.0	2.21	0.05	4.95	0.00
	$a_t = 2$	0.5	0.28	0.41	0.29	0.39
25	$a_t = 0$	98.81	94.96	98.14	94.56	98.92
	$a_t = 1$	0.00	4.50	0.62	4.94	0.00
	$a_t = 2$	1.19	0.53	1.24	0.50	1.08
50	$a_t = 0$	98.4	94.52	98.05	93.99	98.68
	$a_t = 1$	0.0	4.43	0.67	4.88	0.00
	$a_t = 2$	1.6	1.05	1.28	1.13	1.32

For pipes aged 50 years, CMB offers the most cost-effective policy, with Agent-G's following. CMB conducts fewer maintenance actions and more replacements than Agent-G, accounting for the cost disparity. The policies of Agent-E, RM, and SchM have similar costs. Despite SchM conducting more maintenance, its high number of replacements suggests the maintenance interval requires adjustment. These results indicate that the strategies of CBM, SchM, and RM are less efficient for older pipes due to their higher failure probability.

Regarding the *mean pipe severity level* to assess the impact of various policies on pipe degradation, as shown in Table 6. Our analysis reveals a notable correlation between the average actions per policy, detailed in Table 5, and the mean pipe severity level. Specifically, the Agent-G control strategy tends to maintain pipes within a severity level of $k \in [1, 2, 3]$, whereas the Agent-E, CBM, SchM, and RM policies often result in higher severity levels $k \in [4, 5, F]$, which correlates with increased policy costs.

Table 6. Percentage of severity level per policy obtained with Agent-E, Agent-G, CBM, SchM, and RM, evaluated over 100 episodes in the test environment, for different pipe ages.

Pipe age	Severity	Agent-E	Agent-G	CBM	SchM	RM
0	$k = 1$	59.77	58.75	59.94	59.84	58.88
	$k = 2$	33.27	39.14	32.67	38.05	33.15
	$k = 3$	5.39	1.70	6.00	1.79	6.36
	$k = 4$	1.38	0.28	1.13	0.26	1.30
	$k = 5$	0.18	0.13	0.25	0.04	0.31
	$k = F$	0.01	0.01	0.01	0.01	0.01
25	$k = 1$	50.49	41.72	46.88	39.07	46.62
	$k = 2$	38.96	55.27	43.09	55.55	40.86
	$k = 3$	8.37	2.63	8.48	4.85	9.80
	$k = 4$	1.37	0.29	1.18	0.41	1.51
	$k = 5$	0.78	0.07	0.36	0.10	1.18
	$k = F$	0.02	0.01	0.02	0.01	0.03
50	$k = 1$	57.93	44.65	55.01	40.92	54.36
	$k = 2$	32.58	51.40	36.14	50.46	33.09
	$k = 3$	7.50	3.29	7.20	7.34	9.32
	$k = 4$	1.31	0.39	1.19	0.59	1.64
	$k = 5$	0.65	0.25	0.43	0.67	1.55
	$k = F$	0.03	0.02	0.02	0.03	0.03

To summarize, our findings indicate that the Agent-G's policy, derived using DRL, implements a dynamic management strategy that varies with the pipe's age. This strategy encompasses a more passive approach with new pipes, transitioning to active intervention as the pipes age. This indicates the agent's preference for more frequent maintenance actions rather than allowing pipe failures, which incur higher penalties and replacement costs.

Moreover, Agent-G outperforms Agent-E, illustrating the impact of the degradation model assumption. Specifically, Agent-G's prognostic model used during training aligns more closely with the test environment's degradation pattern than Agent-E's, potentially explaining why Agent-G is better equipped to navigate and understand the degradation pattern. This, in turn, enables it to devise a more effective maintenance policy by leveraging a more accurate degradation model.

7.3. Policy analysis over episode

In Section 7.2, we present an overview of policy performances. This section delves into the details per episode to provide further understanding on these policies. Figures 5, 6, and 7 detail the performance of the Agent-E, Agent-G, CMB, and SchM policies for pipes with ages 0, 25 and 50, respectively. The RM heuristic is excluded from this analysis due to its straightforward approach: allowing the pipe to fail before replacing it.

Figure 5 shows that for a brand new pipe: (a) Agent-G performs maintenance on the pipe at approximately 32 years old; (b) Agent-E opts to replace the pipe when it is around 35 years old, which may be attributed to the presence of elements with higher severity levels in that specific episode; (c) CBM chooses not to act, which results in the least expensive policy in this comparison. However, it is observed that some pipe sections reach severity level $k = 5$ throughout the episode. Not taking any action is deemed risky since progressing to $k = F$ becomes more likely and incurs higher costs; (d) SchM effectively controls severity levels but is more expensive than Agent-G's policy due to more frequent maintenance actions.

Figure 6 shows that for a pipe aged 25: (a) Agent-G exhibits increased activity, indicating more frequent maintenance actions, especially as the pipe ages to 50, shortening the maintenance intervals; (b) Agent-E postpones any action until the pipe fails, at which point it replaces the pipe with a new one, akin to RM; (c) CBM also initiates maintenance around the pipe's 50-year mark. However, degradation escalates from age 60, leading to failure at 66. The inability to manage this increased severity results in significant penalty costs, diminishing the effectiveness of this policy; (d) Similarly, SchM manages severity levels effectively until the pipe reaches approximately 70 years of age, at which point degradation accelerates, resulting in failure at 73.

Figure 7 shows that for a pipe aged 50: (a) Agent-G opts to replace the pipe at age 50, followed by maintenance in the subsequent time step. This decision is likely influenced by parts of the pipe being at severity levels $k \in 3, 4$. Such a scenario is plausible, as new pipes can exhibit high severity levels at a young age due to defects in the material or errors during the construction and installation process. This concept is represented in the MSDM by the initial probability state vector (S_k^0). Additionally, Agent-G recommends maintenance at the interval when the pipe reaches the age of 26 years; (b) Agent-E suggests replacement at approximately 62 years, without recommending further maintenance; (c) CMB advocates for maintenance at about 65 years, followed by replacement at 70 years, in line with heuristics described in Section 6.2; (d) SchM consistently performs maintenance at regular intervals, yet faces significant degradation, culminating in failure around 97 years.

8. Discussion and Conclusions

In this paper, we explore the applications of Prognostics and Health Management (PHM) in sewer pipe asset management. Our study focuses on component-level (i.e., pipe-level) maintenance policy optimization by integrating stochastic multi-state degradation modeling and Deep Reinforcement Learning (DRL). The goal is to assess the effectiveness of DRL in deriving cost-effective maintenance strategies tailored to the specific conditions and requirements of sewer pipes.

A key contribution of our work is the integration of prognostics models with a maintenance policy optimization framework. We utilize a tailored reward function that aligns with damage severity levels, enabling a more complex and realistic maintenance optimization setup.

Our methodology includes a real-world case study from a Dutch sewer network, which provides historical inspection data. Through hyper-parameter tuning and policy analysis, we benchmark our optimized policies against traditional heuristics, including condition-based, scheduled, and reactive maintenance.

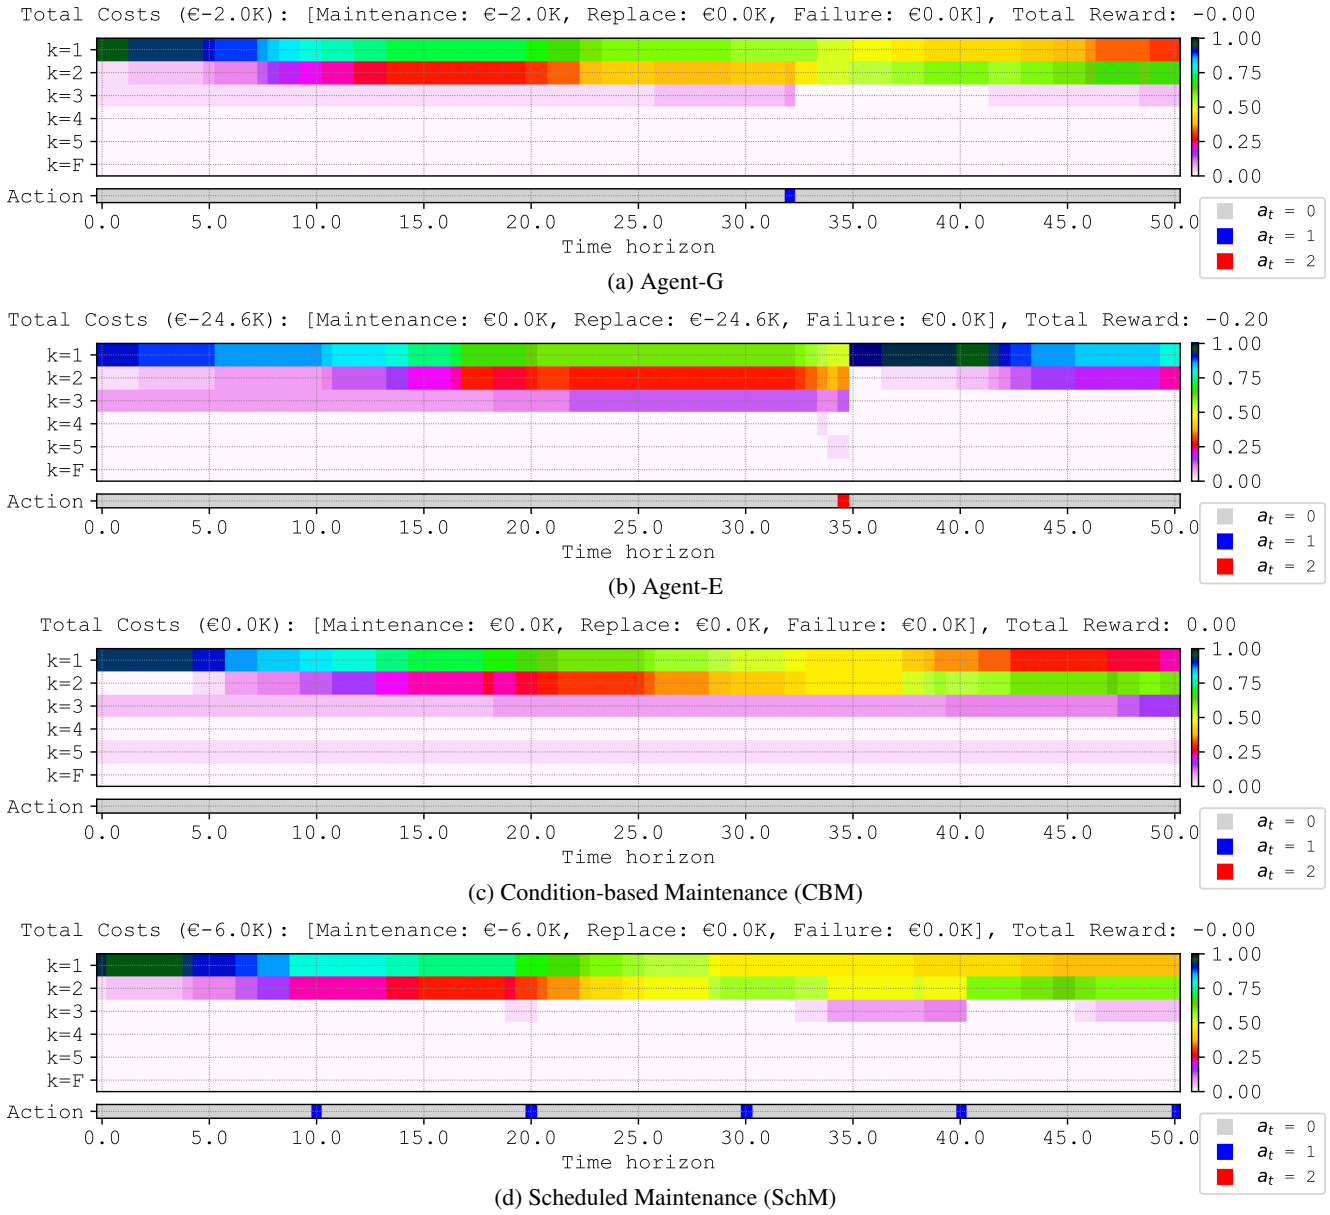
Our findings suggest that agents trained with the Proximal Policy Optimization algorithm are highly capable of developing strategic maintenance policies, adapting to pipe age, and surpassing heuristic baselines by learning cost-effective dynamic management strategies.

To evaluate the impact of degradation model assumptions, we trained one agent using the Gompertz probability density function and another using the Exponential probability density function.

During testing, both agents were assessed in an environment parameterized with the Weibull probability density function. The Gompertz-trained agent, whose behavior more closely resembled the Weibull model, demonstrated better generalization, resulting in more effective maintenance policies compared to the Exponential-trained agent.

Future work: The following directions are identified:

- Advancing toward partially observable state spaces with the introduction of inspection actions, considering context, and leveraging deep learning capabilities.
- Utilizing knowledge acquired by agents to develop explainable and robust heuristics.
- Although this paper focused on a single cohort of pipes, studies in Jimenez-Roa et al. (2022, 2024) show different cohorts exhibit varied dynamics, highlighting the importance of understanding how RL agents adapt.
- Comparing RL-based approaches with other policy optimization algorithms to better understand the capacity of RL methods to achieve global-optima maintenance strategies.
- Investigating various reward functions (e.g., dense) and RL algorithms to determine the most effective for devising maintenance policies.
- Extent to system-level analysis and evaluate aspects such



(a) Agent-G

(b) Agent-E

(c) Condition-based Maintenance (CBM)

(d) Scheduled Maintenance (SchM)

Figure 5. Behavior of policies over an episode for a **new pipe**, showing the health vector over the pipe age and actions per policy: (a) Agent-G, (b) Agent-E, (c) Condition-based Maintenance (CBM), and (d) Scheduled Maintenance (SchM).

as scalability.
- Moving toward multi-infrastructure asset management to promote coordinated management for optimizing costs and minimizing disruption from interventions.

BIOGRAPHIES

Lisandro A. Jimenez-Roa is a doctoral candidate in Computer Science at the University of Twente, The Netherlands. He has a background in civil engineering and has contributed to various projects in structural health monitoring, finite element modeling, and damage detection through data analytics and machine learning. His current research focuses on Prognostics and Health Management, specifically engineering systems within the PrimaVera project (**https://primavera-project.com**), emphasizing multi-state stochastic degradation modeling and maintenance policy optimization using Reinforcement Learning techniques.

Thiago D. Simão is an Assistant Professor in the Eindhoven University of Technology, the Netherlands. He obtained his PhD in Computer Science at Delft University of Technology. Previously, he was a PostDoc researcher at Radboud University Nijmegen. His research interests lie primarily in reliably automating sequential decision-making, focusing on reinforcement learning.

Zaharah Bukhsh is an assistant professor at Eindhoven University of Technology, Eindhoven, Netherlands . She holds a Master's degree in computer science and a Ph.D. in engineering technology from University of Twente, Enschede, Netherlands. Her research focuses on developing data-driven methods with deep learning and deep reinforcement learning. Her research targets broad application areas including asset management, scheduling, and resource optimization. She has contributed to several H2020 and NWO research projects.

Tiedo Tinga is a full professor in dynamics based maintenance at the University of Twente since 2012 and full professor of Life Cycle Management at the Netherlands Defence Academy since 2016. He received his Ph.D. degree in mechanics of materials from Eindhoven University in 2009. He is chairing the smart maintenance knowledge center and leads a number of research projects on developing predictive maintenance concepts, mainly based on the physics of failure models, but also following data-driven approaches.

Hajo Molegraaf completed his PhD at the University of Groningen and has worked as an assistant and postdoc researcher at the University of Geneva and Yale University. Since October 2022, Molegraaf joined as a Research Fellow within the Formal Methods and Tools (FMT) group in the EEMCS faculty at Twente. Additionally, Molegraaf is a co-founder and software developer at Rolsch Assetmanagement, a company based in Enschede, The Netherlands.

Nils Jansen is a full professor at the Ruhr-University Bochum, Germany, and leads the chair of Artificial Intelligence and Formal Methods. The mission of his chair is to increase the trustworthiness of Artificial Intelligence (AI). Prof. Jansen is also an associate professor at Radboud University, Nijmegen, The Netherlands. He was a research associate at the University of Texas at Austin and received his Ph.D. with distinction from RWTH Aachen University, Germany. His research is on intelligent decision-making under uncertainty, focusing on formal reasoning about the safety and dependability of artificial intelligence (AI). He holds several grants in academic and industrial settings, including an ERC starting grant titled Data-Driven Verification and Learning Under Uncertainty (DEUCE).

Mariëlle Stoelinga is a full professor of risk analysis for high-tech systems, both at the University of Twente and Radboud University, the Netherlands. She holds a Master's degree in Mathematics & Computer Science, and a Ph.D. in Computer Science. After her Ph.D., she has been a postdoctoral researcher at the University of California at Santa Cruz, USA. Prof. Stoelinga leads various research projects, including a large national consortium on Predictive Maintenance and an ERC consolidator grant on safety and security interactions.

ABSTRACT

Model-based diagnosis is concerned with diagnosing faults or malfunction of real-world physical or cyberphysical systems using a model of the structure and behavior of the systems. As cyberphysical systems can be extremely large and complex, and the associated computational models will be then equally large and complex, they impose a hard to beat challenge on the computational feasibility of reasoning with such models. When such a model is able to handle the uncertainty associated with diagnostics, giving rise to probabilistic model-based diagnostics, the computational feasibility becomes even harder. This paper: (1) proposes a novel graphical method underlying model-based diagnostics; (2) demonstrates experimentally how a novel, by the authors developed architecture of partitioned positive weighted model counting, is able to handle exact inference to answer a variety of probabilistic queries regarding the health status of a cyberphysical system. Results obtained are well within acceptable time bounds.

1. INTRODUCTION

Cyberphysical systems combine and integrate physical and computational processes often with a special role for sensor information (Lee, 2008). Nowadays, because of the explosive rise in the role of embedded software in physical systems, there are many of such systems, for example industrial printing or vending machines. In particular in a commercial setting, such machines are desired to experience the least possible downtime, as being out of order usually has undesirable, often financial, consequences for the users. Thus there is a need to find the causes of malfunction as quickly as possible, a process usually referred to a *diagnosis*, a terms taken from the field of medicine (Lucas, 1996); the terms *troubleshooting* and *fault-finding* are also often used in engineering. In the case of cyberphysical systems faults or defects concern physical or software components, or possibly their interaction. The purpose of the diagnostic process consists of automated fault finding followed by repair or assisting technicians in a repair job on site (Grievink, 2022).

Automated computer-based diagnosis in engineering has a long-standing tradition, where in particular fault tree analysis is a commonly used technique (Ruijters & Stoelinga, 2015). However, other automated fault detection and analysis methods have also been developed (Dowdeswell, Sinha, & MacDonell, 2020). In the present paper we depart from a framework developed in the 1980s by Johan de Kleer, and which is known as *model-based diagnosis*, MBD for short (de Kleer & Williams, 1987). The adjective 'model-based' comes from the principle that with the design of a machine one possesses already valuable knowledge about its structure or architecture and its functional components and their interactions before the machine is actually produced, purchased, and employed in practice. This knowledge can be put to use in a diagnostic setting.

De Kleer's method of model-based diagnosis is based on comparing qualitative predictions of behavior of a *model* of a given machine with actual observations, which explains why it is also called *consistency-based diagnosis* (CBD) (Reiter, 1987). CBD is traditionally seen as a kind of symbolic or logical assumption-based reasoning (Genesereth & Nilsson, 1987). However, even in the early days of MBD it was realized that probabilistic information could play a role in improving the accuracy of diagnostic solutions (de Kleer, 1991). It was subsequently proved by Judea Pearl that MBD can be mapped to the multivariate probabilistic representation of Bayesian networks (Pearl, 1988). The advantage of Bayesian networks as a formalism of model-based diagnosis is that in principle uncertain, probabilistic knowledge about the occurrence of faults can be integrated and also learned from data.

However, a well-known problem of MBD, and probabilistic MBD is no exception, is that models can be very large and thus inference is often infeasible. There can be little doubt that with the large and complex cyberphysical systems developed today, and even more so in the future, building and performing inference with such models will hit computational obstacles. During the last few years we have been working on moving the boundaries of probabilistic inference by developing a novel framework referred to as *partitioned positive weighted model counting* (that can also be parallelized), inspired by the success of model counting in software verification (Dal & Lucas, 2017; Dal, Laarman, Hommersom, & Lucas, 2021). This framework was shown in various papers to be superior to other probabilistic methods (Dal et al., 2021; Dal, Laarman, & Lucas, 2023). This made us wonder whether it might be a good candidate for model-based diagnosis of large cyberphysical systems. Positive weighted model counting exploits symmetries in probability tables, which typically also occur in models used in MBD.

The main contributions of this paper are as follows:

- A new representation of compositional Bayesian networks that supports developing large probabilistic model-based systems from specifications of system components;
- A novel method of probabilistic model-based diagnosis, we call it *Bayesian* model-based diagnosis, that properly takes into account the dependences between components in MBD, different from an earlier developed and limited method (Grievink, 2022);
- Experimental evidence that our publicly available software tool PARAGNOSIS [1] (Dal et al., 2023), implementing partitioned weighted model counting, supports solving diagnostic problems of systems with different size and complexity, including very large and complex ones.

The organization of this paper is as follows. First, in Section 2, some basic principles of consistency-based diagnosis are introduced, follows by a compact summary of the method of weighted model counting, and the mapping of MBD to Bayesian networks. As our work on partitioned positive weighted model counting has been extensive published, we refer for details about how it works to those publications (Dal & Lucas, 2017; Dal, Michels, & Lucas, 2017; Dal et al., 2021, 2023). In Section 3 the compositional method of assumption-based Bayesian model-based diagnosis is developed. Experimental results are summarized in Section 4, which is followed by conclusions and a discussion of the results in Section 5.

2. BACKGROUND

2.1. Consistency-based Diagnosis

Given specific input and output of a cyberphysical system, the output of the model of the system is compared with the observed output of the (real) system. A discrepancy between these two indicates a fault or malfunction in the actual system and explains the name 'consistency-based diagnosis' (Reiter, 1987). Below, some of the common definitions that occur in the literature on CBD are repeated and adapted, where in particular (de Kleer, Mackworth, & Reiter, 1992) is followed.

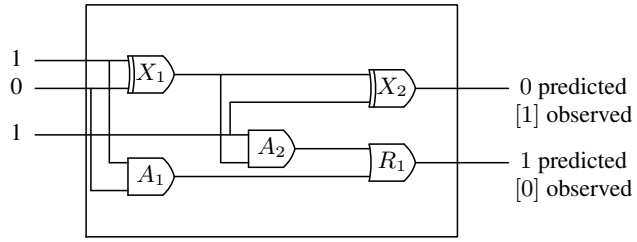

Figure 1. Full adder with inputs and observed and predicted outputs. Here, Obs $= \{\text{in1}(X1) = 1, \text{in2}(X1) = 0, \text{in1}(A2) = 1, \text{out}(X2) = 1, \text{out}(R1) = 0\}$.

A *diagnostic problem* DP is defined as a system SYS together with a *set of observation* Obs: DP $= (\text{SYS}, \text{Obs})$. A *system* SYS consists of a *system description* SD and a set of *components* Comps: SYS $= (\text{SD}, \text{Comps})$. The system description defines the normal behavior of components and how these components are connected by means of first-order logical sentences. Given SYS, a *diagnosis* $D \subseteq$ Comps is defined as a *subset-minimal* set of components that, when behaving abnormally, explains the observation of a faulty system. Formally, a diagnosis is defined as a subset-minimal set $D \subseteq$ Comps such that:

$$\text{SD} \cup \text{Obs} \cup \{\text{Ab}(c) \mid c \in D\} \cup \{\neg\text{Ab}(c) \mid c \in \text{Comps} \backslash D\} \not\models \bot \quad (1)$$

where 'Ab' is the abnormality predicate that indicates that a component c behaves abnormally (and thus $\neg$Ab indicates normal behavior) and $\bot$ is falsum (the left-hand side of $\not\models$ is consistent).

Example 2.1 (Adapted from (Reiter, 1987))**.** *Consider the logical circuit depicted in Fig. 1, which represents a full adder, i.e. a circuit that can be used for the addition of two bits with carry-in and carry-out bits. This circuit consists of two* AND *gates (*$A1$ *and* $A2$*), one OR gate (*$R1$*) and two exclusive-*OR *(*XOR*) gates (*$X1$ *and* $X2$*);* $\text{Comps} = \{A1, A2, X1, X2, R1\}$. *The input and output of components* c *are denoted as* $\text{in}(c)$ *and* $\text{out}(c)$*, respectively.*

The behavior description SD *consists of the following axioms:*

$$\neg\text{Ab}(c) \rightarrow \text{out}(c) = \text{and}(\text{in1}(c), \text{in2}(c)), \textit{ for } c \in \{A1, A2\},$$
$$\neg\text{Ab}(c) \rightarrow \text{out}(c) = \text{xor}(\text{in1}(c), \text{in2}(c)), \textit{ for } c \in \{X1, X2\},$$
$$\neg\text{Ab}(c) \rightarrow \text{out}(c) = \text{or}(\text{in1}(c), \text{in2}(c)), \textit{ for } c = R1.$$

These logical rules describe the normal behavior of each individual component (gate).

[1] https://github.com/gisodal/paragnosis

The component connections are described as follows:

$$\begin{aligned} \text{out}(X1) &= \text{in2}(A2) & \text{out}(X1) &= \text{in1}(X2) \\ \text{out}(A2) &= \text{in1}(R1) & \text{in1}(A2) &= \text{in2}(X2) \\ \text{in1}(X1) &= \text{in1}(A1) & \text{in2}(X1) &= \text{in2}(A1)\ . \\ \text{out}(A1) &= \text{in2}(R1) \end{aligned}$$

With the observations Obs *as indicated in Fig. 1 it is clear that when assuming the empty diagnosis, $D = \emptyset$ — all components are behaving normally — 1 will give an inconsistency, as also indicated in the figure (predicted and observed outputs differ). There are multiple solutions for the diagnostic problem in this case. For example, $D = \{X1\}$, $D' = \{X2, R1\}$, and $D'' = \{X2, A2\}$ are diagnoses.*

2.2. Weighted Model Counting

2.2.1. Bayesian Networks

A *Bayesian network* (BN) $\mathcal{B} = (G, P)$ is a directed acyclic graph $G = (V, A)$ that associates 1–1 random variables X_v to nodes $v \in V$ in the graph (Pearl, 1988). The directed edges $(v, w) \in A$ represent conditional (in)dependence assumptions and P stands for a joint probability distribution of the set of variables X_V defined as follows:

$$P(X_V = x_V) = \prod_{v \in V} P(X_v = x_v \mid X_{\pi(v)} = x_{\pi(v)}) \quad (2)$$

Thus, a BN is defined in terms of a (family of) conditional probability distributions of $X_v \in X_V$ given the variables corresponding to the parents $\pi(v)$ of $v \in V$ in the graph, i.e., $X_{\pi(v)}$, specified as $P(X_v \mid X_{\pi(v)})$, called *conditional probability tables* or CPTs for short in the following.

Posterior probability distributions of the form

$$P(X_U \mid \text{Evidence}), \quad (3)$$

with 'Evidence' a set of *observations* or measurements concerning particular variables $X_v \in X_V$, with typically $v \notin U$, $U \subseteq V$, can be computed based on the specification of a BN —a process called *probabilistic inference* or *reasoning*— using common axioms of probability theory. However, for real-life networks advanced algorithms are required as the computation is NP-hard in general and often quite intensive for real-life networks (Koller & Friedman, 2009).

By exploiting the conditional independence assumptions, BNs represent concise factorizations of a joint probability distribution. The size of the factorization has direct implications toward the cost of probabilistic inference. A more expressive model must be used to in order to exploit properties of CPTs (Chavira & Darwiche, 2008). A prominent way of achieving this is to find a more concise and canonical representation such as a Binary Decision Diagram (BDD) (Bryant, 1986). Compiling a BN to a decision diagram (DD) representation is commonly referred to as *knowledge compilation* (Darwiche & Marquis, 2002), or simply compilation.

Table 1. Three examples of models of the encoding of variable X and associated probability distribution.

	Models					Associated probability
1	x_1	$\overline{x_2}$	$\overline{x_3}$	ω_1	$\overline{\omega_2}$	$W(\omega_1)W(\overline{\omega_2})=0.8 \cdot 1 = 0.8$
2	$\overline{x_1}$	x_2	$\overline{x_3}$	$\overline{\omega_1}$	ω_2	$W(\overline{\omega_1})W(\omega_2)=1 \cdot 0.1 = 0.1$
3	$\overline{x_1}$	$\overline{x_2}$	x_3	$\overline{\omega_1}$	ω_2	$W(\overline{\omega_1})W(\omega_2)=1 \cdot 0.1 = 0.1$

2.2.2. Encoding

Prior to compiling a BN to a DD, we require an encoding to transition from the multi-valued domain of discrete random variables to the Boolean domain. There are multiple ways to do this. We choose to first translate a BN to a Boolean formula with dedicated variables to represent probabilities (Chavira & Darwiche, 2008; Dal & Lucas, 2017).

Conjunctive Normal Form (CNF) from logic, where formulas consist of conjunctions of subformulas of literals with only disjunctions, called *clauses*, is commonly used to facilitate compilation. We create for every $X_v \in X_V$ a set of atoms $a(X_v) = \{x_1, \ldots, x_n\}$. Semantically, $x_i \in a(X_v)$ represents X_v being equal its i^{th} value. In addition, an atom ω_j is introduced for every unique probability in X_v's CPT, i.e., ω_j can refer to multiple distinct entries in X_v's CPT if they represent the same probability. A clause is introduced for each entry of the CPT, with an ω_j atom that has a weight $W(\omega_j)$ that is linked to the actual probability, and $W(\overline{\omega_j}) = 1$. Finally clauses are added to prevent inconsistent representations, such as making sure that a variable cannot get multiple values at the same time. This is illustrated by an example (Dal & Lucas, 2017)

Example 2.2 (Bayesian Network encoding)**.** *Let BN $\mathcal{B}$ be defined for variables $\{X, Y\}$ with factorization $P(X, Y) = P(Y \mid X)P(X)$. For simplicity's sake, we focus on just variable X; X has three values, thus the CPT has 3 entries, in this case only two distinct. To encode X and its probabilities we create atoms $a(X) = \{x_1, x_2, x_3\}$. The atom ω_1 is introduced for $X = 1$, ω_2 for $X = 2$ and $X = 3$ (as they have the same probability), with $W(\omega_1) = 0.8$, $W(\omega_2) = 0.1$.*

The CNF representation is as follows:

$$(x_1 \vee x_2 \vee x_3) \wedge (\overline{x_1} \vee \overline{x_2}) \wedge (\overline{x_1} \vee \overline{x_3}) \wedge (\overline{x_2} \vee \overline{x_3}) \wedge (\overline{x_1} \vee \omega_1) \wedge (\overline{x_2} \vee \omega_2) \wedge (\overline{x_3} \vee \omega_2)$$

The first clause enumerates the possible values of X, whereas the second to fourth clause ensure that X (as a random variable) cannot have more than one value. The last three clauses link a probability to an actual value of X. The encoding includes the truth assignments (models) for variable X as shown in Table 1. Note that the weighted model count sums to 1.0 *for this selection of models. However, there are other*

models of this CNF, e.g., model $\{x_1,\overline{x_2},\overline{x_3},\omega_1,\omega_2\}$*, model* $\{\overline{x_1}, x_2, \overline{x_3}, \omega_1, \omega_2\}$*, etc. Only minimal models sum to* 1.0*, i.e., models with the largest number of negations.*

2.2.3. Compilation

Now that we have an encoding, we can consider its compilation to a *Weighted Positive Binary Decision Diagrams* (WPBDD) (Dal & Lucas, 2017). A WPBDD is an ordered BDD that represents a concise factorization of a Boolean formula f as a (rooted) directed acyclic graph with decision nodes, and two terminal nodes labeled with $\top$ (true) and $\bot$ (false). Each non-terminal node v is labeled with a Boolean variable $\text{var}(v) = x_v$ and has two children, $\text{high}(v)$ and $\text{low}(v)$, with a set of weight variables $\text{weights}(v)$ at the edge to node $\text{high}(v)$ (explaining the adjective 'positive' in WPBDD). Each root-terminal path contains a variable at most once, and in a particular total or partial order.

A CNF encoding as described above acts as an entry point for the language compiler (Dudek, Phan, & Vardi, 2020). Such compilers target different variations of DDs.

The respective DD is built using the typical bottom-up strategy (Bryant, 1986), by applying DD operations to construct a DD representing the encoded formula from the previous step. The process of compiling into a respective DD is by far the most expensive operation, compared to the inference step, which is linear in the size of the DD as desired.

2.2.4. Inference

Inference is performed through *Weighted Model Counting* on the DD, WMC for short (Chavira & Darwiche, 2008; Darwiche & Marquis, 2021). This process sums the weight of every truth assignment. In the decision diagram, these assignments are represented by paths and the weights by edge labels. Edges to nodes $\text{high}(v)$ and $\text{low}(v)$ are solid $\rightarrow$ and dashed $\dashrightarrow$, respectively (see below). Since these paths often overlap in the DD structure, inference through model counting is linear in the size of the target representation (Darwiche & Marquis, 2002).

Let's look at a WPBDD compilation and inference example. A WPBDD exactly represents the encoding provided. In order to perform inference we can trivially transform the logical circuit that the WPBDD represents into an arithmetic circuit.

Example 2.3 (Compilation and inference)**.** *Consider again variable* X *from Example 2.2. For the compiled DD the ordering for variable* X *is ordering* $x_3 \prec x_2 \prec x_1$*. Reduction rules specific to WPBDDs allow the removal of the* x_2 *node to further reduce its size. Each path from the root to the* $\top$*-terminal semantically implies evidence. There are three possible paths shown below. If we have evidence prior to traversing the compiled representation, we only consider the paths that are consistent with the evidence.*

Path	*Logic*	*Semantics*
$x_3 \rightarrow \top$	$\overline{x_1} \wedge \overline{x_2} \wedge x_3$	$X = 3$
$x_3 \dashrightarrow x_2 \rightarrow \top$	$\overline{x_1} \wedge x_2 \wedge \overline{x_3}$	$X = 2$
$x_3 \dashrightarrow x_2 \dashrightarrow x_1 \rightarrow \top$	$x_1 \wedge \overline{x_2} \wedge \overline{x_3}$	$X = 1$

To perform inference, we need to link to the probabilities that allows us to compute $P(X = 3) = 0.1$*, by the assignment* $(x_1, x_2, x_3) = (\bot, \bot, \top)$.

The tool PARAGNOSIS offers important ways to optimize compilation and inference by partitioning and parallelization (for details see (Dal et al., 2021, 2023)).

2.3. Mapping to a Bayesian Network

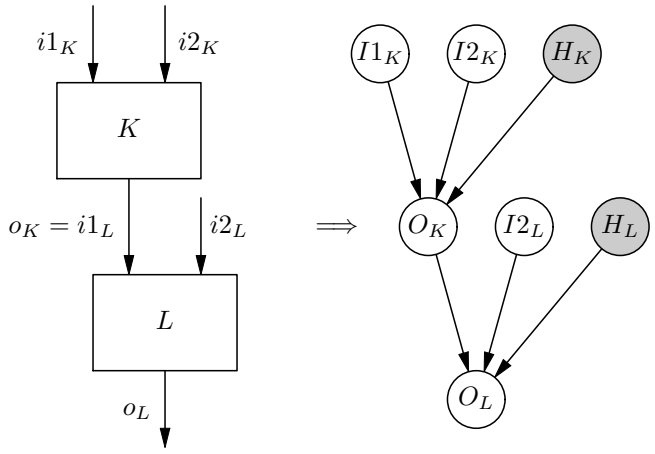
To add a probabilistic aspect to consistency-based diagnosis, a logical diagnostic problem can be mapped to a Bayesian network. There are different ways for translating a diagnostic problem into a *Bayesian diagnostic problem*. Two of these will be highlighted. One of these is the traditional method proposed by Pearl (Pearl, 1988), and implemented later by Srinivas (Srinivas, 1994), and the other is a more recent adaptation introduced by us. The latter one is used for this research, but since it is based on the traditional method both will be expanded upon.

2.3.1. Pearl's Method

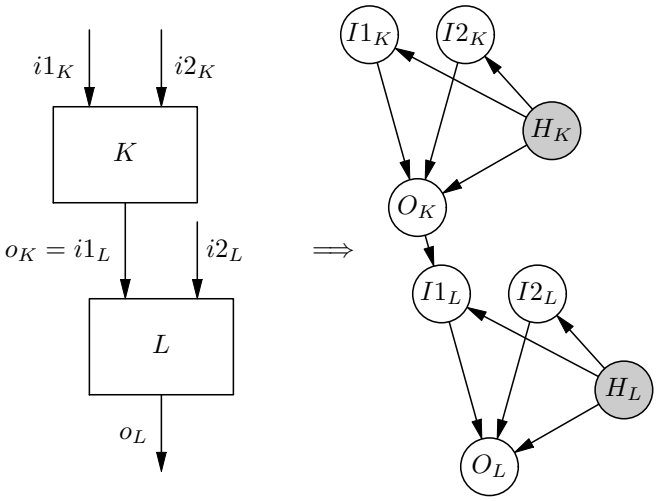
Following Pearl's method (Pearl, 1988), in Fig. 2a an abstract 2-component system has been translated into a Bayesian network. Each input and output of a component are modeled as nodes. A component is modeled as an output node that is the child of all its input nodes. Note that one of the inputs of component L is the output of component K and thus the output node of K is directly linked to the output node of L. Next to these, per component, a health node H (also called 'abnormality node' in the literature) is added as the parent of the output node. This node corresponds to the abnormality predicate in MBD and similarly indicates whether or not the component behaves abnormally: the abnormality literal of the traditional approach could be mimicked by assigning the values 'normal', corresponding logically to the assumption '$\neg\text{Ab}(c)$', whereas the value 'abnormal' would correspond to '$\text{Ab}(c)$'. However, a disadvantage of this approach is that health nodes and input nodes are independent; they only become conditionally dependent when a common child of input nodes or a descendant of the child is instantiated to a value (Pearl, 1988).

2.3.2. Method Based on Connected Health Nodes

The method which is used in the present paper no longer assumes that inputs and health nodes are independent. The health nodes support enforcing extra dependencies between the inputs and outputs, and when none of the children or descendants of the children of the input nodes are instantiated. This method is illustrated in Fig. 2b. Note that in this repre-



(a) Pearl's method with health nodes; health nodes shaded.



(b) New method with health nodes connecting inputs and output; health nodes are shaded.

Figure 2. Two methods of mapping of a simple system model with two components K and L to a Bayesian network.

sentation, all inputs are explicitly represented in the Bayesian network and the relationship between the output of the previous subpart (e.g. component K) and the next subpart (e.g. component L) is represented by an arc between the output node and one input node (e.g. the arc $O_K \rightarrow I1_L$). The conditional probability distribution of any connected output node O, $P(O \mid I_1, \ldots, I_n, H)$, is such that $P(O \mid I_1, \ldots, I_n, H = \text{normal}) \in \{0, 1\}$, dependent on the value of input variables I_k, with $k = 1, \ldots, n$.

2.3.3. Establishing a Bayesian Diagnosis

With the logical diagnostic problem mapped to a Bayesian diagnostic problem, probabilistic inference methods can be used to derive whether or not the components behave correctly as expected to form a diagnosis (Pearl, 1988).

Before such derivation can take place, first the evidence, consisting of observed values of inputs and specific outputs, should be included, which is analogous to the observations 'Obs' in MBD. With probabilistic inference methods, the posterior probabilities of each of the chosen health nodes can be calculated. Then for a given set of health variables H, a *diagnosis* is defined as follows:

$$D = \arg\max_h P(H = h \mid \text{Evidence}, \text{Health-assumptions}) \tag{4}$$

i.e., the assignment h to H with the maximum probability, where it is possible to condition on the health variables not included in H by 'Health-assumptions', the other health variables that are given an (assumed or observed) value. We call this process *assumption-based Bayesian model-based diagnosis*, or Bayesian MBD for short.

The same method can be used for Pearl's Bayesian-network structure of a diagnostic model. However, in that case it is mandatory to instantiate the last output variables to enforce dependence between input and health values and one can no longer simulate various flow schemes.

3. METHODOLOGY

To investigate whether weighted model counting with partitioning offers a suitable and fast algorithm for Bayesian model-based diagnosis, some Bayesian MBD models were designed. Unfortunately, it is virtually impossible to get access to large industrial MBD systems with their associated data for a publication, because of the industry's fear of disclosure of competition-sensitive information to the public domain. For this reason, we had to resort to designing an artificial model, that nevertheless was inspired by existing pipe systems as used in the chemical and oil industry.

The research question that is explored in the remainder of this paper is whether partitioned positive weighted model counting can effectively deal with large Bayesian MBD models in such a way that acceptable diagnostic results are obtained. For this purpose the PARAGNOSIS toolkit was implemented (Dal et al., 2023).

3.1. Basic Elements

Bayesian MBD requires the development of Bayesian-network models of systems, where the models consist of *components*, where some of those components are identical in nature, and compositional ways to merge these models together to build an overall model of a system. The result will be an abstraction of the real-world system that reflects both structure and behavior of the real-world system and that can be used for simulation purposes. In addition for MBD it is necessary to include *behavior modes*, e.g., whether the component is behaving normally or abnormally (other modes are sometimes also used) for each of the components that could be defective, which will be represented as *health variables*. Finally,

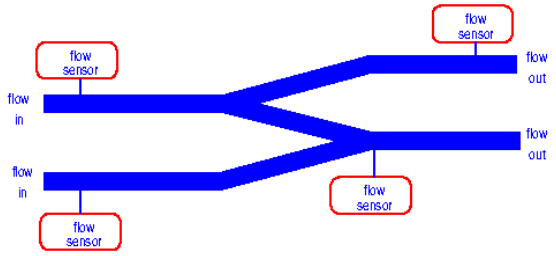


Figure 3. System of connected fluid pipes with one join, one split, and four flow sensors.

information about the behavior of a component is obtained through *sensors*.

3.2. Generating a System

Consider a pipe system, such as the one shown in Fig. 3, that consists of connected pipes, joints of pipes, and splittings of pipes (splits) that transport a fluid, e.g., water or oil, and have an input and output of fluid. The flow of the fluid is measured by means of *flow sensors* and is discretized into three states: 'maxflow', 'lowflow', and 'noflow'. Each pipe has one flow coming into it and one flow going out of it; if pipe x behaves normally:

$$\forall x(\text{PipeIn}(x) = v \rightarrow \text{PipeOut}(x) = v)$$

with v a free variable standing for a state. However, the actual health status of the pipe is ignored here, and assumed to be normal. Alternatively, if we want to take into account the health status and pipe x has a leak, the outgoing flow will be lower than the incoming flow:

$$\forall x((\text{PipeIn}(x) = \text{maxflow} \quad \wedge \quad \text{Health}(x) = \text{leak}) \rightarrow \text{PipeOut}(x) = \text{lowflow}))$$

whereas for normal health we get:

$$\forall x((\text{PipeIn}(x) = v \quad \wedge \quad \text{Health}(x) = \text{normal}) \rightarrow \text{PipeOut}(x) = v))$$

Thus, it is needed to include the health status as an additional condition. Similar logical specifications can be developed for the other elements of pipe systems, i.e., the joints and splittings.

As we use individual pipe components to develop (generate) pipe systems of various complexity and size, as is also done when developing real-life pipe systems, we will number pipe components from input to output flow of the entire system, in terms of two parameters: width (from left to right) and height (top to bottom) of the directed graph (starting with 1). We come back to this issue in Section 4.

A clear disadvantage is that uncertainty in the health status and the likelihood that a leak may give rise to low or no flow is missing in the logical representation. Bayesian model-based diagnosis will support representing this important aspect of diagnosis, i.e., the ability to deal with uncertainty, as will be discussed below.

3.3. Uncertainty and Bayesian-network Components

To model a system that incorporates uncertainty, we need design Bayesian-network components that correspond to the various parts of the real system. Based on the mentioned specifications in the section above, we distinguish pipe, join, and split Bayesian-network components. The health status of a pipe component is controlled by a health variable, called variously 'JoinHealth', 'PipeHealth', 'SplitHealth'. As above, the continuous flow is mapped to discrete values, we distinguish three flow values: maximal (maxflow), low (lowflow), or absent (noflow).

The three basic Bayesian-network components are depicted in Fig. 4, 5, and 6. These can be put together in various topologies giving rise to a plethora of pipe systems. In addition sensors can be added to components to measure the status of the flow in the individual pipes. Sensor readings will be used below as evidence in the experiments to diagnose faults in the different pipe systems. Software and figures have been generated using the R language (R Core Team, 2024), the R-library bnlearn (Scutari, 2024), with GeNIe Modeler[2] for producing graphical figures.

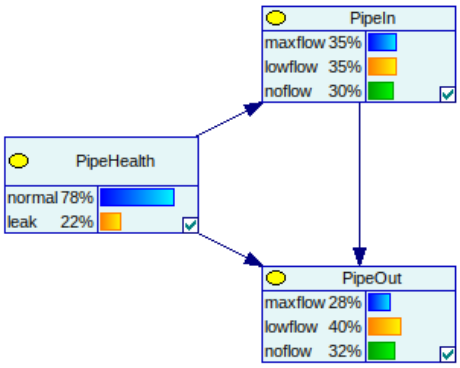

Figure 4. Pipe-shaped component; there is no need to model the actual pipe as it is sufficient to represent the input and output of the pipe and how these relate to each other by means of health modes.

3.4. Compositionality by Probability Distributions

Each pipe is modeled as a flow out of 'PipeOut' with one flow coming into 'PipeIn'. The prior probability of a pipe's health being normal is set to 0.8 ($P(\text{PipeHealth} = \text{normal}) = 0.8$). The distribution of the input of the pipe depends on the output of the previous component in a deterministic manner,

[2] https://www.bayesfusion.com/genie

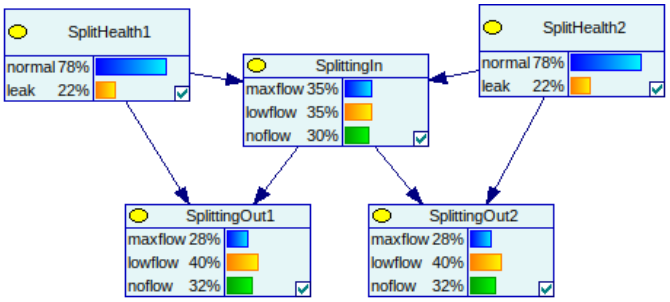

Figure 5. Split-shaped component consisting of a single input and in this case two outputs. In addition, each output is controlled by a health mode.

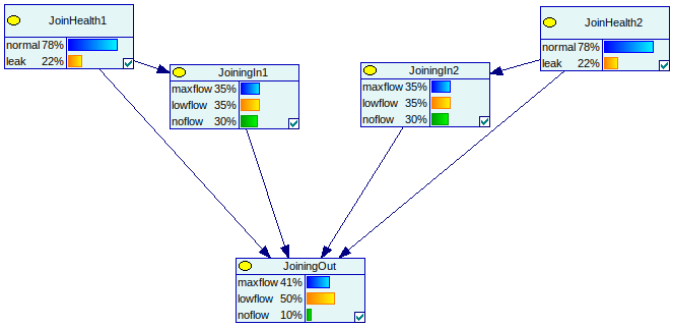

Figure 6. Join-shaped component consisting of two (or more) inputs and a single output that merges the inputs. In addition, the actual merge is controlled by one health node per input.

i.e., we do not consider defects between components. Since this structure is the same for every pipe, the CPT of each pipe is also identical such that the probability distribution

$$P(\text{PipeOut}_i \mid \text{PipeIn}_i = v, \text{PipeHealth}_i = w)$$

is the same for each i, but varies for specific values of v and w as shown in Table 2. In case the component behaves normally, there is no impact on the flow of the pipes, which reflects the logical specifications of Section 3.2. Furthermore, the CPT reflects the impact of a leaking pipe. Given a normal flow, if the pipe is leaking, there is a high probability the flow is reduced, and in severe cases, it may even lead to no flow in the output. If there is low flow in the input, we assume

Table 2. CPT for the output node of a pipe.

		PipeOut$_i$		
		maxflow	**lowflow**	**noflow**
PipeIn$_i$	**PipeHealth$_i$**			
maxflow	**normal**	1	0	0
	leak	0.1	0.8	0.1
lowflow	**normal**	0	1	0
	leak	0	0.8	0.2
noflow	**normal**	0	0	1
	leak	0	0	1

that a leaking pipe has less impact and there is still a high probability there is a low flow in the output, though it may be diminished to no flow.

The split-shaped component is modeled in a similar manner to a pipe, with the exception that this component contains multiple health and output nodes. That is, the prior distributions $P(\text{SplitHealth}_i) = P(\text{PipeHealth}_j)$, the distribution of the 'splittingIn' is determined by the output in its parent component, and

$$P(\text{SplittingOut}_i|\text{SplittingIn} = v, \text{SplitHealth}_i = w) = P(\text{PipeOut}_j|\text{PipeIn}_j = v, \text{PipeHealth}_j = w)$$

for values of i, j (instances of the named components), v and w.

4. Experiments and Evaluation

We have checked the validity of the proposed models in order to prove their usefulness. For the purpose of evaluating the diagnostic capabilities of our weighted model counting method, the 3rd aim of the research, we have generated pipe Bayesian networks 'pipes-sensors-w-h' with height h and width w as described in Section 3.2. This results in w parallel pipes that run h layers deep. Each pipe in the first layer is directly connected to one pipe in the second layer downstream, and so on, for h layers. This effectively lengthens the pipes in the first layer, and creates w parallel pipes of length h. Each pipe in every layer has a sensor that registers *flow* or *noflow*, and is identified by the coordinate in its name. For instance, 'sensor2_3' is the sensor attached to the second pipe in layer 3.

4.1. Experimental Setup

We report some experimental results of our software tool PARAGNOSIS and various pipe Bayesian MBD models. All below experiments ran on a system with as CPU an Intel Hexa Core i7-8750H (2.20-4.10Ghz), 9Mb cache 45W, with Kingston HyperX 16Gb (2× 8Gb) DDR4 2400Mhz RAM.

Evidence is only set on 'FlowOut', 'FlowIn', and (some of the) sensors. Only consistent evidence is considered. This means that 'sensor2_i' $\geq$ 'sensor2_j', for $i < j$. In other terms, it is impossible for an upstream pipe to have no flow and for a downstream pipe to have flow at the same time. We also only consider FlowIn $>$ FlowOut. When we say *maxflow* to *lowflow* or *maxflow* to *noflow*, this means from FlowIn = *maxflow* to FlowOut = *lowflow*, or to FlowOut = *noflow*, respectively.

Consider network 'pipes-sensors-5-2' (5 parallel pipes, 2 layers deep). Table 3 shows diagnostic results for *maxflow* to *noflow*, Table 4 for *maxflow* to *lowflow* and Table 5 for *lowflow* to *noflow*. To allow quick reading we used the following abbreviations: 'pH' stand for 'pipeHealth'; 'jH' for 'joinHealth'; 'sH' for 'splitHealth', respectively. We compute the

Table 3. Results for network 'pipes-sensors-5-2' for maxflow to noflow. Posteriors are computed for health nodes and indicate the probability of a leak. Probabilities preceded by '+' indicate the posterior's increase compared to the prior. sensor5_2	pH5_2 (0.579)	pH5_2 (+0.354)	pH5_1 (0.444)	pH5_1 (+0.219)
	jH1 (0.390)	sH5 (+0.039)	pH5_2 (0.444)	pH5_2 (+0.219)
	jH2 (0.390)	jH1 (+0.011)	jH1 (0.380)	sH5 (+0.103)

posteriors of value *leak* for all health variables, given the evidence that a set of sensors is set to *noflow*. This set can be found in the leftmost column. 'FlowOut' and 'FlowIn' are also observed respectively.

We compare two experiments. Columns 2-3 represent the experiment where all sensors are observed. Unobserved sensors (those not present in column 1) are set to *flow*. Columns 4-5 represent the experiment where unobserved sensors are not set. Columns 2 and 4 contain the health variables with the highest *leak* probability, whereas column 3 and 5 contain the health variables with the most increased *leak* posteriors, compared to the posteriors computed with only 'FlowOut' and 'FlowIn' in the evidence.

4.2. Observations and Diagnostic Results

The posteriors in Table 3 (*maxflow* to *noflow*) show that diagnoses are consistent with the evidence. Consider evidence 'sensor1_1' and 'sensor1_2' equal to *noflow* and all remaining sensors are set to *flow*. The most likely location for a leak is 'pipeHealth1_1'. When the evidence does not include values for sensor1_1, we see that pipeHealth1_2 indicates a leak. Resulting diagnoses, consisting of the highest probabilities for the health variables, seemed to correspond to what we expected.

When removing the *flow* sensors from the evidence we see that the evidence 'sensor1_2' does not lead to a definitive leak (a probability greater than 0.5) as indicated by pipeHealth1_2. However, pipeHealth1_2 has the highest leak probability along with upstream pipeHealth1_1. Their posteriors also have increased the most as indicated in the last column. This finding is also logical, we have not set 'sensor1_1' to *flow*, thus the leak can still be in any layer.

For Table 4 and Table 5 we see the same behavior, thereby validating the diagnostic capabilities of our Bayesian MBD approach.

4.3. Larger Networks

We have created larger systems using the description in Section 4.1, and perform weighted model counting using PARAG-

Table 4. Results for network 'pipes-sensors-5-2' for maxflow to lowflow. Posteriors are computed for health nodes and indicate the probability of a leak. NOSIS (Dal et al., 2023). It is clear that the created systems are particularly strenuous on the inference side, due to the joining node in the network. Its CPT increases exponentially when width w increases. Table 6 shows compilation and inference times of these networks. The results reflect the aforementioned comment, as compilation and inference time most notably increase as the width of the network increases. As a comparison, the well known Munin network (Jensen & Andreassen, 2008) is considered to be large, and has 1041 variables with 98423 probabilities (Dal et al., 2021). This demonstrates the inference capabilities of weighted model counting using PARAGNOSIS (Dal et al., 2023). Fig. 7 show a nearly linear increase in compilation time with respect to the number of probabilities in the networks. However, the increase in compilation and inference time is more exponential in nature as we increase the width of the network.

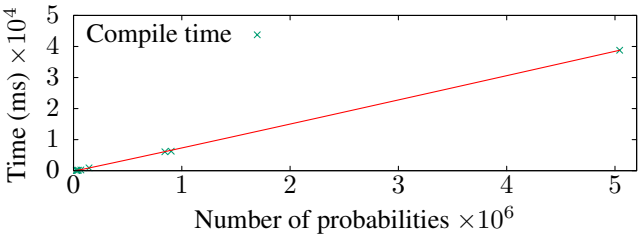

Figure 7. Compilations time with respect to the number of probabilities.

5. DISCUSSION AND CONCLUSIONS

Following the analysis of the diagnostic behavior, it appears that the compositional Bayesian-network structures developed in the sections above display behavior that is at least partly natural and intuitive. For example, a Bayesian model-based diagnostic model of a pipe system that has no input flow will raise an inconsistency in its (conditional) probability distribution if its output flow is assumed to be low or maximal. Another interesting aspect of the behavior is that faults are assumed to be closest (in terms of path length) to the entered observations that are incompatible with the expected behavior. This is a consequence of the propagation of probabilistic

information through the network which reflects the observations combined with the associated uncertainty derived from the conditional probability tables. At first thought, one may think that this behavior is not compatible with the actual real world, as one would expect that for identical components, the likelihood of failure would also be identical independent of where the component is located in the overall system. However, as *only* by observing flow input and output and sensor data allows one to locate faults, the probabilistic reasoning provided by a Bayesian model-based diagnostic model rightfully exploits that information to the maximal extent and does indeed offer information where to look first.

In principle, the Bayesian-network network structure and its associated probabilistic parameters can be learned from observational data of a working real machine, although this will be associated with some major challenges. Where it would be straightforward to learn the prior distribution of health variables from the data, for example for 'PipeHealth', it would be harder to learn the conditional distributions

$$P(\mathrm{PipeOut}|\mathrm{PipeIn} = v, \mathrm{PipeHealth} = w),$$

for values of v, w, from data, partly because these probabilities are supposed to represent generic local probabilities, whereas in real-world systems quite a lot of the local behavior is determined by non-local behavior arising elsewhere in a system. Measurements that fully explain local behavior of components will usually not be available. Instead, available sensor data can be exploited, and basically this requires the development of new methods to answer questions of how local probability distributions can be approximated with the data from real-world systems that *can be* measured. Since parameter learning does not appear straightforward, it can be expected that structure learning will be even harder. However, here one has to keep in mind that for cyberphysical systems there often is quite some knowledge available already about its architecture and functional components, which clearly makes this problem much less challenging. Thus the positive message is that with relatively little effort a good starting point for developing a Bayesian model-based diagnostic model is within reach.

It should be mentioned that the example pipe model which

Table 6. Compilation and inference times for pipes-sensors-w-h, where compilation size is the number of arithmetic operators in the compiled representation.

Network		Number of	Number of	Compilation	Compilation	Maginalization

7	200	5631	902081	645177	6275.068	42.671
8	10	355	5043465	463594	38781.416	36.785

was employed in the research, has some limitations. In the first place, because of the restriction in our research to probabilistic inference in discrete Bayesian networks. It would have been more natural to use hybrid Bayesian networks to represent the behavior of a pipe system, with continuous variables for the representation of flow and sensor information and discrete for the health variables. Nevertheless, discrete variables do allow one to approximate continuous variables usually to a sufficient degree. Furthermore, in the context of flow modeling, the assumption that flow can be modeled by a directed acyclic graph may be questioned, although propagation of probabilistic information goes in both directions, in and against the direction of the arcs.

The issues mentioned above do not interfere with other conclusions concerning the probabilistic diagnostic method designed and whether exact probabilistic inference is feasible for large diagnostic problems. We have also tested large versions of our model-based diagnostic models, in order to investigate the limits of weighted model counting. We are able to perform weighted model counting in networks that are significantly larger than the largest networks in the field of Bayesian networks (Dal et al., 2023).

All in all, this research contributes to ideas on how Bayesian model-based diagnosis can be applied to large cyberphysical systems. Future research should shed light on whether the proposed probabilistic diagnostic methods can be of value in diagnosing faults in other systems than the pipe systems we studied.

ABSTRACT

Modern manufacturing equipment offers numerous configurable parameters for optimization, yet operators often underutilize them. Recent advancements in machine learning (ML) have introduced data-driven models in industrial settings, integrating key equipment characteristics. This paper evaluates the performance of ML models in classification tasks, revealing nuanced observations. Understanding model decision-making processes in failure detection is crucial, and a guided approach aids in comprehending model failures, although human verification is essential. We introduce *MOXAI*, a data-driven approach leveraging existing pre-trained ML models to optimize manufacturing machine parameters. MOXAI underscores the significance of explainable artificial intelligence (XAI) in enhancing data-driven process tuning for production optimization and predictive maintenance. MOXAI assists operators in adjusting process settings to mitigate machine failures and production quality degradation, relying on techniques like DiCE for automatic counterfactual generation and LIME to enhance the interpretability of the ML model's decision-making process. Leveraging these two techniques, our research highlights the significance of explaining the model and proposing the recommended parameter setting for improving the process.

1. INTRODUCTION

Today's highly automated manufacturing equipment often provides many configurable parameters to ensure optimal production and accommodate an increased range of products. In practice, machine operators and process engineers rely on a limited set of well-understood key parameters for process controlling and optimization, overlooking the broader space of configurable options and underutilizing the potential to enhance equipment effectiveness. The increased demand for individualization and, consequently, the decrease in batch sizes amplify this effect and further increase the workload for operators. Recent advances in machine learning have led to a surge in data-driven AI/ML models deployed in industrial scenarios for applications such as quality inspection and predictive maintenance, which have integrated key characteristics and patterns of production equipment.

The demand for explainability becomes crucial to optimizing complex manufacturing and production processes as models grow more intricate, resembling "black boxes" that hinder users from understanding the rationale behind predictions. Explainable Artificial Intelligence (XAI) methods address this challenge by providing human-understandable explanations for data-driven decisions. In XAI, two primary categories are evident (Molnar, 2020): model-agnostic and model-specific approaches. Model-agnostic techniques, such as feature importance and surrogate models, offer insights into decision-making processes across various models. Conversely, model-specific methods delve into a model's intrinsic aspects, such as coefficients in linear regression or visualizing decision cuts in decision trees. Local and global scopes characterize explanations, with techniques like Local Interpretable Model-Agnostic (LIME) (Ribeiro, Singh, & Guestrin, 2016), and Shapely Additive Explanations (Lundberg & Lee, 2017) offering local insights. Another popular approach in XAI is counterfactual explanations (Ates, Aksar, Leung, & Coskun, 2021; Jalali, Haslhofer, Kriglstein, & Rauber, 2023), which determine changes to input data necessary for altering a model's output.

In this work, we strive to automate the process of providing recommendations to machine operators in an interpretable manner, empowering them to understand and adjust parameters effectively for optimal performance (Fig. 1). For this purpose, we introduce *MOXAI* tuning, a data-driven approach

leveraging existing pre-trained AI/ML data models to optimize manufacturing machine parameters by applying model-agnostic counterfactual explanations. Given that numerous manufacturing optimization and predictive maintenance tasks are framed within a binary classification –distinguishing between healthy and damaged assets, or regression – predicting health indicators or remaining useful life, counterfactuals emerge as a compelling solution.

To demonstrate the concept and applicability of the proposed approach, we apply MOXAI on the AI4I 2020 Predictive Maintenance Dataset (Matzka, 2020), which is a simulated dataset designed to mirror authentic predictive maintenance data typically observed in industrial manufacturing settings. Applying MOXAI to those samples where the model predicts machine failures, we can analyze the rationale behind these predictions and obtain suggested modifications to fine-tune different process parameters and prevent machine failures. By querying MOXAI for explanations, we assume that mitigating the reasons behind the model failure prediction will result in an enhanced quality outcome. MOXAI explanations are constrained to a subset of features directly or indirectly controlled by the operator. Evaluations involve comparing model suggestions with production settings to quantify the impact on machine failures, by applying LIME to verify the explanations discovered.

The rest of the paper is structured as follows: First, an overview of the related work is given in Section 2 . Section 3 introduces MOXAI. Section 4 describes the experimental setup considered for evaluation purposes, presenting experimental results. Further discussion on results and MOXAI's approach is presented in Section 5. Finally, Section 6 concludes the paper.

2. Related Work

Two main categories emerge in the domain of XAI: model-agnostic and model-specific approaches. Model-agnostic techniques do not rely on specific model characteristics and can generally be applicable across various models to provide insights into their decision-making process (Molnar, 2020). Such methods include feature importance (e.g., shapely values (Lipovetsky & Conklin, 2001)) and model approximation techniques (e.g., surrogate models (Ribeiro et al., 2016)). Conversely, model-specific approaches study the intrinsic aspects of a model and offer a deeper understanding of its learning structure. For instance, coefficients of a linear regression model, visualization of decision cuts of a shallow decision tree, or more complex approaches such as Layer-Wise propagation explanations (Bach et al., 2015), DeepLift (Shrikumar, Greenside, & Kundaje, 2017), and Class Activation Map (Zhou, Khosla, Lapedriza, Oliva, & Torralba, 2016), which visualize the distributed weights of a neural network.

The scope of the explanations provided by either of the aforementioned techniques can be either local (explaining one sample) or global (explaining all the samples) (Molnar, 2020). Local Interpretable Model-Agnostic (LIME) (Ribeiro et al., 2016), and Shapely Additive exPlanations (Lundberg & Lee, 2017) are popular techniques that produce local explanations. Recent studies suggest that the comprehensibility of local explanations, specifically when including the counterfactuals, increases the human understanding of the model's decision boundary (Jalali et al., 2023). Counterfactual explanations are "hypothetical samples that are as similar as possible to the sample that is explained while having a different classification label" (Ates et al., 2021). Therefore, we argue that combining a local explainability approach with generating counterfactuals can help an end user understand the small meaningful changes that cause the shift in the model's decision with minimal computational effort.

Many XAI approaches have been applied in the literature to address manufacturing optimization problems. Schockaert et al. (Schockaert, Macher, & Schmitz, 2020) propose an approach for local interpretability of a model optimized on training data, which forecasts the temperature of the hot metal a blast furnace produces. Combining a Variational AutoEncoder (VAE) with LIME significantly improves generated synthetic samples for training the ML model. Seiffer et al. (Seiffer, Ziekow, Schreier, & Gerling, 2021) develop a framework to detect temporal changes in manufacturing data with SHAP values to enhance error prediction. The framework detects and handles concept drift so that the generated ML models are of sufficient quality in the long term. Jakubowski et al. (Jakubowski, Stanisz, Bobek, & Nalepa, 2021) developed an LSTM autoencoder model for detecting anomalies in the hot rolling process to produce steel coils. They applied SHAP explanations to determine the reasons for anomalies. Regarding model interpretability, Jakubowski et al. (Jakubowski, Stanisz, Bobek, & Nalepa, 2022) employed the SHAP method and counterfactual explanations to gain insight into the decisions made by their trained models. These explanations effectively highlighted the features responsible for the abnormal state of the mill or work rolls, helping identify the anomaly's root cause. Ameli et al. (Ameli et al., 2022) employ XAI methodologies to determine the specific sensors exhibiting anomalies, enhancing decision-making within glass production monitoring. These sensors are localized, analyzing the cause of anomalies by saliency XAI. The approach of Senoner et al. (Senoner, Netland, & Feuerriegel, 2022) involves the development of a data-driven decision model by leveraging high-dimensional data with nonlinear relationships alongside SHAP to discern the intricate relationships between production parameters and manufacturing process quality.

In summary, XAI methods are sporadically utilized in production and predictive maintenance to optimize models and

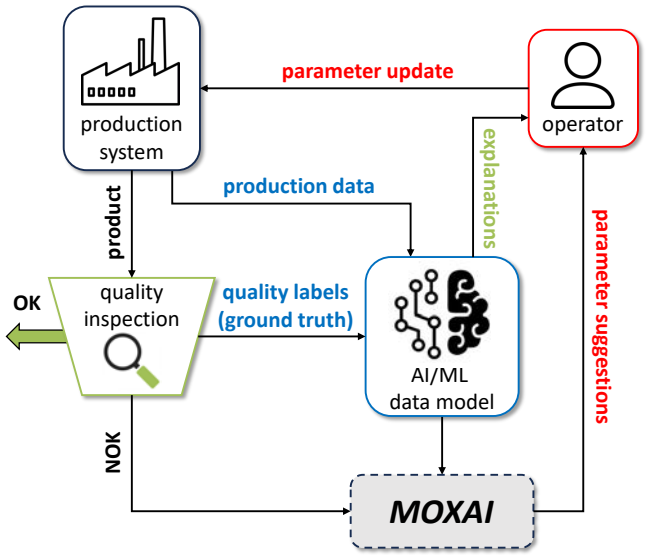

Figure 1. MOXAI information flow for parameter recommendations.

enhance understanding. The approach involving counterfactuals has been minimally employed thus far despite its considerable promise in this domain.

3. Methodology

The general idea of MOXAI is to extract suggestions for *production parameters* (i.e., part of the AI/ML model input features) leading to a desired manufacturing target, relying on pre-trained AI/ML models, and using XAI local explanations through so-called counterfactual instances. A counterfactual instance is a synthetic data point similar to the original instance but with a different model outcome. It is created by perturbing the model's input parameters within certain bounds. Our goal through counterfactual explanations is to answer the question *"what changes to the input (production) parameters of the model would have resulted in a different prediction?"*. MOXAI allows for faster fine-tuning of the configuration of a production process by iterating over instances for which the production output is not as desired.

3.1. Automatic Parameter-Settings' Recommendation

We developed MOXAI to guide machine operators toward better production parameters in case of product quality deviations. We envision a scenario in which process control, quality inspections, or data-driven models indicate a deviation, and the operator is uncertain how to modify the configuration. MOXAI leverages methods from explainable AI to suggest an optimized configuration based on the most recent sample. It requires an existing data model for product quality prediction based on the process parameter and configuration. Our model-agnostic method requires the changeable machine configuration to be part of the model input.

We use the framework for Diverse Counterfactual Explanations (DiCE) (Mothilal, Sharma, & Tan, 2020) to generate recommendations. We leverage counterfactuals to suggest machine parameters that produce good product quality according to the data model. DiCE aims to generate actionable counterfactual sets, ensuring that individual counterfactual examples are feasible and diverse. To achieve this, DiCE adapts diversity metrics through diversity via Determinantal Point Processes (Kulesza, Taskar, et al., 2012) and incorporates feasibility using proximity constraints and user-defined constraints. Process parameters are optimized by extracting the model's capability to determine which parameters lead to a high-quality product. It also addresses sparsity by considering the minimal number of features that must be changed to transition to the counterfactual class. Additionally, it allows users to specify constraints on feature manipulation, such as box constraints on feasible feature ranges, to ensure the practicality of counterfactual examples within real-world constraints. The MOXAI workflow is depicted in Figure 1.

3.2. Human-Guided Correction of Model Failures

To understand the model's decision boundary for detecting defected cases from no-defect cases, we apply LIME, which also offers understandable visualizations for operators and developers to understand why the model failed to detect defective samples. LIME produces instance-based explanations by estimating the decision boundary of the black-box model within a narrow neighborhood. The underlying assumption is that a linear model can effectively approximate the local decision boundary of the black box. The coefficients of this linear model then elucidate the contribution of each feature to the prediction of a sample within this neighborhood. Consequently, LIME's explanations are represented by feature value boundaries. These boundaries signify the impact of each feature; when the feature values fall within these boundaries in a given local neighborhood, they influence the model's decision toward or away from a particular class.

MOXAI's correction algorithm utilizes LIME and examines the top five common explanations provided by this approach for all instances. It performs the following steps: it counts the frequency of these explanations; it then ranks the explanations based on their frequency counts. Next, it records the lowest and highest bounds observed for the most influential feature in the explanations. Human input may be needed from a domain expert who has viewed the data and understands the feature boundaries at this stage. This is necessary because LIME sometimes presents an upper or lower-bound inequality. In such cases, we need to determine the missing boundary. The algorithm then iterates over the generated list and replaces the corresponding feature in the explanations with a randomly generated float within the boundary range. We continue the iteration if this alteration does not rectify the model's prediction. If the alteration corrects the prediction,

Table 1. Results of trained models on the test set.

	Recall	Precision	F1-Score
Nearest Neighbor (KNN)	0.97	0.97	0.97
Decision Tree (DT)	0.99	0.99	0.99
Random Forest (RF)	0.99	0.99	0.99
Gradient Boosting (GBM)	0.99	0.99	0.99
Neural Network (MLP)	0.97	0.94	0.96

Table 2. Detailed results of the trained decision tree on the test set.

	Accuracy	Recall	Precision	F1-score
HDF	0.99	0.95	0.93	0.94
PWF	0.99	0.92	0.89	0.90
OSF	0.99	0.73	0.87	0.78
Machine-Failure	0.99	0.99	0.99	0.99

we proceed to the next misclassified sample. We further emphasize that this approach merely identifies the approximate decision boundary of the model rather than identifying the actual cause of the defect. We can only observe the parameter responsible for the model's misclassification, which may or may not directly correlate with the underlying cause of the defect. The outcomes of this algorithm are discussed in Section 4.3.

4. Experimental Setup and Results

We demonstrate MOXAI's operation using the AI4I dataset, a synthetic dataset commonly used in the scientific community. The AI4I dataset covers a realistic industrial use case and provides an analytical definition for most error types, which can be used to validate corrections as suggested by MOXAI. The dataset consists of 10,000 samples with five numerical features of a milling process, a categorical feature for different product types, and the target variables, which describe the state of five error types:

- Tool wear failure (TWF): The tool fails after a random up-time between 200 - 240 minutes.
- Heat dissipation failure (HDF): The tool fails due to small temperature differences between the tool and air and slow rotational speeds.
- Power failure (PWF): The tool fails for very high or very low power, defined as the product of torque and rotational speed.
- Overstrain failure (OSF): Product variant-dependent error for high tool wear and torque combination.
- Random failures (RNF): A randomly assigned error type.

We exclude TWF and RNF failures from the evaluations due to their random component, as we require an analytical definition of the error for validation.

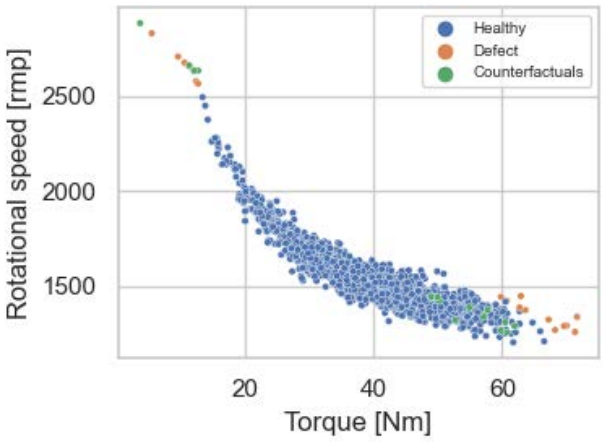

Figure 2. Power Failure (PWF) healthy and defect samples in the test set, as well as generated counterfactual samples, for rotation speed vs. torque of the milling process.

4.1. Data Preprocessing and Modeling

The machine learning model is the core of our approach, and we trained different models following standard best practices. We use a stratified split of 80% of the data for training/validation and 20% for testing, resulting in 7714 samples for the healthy state and 234 defects, of which 115 are HDF, 94 are PWF, and 95 are OSF – note that some machine defects are a combination of multiple failures. The imbalance in the data can be seen as an indication for up-sampling approaches such as SMOTE (Chawla, Bowyer, Hall, & Kegelmeyer, 2002). Still, our experiments showed no significant improvement, and our reported models are trained on the provided data only. We performed experiments using five different model architectures implemented by scikit-learn[1]: k-nearest neighbors , Decision Tree, Random Forest, Gradient Boosting, and Neural Network, and report the results in Table 1, as well as the breakdown of the best-performing model in Table 2, where we see that the detection of the HDF and PWF are more trivial than ODF, which is consistent among the models. Therefore, we can assume that the misclassification of machine failure is potentially caused by detecting the OSF.

4.2. Parameter-Setting Recommendations

MOXAI uses DiCE as an explainer backend, which was initialized using the trained model and the training data. We use the genetic algorithm provided by DiCE, as it supports parameters that prioritize counterfactuals similar to training data and thus avoid regions in the parameter space that are not well defined due to missing training data. We allow variation in all features, but real-life use cases will likely require limiting the parameters that can be modified at the machine.

Table 3. Accuracy of suggested parameters.

	KNN	DT	RF	GBM	MLP
HDF	0.89	1.0	1.0	0.94	0.78
PWF	0.91	1.0	1.0	1.0	0.71
OSF	0.58	0.95	0.95	0.84	0.47
overall_accuracy	0.81	0.98	0.98	0.93	0.68

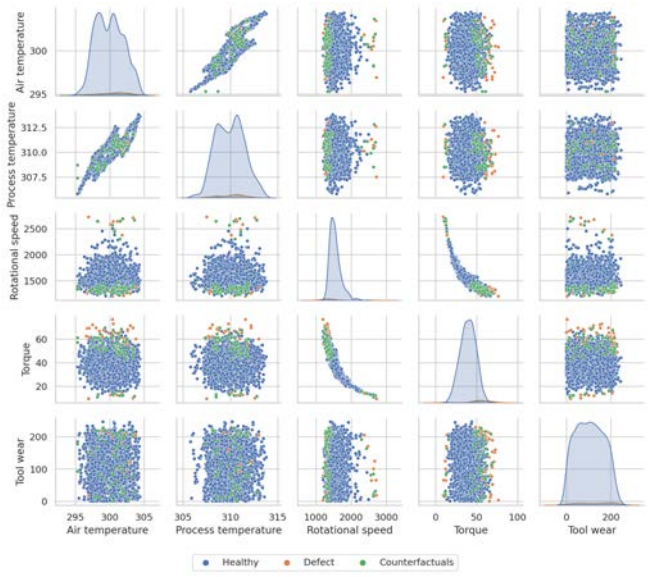

Figure 3. Pairplot of the test set and created counterfactual samples, for the five different numerical features characterizing the milling process.

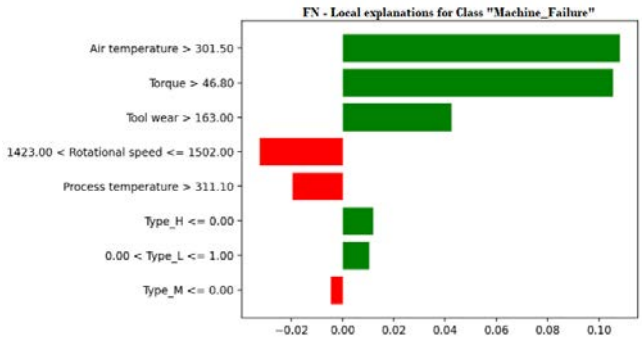

Figure 4. LIME's local explanations for a misclassified sample as not a machine failure (FN).

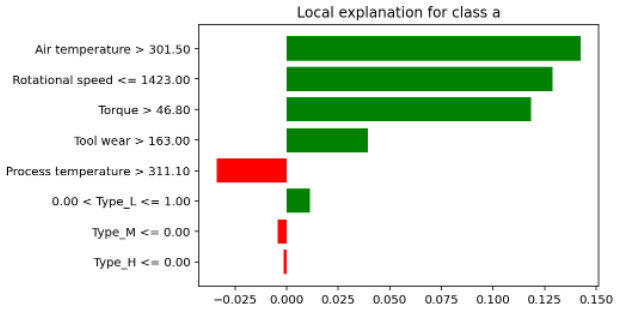

Figure 5. LIME's local explanations for a sample correctly classified as a machine failure (TP).

To evaluate MOXAI, we use the analytic definition of errors provided by the AI4I dataset creators. For each defective sample of the test set, we use MOXAI to calculate a suggested set of machine parameters. Figures 2 and 3 depict the healthy and defective samples in the test set and the generated counterfactuals. We take the error definition to determine if the solution proposed by MOXAI actually solved the problem and corresponded to a healthy product. We report the percentage of successful corrections as accuracy in Table 3.

4.3. Correction of Model Failures

We generate LIME explanations for each failed sample using the models discussed in the preceding section. We encounter 21 failed samples, comprising 15 false negatives (FNs) and six false positives (FPs). Through the analysis of modeling separated failure modes, we noticed that these misclassifications predominantly stem from the model's failed attempt to detect PFW and OSF accurately. We extract the explanations using the algorithm detailed in Section 3.2. To correct false positives (FPs), we randomly generate float values within the approximate feature range identified by LIME to produce counterfactual instances. We leverage our understanding of value ranges given by dataset providers, contributing to failures in each specific mode, to rectify errors in parameter settings. Similarly, we apply this method to false negatives (FNs), mostly from inaccuracies in process temperature values. By generating counterfactual instances, we illustrate the adjustments required in parameter values to identify defective samples accurately. In Figure 4 and Figure 5, we demonstrate a comparison of a true positive (correctly detected machine failure) with a scenario where the model predicted a failure as "not a failure" with low confidence (the prediction probability for the class Failure is 0.47) explained by LIME. The plot shows that, even though the features *Air temperature, Torque* and *Tool wear* are positively contributing to this prediction being a failed sample, the values of *Rotational speed* and *Process temperature* are shifting the model's decision towards the class "not a Failure". MOXAI suggests a minor change of *Process Temperature* to a value slightly smaller than 311.10, creates a counterfactual, and corrects this prediction. In practice, the domain expert should verify whether this change is valid and does not contradict the definition of this failure mode.

5. Discussion

The evaluation of model performance in a classification task unveils nuanced observations. While all models exhibit satisfactory accuracy in data classification, their effectiveness

in generating reliable counterfactual samples varies. Notably, tree-based models emerge as the most robust, surpassing alternative methodologies, such as Multi-Layer Perceptron (MLP) and K-Nearest Neighbors (KNN). Furthermore, an analysis of error types reveals differences among model performances. Specifically, most models demonstrate proficiency in addressing tool wear (PWF) and heat dissipation (HDF) errors but struggle when confronted with errors arising from multiple product types (OSF). These findings underscore the importance of assessing classification accuracy and considering models' ability to provide dependable counterfactual samples and their efficacy in handling diverse error types. Moreover, the current state of MOXAI is limited to the parameters within the proximity of its training set. Therefore, it cannot suggest optimizations for unseen production scenarios. One approach to address this limitation could be the usage of digital twin solutions that are more flexible when it comes to approximating new parameters and production settings.

We underscore the significance of comprehending the model's decision-making process in failure detection and why these particular counterfactuals were suggested. A guided approach aids in understanding why a model failed and whether the model's identified correlations are logical. While MOXAI offers an interpretable and human-in-the-loop system for comprehending model failures and suggesting meaningful samples tailored to this specific use case, the semi-automatic counterfactuals produced by our human-guided approach could benefit from considering feature co-linearities and interactions, and a domain expert should verify them to exclude nonsensical examples. This process is crucial for gauging the model's reliability and assessing the suitability of a fully automated counterfactual generation module. Therefore, the operator can plainly trust the model's recommendations to choose the best settings based on the explanations provided by LIME's output.

6. Conclusion

The approach of XAI to enhance data-driven process tuning for optimizing production or predictive maintenance is promising. MOXAI proposes a data-driven, XAI-powered approach to optimizing manufacturing machine parameters, relying on pre-trained ML models of any nature. We have trained different ML models for failure prediction in a popular synthetic dataset representing a realistic industrial scenario, applying MOXAI's information flow to identify potential corrections to improve failure samples and improve understanding of the operation of these ML models.

DiCE is a key element in automatically generating counterfactual explanations, which can assist operators in adjusting process settings so that machine failures or degraded production quality can be reduced. Applying LIME explanations to address false predictions within our model proved insightful. We successfully rectified both false positives and false negatives by analyzing failure modes and generating counterfactual instances based on LIME insights. Additionally, our demonstration of LIME's output underscores its potential to enhance model decisions' interpretability.

Enhancing the understanding of counterfactual methods is important for future advancements. This ensures that such methods foster a causal understanding for human operators while avoiding any risks of biased, sub-optimal, or erroneous explanations.

ABSTRACT

This paper presents a Natural Language Processing (NLP) method aimed at detecting faults within field failure reports of drilling tools. It builds on the definition of entities specifically matched to our unique requirements. These entities have been annotated within the dataset under the guidance of a Subject Matter Expert (SME), laying a foundation for our NLP method. By utilizing a model based on bidirectional encoder representations from transformers, the method achieves an F1-score of 88% in identifying entities and consequently detecting faults within field failure reports. This work is part of a long-term project aiming to construct a failure analysis and resolution system for drilling tools.

1. INTRODUCTION

The oil and gas industry relies heavily on logging tools that operate in extreme environmental conditions, including elevated temperatures, vibrations, and pressures. Such conditions can accelerate the degradation of tools, leading to potential failures. These failures not only compromise operations by providing inaccurate information but also result in delayed deliverables, tool repair, or even cancellation of the entire operation. Such setbacks translate into nonproductive time and substantial financial losses. Efficiency and speed in the maintenance process are critical when a logging tool fails. The maintenance team tackles the task of navigating extensive unstructured data to identify patterns of failures. Streamlining this maintenance workflow is essential to expedite the turnaround time of the tool, achieving its swift return to operational readiness and minimizing nonproductive intervals and associated financial losses. Manual analysis of these data proves extremely time-consuming in the context of an industry where avoiding downtime is a priority.

While Prognostics and Health Management (PHM) methods have been successfully utilized to enable predictive maintenance, this approach has its limitations (Mosallam, Laval, Youssef, Fulton, & Viassolo, 2018; Mosallam, Kang, Youssef, Laval, & Fulton, 2023; Mosallam, Youssef, et al., 2023; Kang et al., 2022). It primarily relies on equipment sensor data and does not take into account the rich source of information in maintenance logs, such as failure reports, asset performance, maintenance policies, and failure patterns collected during the life cycle of asset management. Through computerized analysis, i.e., NLP, it is possible to make the process considerably more efficient (Stenström, Al-Jumaili, & Parida, 2015). For instance, (Juan Pablo Usuga Cadavid & Fortin, 2020) utilized an NLP model named CamemBERT (Bidirectional Encoder Representations from Transformers) to predict the criticality and duration of maintenance issues based on free-form text comments from operators (Martin et al., 2019). Despite the unstructured and imbalanced nature of maintenance logs, the authors suggest that their approach can pro-

vide significant advantages in coupling production scheduling with maintenance logs, enabling the adaptation of planning to the shop floor. Despite the recent and rapid development of the NLP field, extracting meaningful insights from maintenance logs remains a challenging task. (Brundage, Sexton, Hodkiewicz, Dima, & Lukens, 2021) argue that current NLP tools are not suitable for engineering data and propose a domain-driven approach called Technical Language Processing (TLP). They suggest that key NLP tools need to be adapted to the maintenance domain based on available maintenance text-based data. For example, (Naqvi, Ghufran, et al., 2022) introduced a TLP approach utilizing a Case-Based Reasoning (CBR) framework paired with a domain-adapted BERT model to address maintenance issues through textual data from mining operations. This approach, particularly the use of a Transformer-based Sequential Denoising Autoencoder (TSDAE) for unsupervised fine-tuning and cosine similarity for case assessment, underscored the importance of domain-specific model training (Wang, Reimers, & Gurevych, 2021). (Lee & Marlot, 2023) proposed Oil & Gas domain-relevant entity and relationship extraction from drilling reports. The approach involves training a Named Entity Recognition (NER) model to identify key information or failure symptoms in the reports, such as equipment, operations, or events, which can be considered a fault detection task from maintenance logs. This is followed by a Relation Extraction model that identifies the relationships between the entities and recommends early mitigation using historical data. The authors also applied data augmentation techniques to increase the data samples and improve the model's performance in detecting rare entities. Finally, (Naqvi, Varnier, Nicod, Zerhouni, & Ghufran, 2022) propose an NLP method for fault diagnostics from maintenance logs. The study finds that fine-tuning CamemBERT outperforms classical NLP approaches and that data augmentation using deep contextualized embedding further improves performance.

We present an NLP-based fault detection approach leveraging a NER model based on the BERT framework for Logging-While-Drilling Service (LWD) (Hansen & White, 1991) (Figure 1). This approach addresses equipment failures within unstructured data, offering a robust solution for the oil and gas industry. The BERT model, chosen for its advanced contextual understanding of words in text, excels at identifying and classifying key entities related to equipment failure and operational procedures within textual data. Custom and actionable entities were defined through extensive data labeling to enhance the model's proficiency in recognizing relevant information.

The rest of this paper is structured into four sections. Section 2 presents a description of the failure investigation process. The method and the results are presented in section 3 and 4, respectively. Finally, section 5 concludes the paper.

Figure 1. Multifunction LWD Service.

2. Failure Investigation Process

Field incidents and maintenance data are utilized to construct the dataset required for this work. These data are stored across various business systems in diverse formats. Field incidents are reported in the Failure Investigation Business System known (FIBS). Field Crew generates a field failure report which includes the following details:

1. Basic event information, including event date, location and the suspected failed technology.
2. The primary content is the "Field Failure Description," a free-text input where the Field Crew documents all their observations concerning the event sequence and the failure symptoms of suspected technology. This part is the cornerstone of our analysis, as identifying historical events with similar failure symptoms is crucial.
3. The "Remedial Actions Attempted," also a free-text input, where the Field Crew records all the actions that they attempted to restore the tool to normal operation.

Maintenance Data is primarily stored in a maintenance business system. A field failure Work Order (WO) is generated for each technology implicated in field incidents and flagged by the field crew when creating the FIBS report. The main section of each Work Order for technicians involved in failure investigations is the failure description section, where they provide free-text input on analysis, testing, and findings. This segment serves as a valuable source of insights and knowledge, helping others who may encounter similar failures with the same technology. After completing the investigation and if any failed components are identified, this failed part is then recorded in a dedicated business system. The failed components are confirmed immediate causes in all historic incidents, which can be utilized to establish a failure Pareto chart, illustrating the probability of specific causes for distinct failure symptoms. The failure investigation process is summarized in Figure 2.

Figure 2. Failure Investigation Process.

A critical part of this process is analyzing failure reports of LWD service to determine whether the downhole conditions

have had any detrimental effects on the operability. Due to the complexity of this service, analysis of this vast amount of data is very time-consuming and prone to error if performed manually. Therefore, fault detection from maintenance logs is of utmost importance for operation. An automated tool, which can determine different failure symptoms from maintenance logs with minimal user input, removes variability, eliminates human error and provides an efficient decision on the required maintenance in a fraction of the time. The reliability benefits are clear and provide significant cost savings both for the client in terms of reduced Non-Productive Time at the rigsite and for the Original Equipment Manufacturer in terms of reduced Materials and Supplies (M&S) during maintenance and troubleshooting.

3. Proposed Method

Currently, this work focuses solely on one technology, a multifunction Logging-While-Drilling tool designed for oil and gas well drilling applications. This technology integrates a comprehensive suite of formation-evaluation measurements (resistivity, porosity, density, natural gamma-ray, etc.) and drilling parameters (temperature, pressure, shock, vibration, etc.) into a single housing. Given the domain-specific nature of the data, it was necessary to create bespoke entities tailored to our unique requirements. This crucial task was carried out by an SME. The SME annotated key entities within a vetted dataset, laying the groundwork for a robust NLP model. This model is adept at identifying and categorizing phrases that fall into predefined entity groups, each critical for deciphering the complex narratives within the data:

1. Failure Symptom: This category captures the explicit details of failures, such as 'png stopped firing' or 'no porosity data.' Identifying these allows for a precise understanding of the failure characteristics.

2. Data Channels: These entities encompass technical log parameter values like 'state changing to 2304.' Their recognition is vital for correlating technical readings with failure events.

3. Operational Actions: This group includes actions taken in response to issues, such as 'downlink to shutdown png.' Understanding these actions aids in assessing the effectiveness of operational responses.

4. Drilling Conditions: These entities report on the physical conditions during drilling, like 'top cement was tagged.' Recognizing these conditions is essential for contextualizing failures within their operational environment.

The proposed method consists of three steps: data collection, data preparation, and modelling, as illustrated in Figure 3.

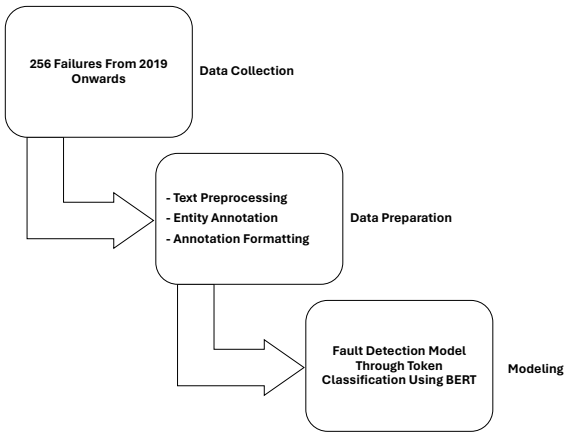

Figure 3. Proposed Method.

3.1. Data Collection

The dataset comprises 256 failure descriptions, extracted from internal database tables, focusing on data from the year 2019 onwards. This time restriction was applied because the majority of relevant and validated data, as identified by the SME, begins from this period.

3.2. Data Preparation

The data processing involved three main steps: text preprocessing, entity annotation, and adaptation to the dataset format of the (*Hugging Face*, Accessed: 2024-05-27) library, a widely-used platform that provides pre-trained models for natural language processing tasks:

1. Text Preprocessing: In this step we concentrated on removing non-alphanumeric characters and converting all text to lowercase to ensure uniformity and reduce complexity in the dataset. Additionally, we removed sections of text that originated from application-dependent formatting, such as incident dates and job numbers, as these did not contribute valuable information for fault detection.
2. Entity Annotation: We utilized syntactic strategies to ensure qualitative consistency throughout the entire dataset. A significant decision in this process was to include verbs and adverbs in all entity categories. This approach was adopted to maintain grammatical consistency across entities, which is crucial for reducing the risk of misclassification. The annotation was executed by the SME using the Doccano application, resulting in a JSON (JavaScript Object Notation) file, a format used for storing structured data. This file contains failure descriptions and lists of three chained elements, detailing the starting character, ending character, and associated category for each entity. While only 256 reports were labeled, the annotated data itself is extensive, with each failure description often containing multiple annotated phrases and entities.

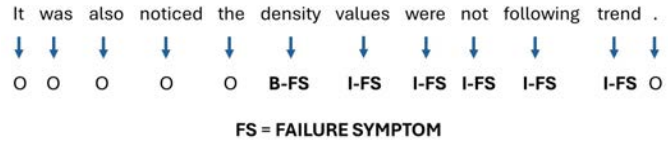

Figure 4. Hugging Face IOB Formatting.

3. Annotation Formatting: We converted generated annotations into a format compatible with the Hugging Face token classification paradigm. After validating the model, a corresponding tokenizer was utilized to divide the text into subwords. Subsequently, the character spans from Doccano were converted into Inside-Outside-Beginning tagging (IOB) format, a requirement for Hugging Face. An example of such formatting can be observed in Figure 4, where some tokens in a sentence are assigned the corresponding IOB formatted *FAILURE SYMTPOM* labels. The total amount of BI tags is $11,333$ as illustrated in Figure 5. The tokens ids and attention masks were also retained during the final conversion to the Dataset object. This object adheres to best practices for data splitting in cross-validation, featuring a distribution of 204 instances for training, 26 for validation, and 26 for testing.

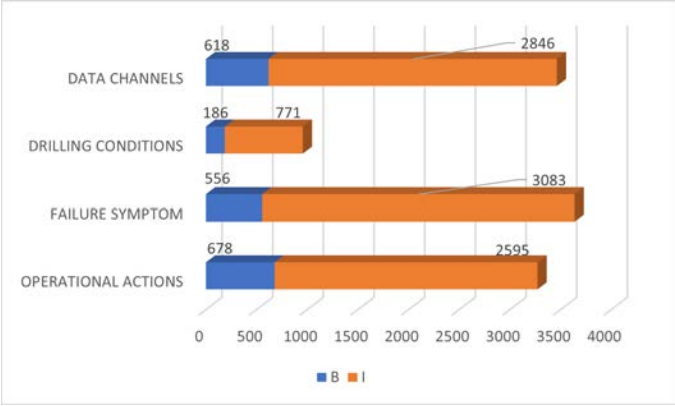

Figure 5. Bar Distribution Graph of BI-tags.

3.3. Modeling

Formally, we can define every failure description report, X, as a sequence of tokens:

$$X = \{x_0, x_1, ..., x_n\} \tag{1}$$

where x_i represents the i_{th} token in the report.

Our objective is to obtain a sequence of predicted labels, Y,

$$Y = \{y_0, y_1, ..., y_n\} \tag{2}$$

where y_i is the label of the x_i token.

For this purpose, we began by examining various unsupervised learning models to extract insights from text. However, we found that at the time of solution development, none were trained on an industry-specific corpus. Most available NER models were designed to identify general entities like date, location, person, and company, which did not align with our business-specific needs.

After completing the annotation of entities, we undertook a comparative analysis of several NLP models. This included, but was not limited to, Spacy NER, "distilbert-base-uncased", and "bert-base-cased". Our objective was to identify the most suitable model for our fault detection use case. Among these, "bert-base-cased" demonstrated initially promising results. Consequently, we focused on fine-tuning its hyperparameters to optimize performance.

The BERT model is pretrained on two tasks: masked language modeling and next sentence prediction. Each token in BERT is represented by a combination of its token embedding, segment embedding, and position embedding. During our fine-tuning process, we utilized BERT's default activation function, GELU, along with a final classification layer that employs a softmax function to determine class probabilities. For token classification, we extract the hidden layer representation of each token and apply the softmax function to compute the probabilities for each class.

The formula for the softmax function is detailed below, where K is the number of classes and z_i is the output of the classification layer:

$$Z = [z_0, z_1, ..., z_K] \tag{3}$$

$$s(z_i) = \frac{e^{z_i}}{\sum_{j=1}^{K} e^{z_j}} \tag{4}$$

4. Results

In line with the time constraints of our business objectives, we explored the hyperparameter space for the "bert-base-cased" model exhaustively. To evaluate our model's performance, we primarily focused on the F1-score, a metric derived from precision and recall. The formulas for precision, recall, and F1-score are provided below:

$$precision = \frac{TP}{TP + FP} \tag{5}$$

$$recall = \frac{TP}{TP + FN} \tag{6}$$

$$F1 - score = 2(\frac{precision * recall}{precision + recall}) \tag{7}$$

Entity	Precision	Recall	F1-score	No. of Instances
B-DATA CHANNELS	0.92	0.94	0.93	3816
I-DATA CHANNELS	0.81	0.74	0.78	2378
B-DRILLING CONDITIONS	0.50	0.18	0.27	227
I-DRILLING CONDITIONS	0.59	0.27	0.37	1073
B-FAILURE SYMPTOM	0.63	0.80	0.71	450
I-FAILURE SYMPTOM	0.72	0.79	0.75	2711
B-OPERATIONAL ACTIONS	0.50	0.78	0.61	460
I-OPERATIONAL ACTIONS	0.59	0.49	0.54	1708
macro avg	0.69	0.64	0.68	4762
weighted avg	0.88	0.88	0.88	4762

Table 1. Classification Report of BERT Checkpoint.

This effort led to a satisfactory model checkpoint, achieving an F1-score of 88%. This score reflects the model's precision and reliability in recognizing entities (See Table 1).

The most effective entities identified by the model were Data Channels and Failure Symptom, with weighted averages of 81% and 74% respectively. These averages were calculated by multiplying the F1-score by the corresponding support value and dividing by the sum of support for each BI-tags pair. Operational Actions showed average performance with a 55% score, while Drilling Conditions lagged at 35%. The lower performance in these categories correlates with a reduced token support count, indicating the model's sensitivity to class imbalances.

Our analysis of the text data revealed that the weakly predicted categories had less variance in our validated data sample, underscoring the need for more representative data for these categories. Other insights pertain to the nature of technology failures. We observed that there are a limited number of ways in which failures manifest, and this limitation aided the model's performance in identifying well-represented entities. Specifically, certain phrases indicating a specific techlog parameter value or failure symptom recur more frequently in the failure descriptions.

5. Conclusions

In this paper, we presented a fault detection NLP-based method from maintenance logs. The methods builds on identifying four technical-defined entities, essential to the failure investigation process. This approach entailed fine-tuning "bert-base-cased" model which achieved an F-1 score of 88%, underscoring the model's precision and reliability in recognizing critical entities.

The practical implications of our work are significant, with the potential to improve operational decision-making through enhanced pattern recognition in historical failure data. The impact of our findings is geared towards improving operational efficiency, reducing downtime, and cutting costs.

In future work, we aim to expand our research from identifying failures to comprehensively diagnosing them. This will involve a more detailed examination of failure events to extract insights into their causes and impacts. By advancing from simple detection to in-depth diagnostics, we will offer not just identification but also solutions.

Additionally, we intend to develop a Case-Based Reasoning system that will complement our NLP framework. This system will feature a similarity model to gather and compare similar cases, bringing forward solutions that have been effective in the past. This enhancement is expected to not only pinpoint failures but also recommend validated resolutions, thereby streamlining the path from problem recognition to problem-solving.

The integration of the CBR system is expected to leverage historical insights and expert knowledge, evolving into a dynamic model that improves with each new dataset. This step will mark a significant advance in intelligent fault detection systems, pushing the boundaries of what is currently possible in operational efficiency and safety.

BIOGRAPHIES

Corina Maria Panait is a Data Scientist at SLB Romania, within the Data Science & AI Hubs. Her 1.5 years of experience in the company concentrate on NLP solutions, designed to obtain quick insights from unstructured text data in the following business areas: PHM, Health & Safety and Generative AI. Corina holds a Master's in Data Science from the University of Bucharest and a Bachelor's in Economics Cybernetics from the Bucharest Academy of Economic Studies.

Qian Su is currently a Technical Engineer for the Offshore Atlantic Basin Well Construction. In her role, she provides technical support with a focus on electronics for failure investigations, conducts reliability improvement initiatives, and digital applications. Qian holds a Master's degree in Electrical Engineering from the Institut National des Sciences Appliquées de Lyon.

Nahieli Vasquez is a Data Scientist with SLB France for around a year and a half. She has several years of experience working in NLP applications. Prior to this position, she has worked in applying NLP methods to curriculum vitae scoring and social network moderation. Her areas of interest include NLP, Gen AI, Cloud services and End-to-end product development. She holds a Master Degree in Quantitative Economics and Econometrics from El Colegio de Mexico.

Ahmed Mosallam is the Data Science & AI European Hub Manager at SLB technology center in Clamart, France. He has his Ph.D. degree in automatic control in the field of PHM from University of Franche-Comte in Besanc¸on, France. His main research interests are signal processing, data mining, machine learning and PHM.

Fares Ben Youssef Fares Ben Youssef is the Reliability and COSD Manager, where he leads a team of Engineers and Technicians focused on several aspects of Well Construction for Offshore Atlantic basin. His responsibilities include delivering Fit for Basin projects, which involve digital, material, mechan-

ical, and electrical design changes tailored to the Offshore Atlantic basin requirements. In 2011, Fares earned a Master's degree in Electronics and Telecommunication Engineering from the University of Paris-Saclay, France.

Olexiy Kyrgyzov graduated with B.S. and M.S. in CS in 2001 and 2002, respectively, from Dnipro National University (Dnipro, Ukraine). He received his Ph.D. in EE from the Northeastern University (Boston, USA) in 2010, where he worked on research projects as an assistant of Prof. Deniz Erdogmus. The topic of his dissertation was 'Non-redundant tensor decomposition'. After graduation he moved to France and worked on a wide range of projects in state research centers. He is currently a senior data scientist in DS&AI Hub Eur at SLB (Clamart, France). His research focuses on machine learning and artificial intelligence with applications to signal processing, natural language processing, and image analysis. He works to solve real-world Oil & Gas data analysis problems with delivering final compact and efficient products.

ABSTRACT

Traditionally, companies have relied on vibration based condition monitoring technologies to implement condition based maintenance strategies. However, these technologies have drawbacks, such as the requirement of contact accelerometers. As an alternative, acoustic condition monitoring is non-invasive and allows for easy deployment. Furthermore, the use of microphones potentially enables the monitoring of multiple components using a single sensor, making the monitoring system scale better with machine or production complexity. However, microphone signals typically show a low signal-to-noise ratio (SNR), impacted by the high level of background noise which is often present in industrial environments. Particularly, the traditional method for monitoring the health condition of rolling element bearings, based on assessing whether the squared envelope spectrum of the bearing signal exceeds a given threshold at the fault frequencies, cause too many false positives when applied directly to microphone signals. It is therefore crucial to develop strategies to increase the robustness of acoustic monitoring methods. In this paper, we present and evaluate two data-driven strategies to robustly diagnose bearing faults from a microphone signal. Our proposed strategies are noise weighting based on the detection of background noise, and an artificial intelligence (AI) model that uses as input a combination of the traditional bearing fault frequencies and the mel spectrum of the microphone signal. These methods leverage both domain knowledge and data-driven techniques to increase the detection robustness. Our approach is implemented as a model trained and tested on bearing accelerated lifetime tests performed in the Smart Maintenance Lab setup at Flanders Make. Our results show that the use of our proposed strategies leads to significant improvements in diagnostic performance and time to first detection over noise-unaware acoustic monitoring methods.

1. INTRODUCTION

Condition monitoring involves the continuous monitoring of machine parameters to detect changes that are indicative of a developing fault. This a key component of condition based maintenance, the strategy that schedules maintenance actions based on the current health diagnosis of machine components, with the goal of reducing equipment downtime and total maintenance cost. The detection of faults in rolling element bearings is of special interest, since they are critical components of rotating machinery, and their faulty signals are often masked under other dominant sources (Randall, 2011). The use of accelerometers is the most common approach for monitoring bearing and gear faults, as vibrations often carry early information of their incipient damages (Lee et al., 2014).

There exist a wide range of well-established signal processing methods that are applied to vibration signals in order to estimate the health condition of a bearing. One of the most successful methods is envelope analysis, whose comprehensive description is given in (Randall & Antoni, 2011). It relies on the extraction and tracking of the fault characteristic frequencies in the squared envelope spectrum (SES) of the vibration signal generated by the bearing. As their name suggests, these frequencies are related to the bearing faults, and contain an increasing amount of energy as faults become more serious. For bearings operating under conditions of low load and low rotational speed, a different method based on stochastic resonance is proposed and shown to outperform envelope analysis in (Ompusunggu, Devos, & Petre, 2013).

However, a disadvantage of diagnosis techniques based on vibration analysis is that the accelerometers should be mounted close to the rotating component of interest. Consequently, several accelerometers are needed to monitor multiple bear-

ings, and accessibility constraints may render this impossible.

As an alternative to overcome these limitations, acoustic non-contact sensors such as microphones have recently drawn attention mainly for two reasons. First, they allow for easier deployment, as they do not need to be physically mounted by bolts, glue or magnets. Second, microphone signals may acquire information from several bearing signatures, potentially enabling the monitoring of multiple components with fewer sensors than in schemes based on accelerometers. Nevertheless, microphones will unavoidably collect signals from undesirable noise sources mixed with the signals emitted by the bearings. In industrial environments, these noise sources are generally quite strong and varied in nature, leading to microphone signals with low signal-to-noise ratio (SNR) that result in poor diagnosis performance. For this reason, dedicated methods to increase the robustness to background noise are crucial in acoustic monitoring.

Due to the wide array of different noise sources present in industrial environments, data-driven strategies are a powerful tool to increase the robustness of acoustic monitoring. In a data-driven strategy, healthy and damaged bearings are classified by a data-driven model trained using a set of relevant acoustics features. In (Mian, Choudhary, & Fatima, 2022), six sound quality features from microphone signals were used to train a support vector machine to diagnose bearing damages. For the diagnosis of bearing, rotor and stator faults in induction motors, a frequency domain feature extractor method combined with a nearest neighbour classifier is proposed and shown to perform well in (Glowacz, 2019).

Another commonly used strategy to achieve robust acoustic monitoring relies on microphone arrays and beamforming. The works presented in (Cardenas Cabada, Leclere, Antoni, & Hamzaoui, 2017; Ricardo Mauricio, Denayer, & Gryllias, 2022, 2023), and references therein, show that this strategy can produce good diagnosis results for bearing monitoring using beamforming. However, the requirement of multiple microphones and precise positioning increases the practical complexity of implementing this solution. For this reason, we consider beamforming strategies outside of the scope of this work, and focus on data-driven strategies using a single microphone.

In this paper we propose two data-driven methods to increase the robustness of the diagnosis of bearing faults using acoustic sensing. Our first approach is noise weighting based on the detection of background noise, and the second one is an artificial intelligence (AI) model whose input is a combination of the bearing fault frequencies and the mel-spectrum of the microphone signal. These methods integrate both domain knowledge and a data-driven technique, and they are trained and tested on bearing accelerated lifetime experiments performed in the Smart Maintenance Lab setup at Flanders Make. The goal is to evaluate the performance of our proposed methods, and show that acoustic monitoring is a cost effective and practical alternative to vibration monitoring.

The rest of this paper is structured as follows. In Section 2, the well-established envelope analysis method for bearing fault diagnosis is reviewed, and an explanation of its poor performance when applied to acoustic sensing is provided. Our two proposed data-driven methods for robust acoustic bearing fault diagnosis are detailed in Section 3. A description of the experimental setup is given in Section 4, which includes the performed bearing accelerated lifetime experiments, the acoustic scene, and the parameters of the signal processing and AI models. The performance of our proposed methods is evaluated and discussed in Section 5. Finally, the main conclusions are summarized in Section 6.

2. PROBLEM STATEMENT

Rolling element bearings are a crucial component in a wide variety of rotating machinery. However, over time they can develop faults such as surface fatigue defects or wear. For localized faults, as the rolling elements strike a fault in the inner or outer race, an impulse is generated that excites high frequency resonances on the structure between the bearing and the sensor location.

2.1. Vibration-based bearing fault diagnosis

The vibration signals from a faulty bearing can be modelled as a modulated blend of several signal components: an impulsive signal associated with the fault, the high frequency signals related to the the dynamics of other machine components such as the shaft and gears, the modulation between these signals and additional noise. The well-established method for bearing diagnostics is the so-called envelope method, which first enhances the impulsive signal generated by the fault, and then estimates the energy at the fault characteristic frequency and its harmonics from its squared envelope spectrum (SES). A complete explanation of the method is provided in (Randall & Antoni, 2011).

In this paper we focus on inner race faults, for which the fault characteristic frequency is the ball pass frequency, inner race (BPFI), given by

$$f_{\text{BPFI}} = \frac{n f_r}{2} \left\{ 1 + \frac{d}{D} \cos \phi \right\}, \tag{1}$$

where f_r is the shaft speed (frequency), n is the number of rolling elements, d is the diameter of the rolling elements, D is the pitch diameter , and ϕ is the contact angle. Other fault characteristic frequencies are the BPFO (ball pass frequency, outer race) and the BSF (ball spin frequency), corresponding respectively to outer race and rolling element faults.

In order to quantify the presence and severity of an inner race fault, we use as a feature the median of the SES value at the

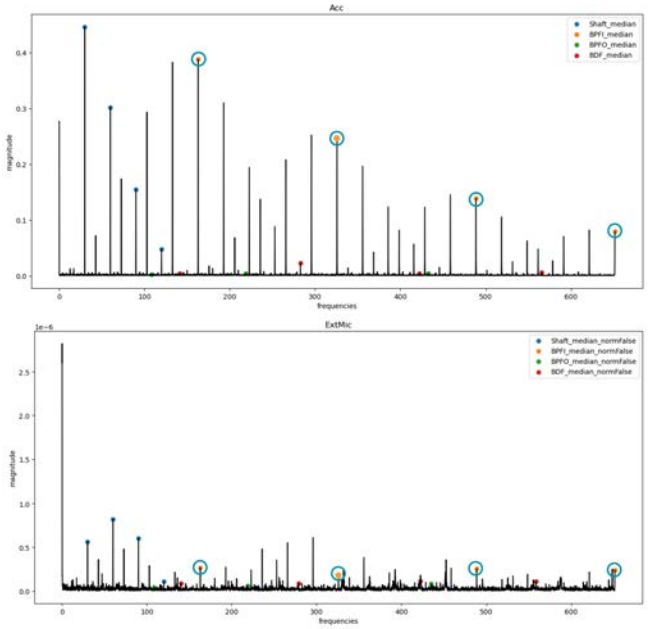

Figure 1. The squared envelope spectrum (SES) of the signal produced by a bearing with an inner race fault, acquired with an accelerometer (top) and a microphone (bottom). The BPFI and its first three harmonics are encircled in blue. The shaft frequency, BPFO and BDF (twice the BSF) are indicated for the sake of completeness.

BPFI and its harmonics. Throughout the rest of the paper, we refer to this feature as the BPFI feature. Mathematically, it is expressed as

$$\xi_{\text{BPFI}} = \underset{k}{\text{median}} \left\{ Y(k f_{\text{BPFI}}) \right\}, \quad k \in \{1, \ldots, n_{\text{harm}}\}, \quad (2)$$

where $Y(k f_{\text{BPFI}})$ denotes the peak magnitude of the SES at the k-th harmonic of the BPFI, $\underset{k}{\text{median}}\{\cdot\}$ denotes the median value of the set indexed by the integer k, and n_{harm} is the number of harmonics considered. Finding the peaks is done by searching the maximum SES magnitude around the theoretical fault frequency (Eq. 1) and its harmonics, within a pre-defined range tolerance.

2.2. Noise-unaware acoustic diagnosis

The direct application of diagnosis based on the fault characteristic frequencies, such as the BPFI, to acoustic sensing presents two problems. The first is that microphone signals are generally weaker than vibration signals, due to the larger distance between the microphone and the bearing. An example of this issue is provided in Figure 1, which shows a comparison of the SES from an accelerometer and a microphone signal produced by a bearing with an inner race fault. The BPFI and its first three harmonics can be easily identified in the accelerometer SES, while they cannot be clearly distinguished from the noise floor in the microphone SES.

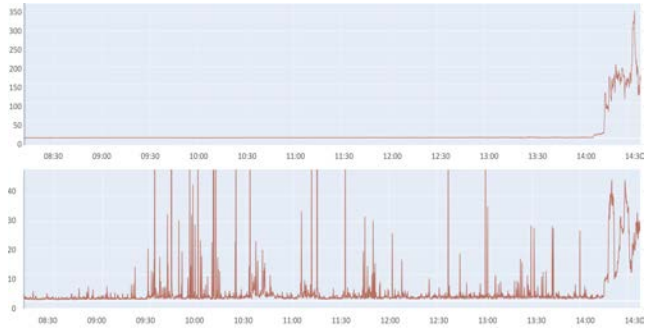

Figure 2. Comparison of the BPFI feature ξ_{BPFI} between an accelerometer (top) and a microphone signal (bottom) over a bearing accelerated lifetime.

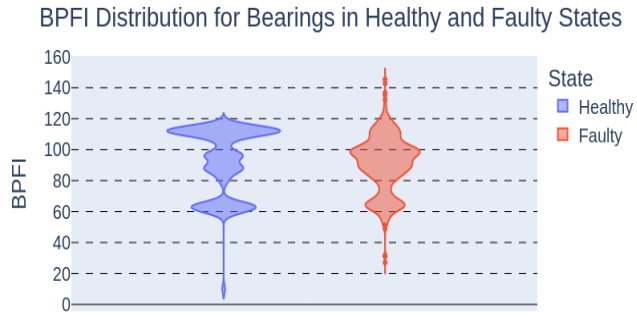

Figure 3. Comparison of the distribution of microphone-based BPFI feature ξ_{BPFI} between healthy and faulty states over the entire dataset.

The second problem is that the background acoustic noise is considerably stronger than the noise present in a vibration signal acquired by an accelerometer, and more diverse in nature due to the wide variety of potential noise sources present in industrial environments. As a result, microphone signals typically have a significantly poorer SNR. Moreover, due to this background noise, there will be additional energy present in the BPFI and its harmonics even when the bearing is healthy, leading to a great number of false positives over the bearing's lifetime.

This matter is illustrated in Figure 2, where a comparison is shown between the BPFI feature of an accelerometer and a microphone signal over the lifetime of a bearing in one of our accelerated lifetime experiments. The experimental setup and conditions are described in Section 4. It can be readily seen that the BPFI feature in the accelerometer signal displays a clear distinction between the healthy and faulty states of the bearing, while the BPFI feature in the microphone signal exhibits many spikes during the healthy state, leading to an unreliable diagnosis of the bearing inner race fault. Figure 3 further demonstrates the difficulty by showing the great overlap between the distributions of BPFI feature values acquired through the microphone for bearings in healthy and faulty states.

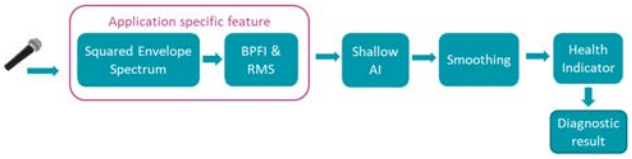

Figure 4. Diagram of the noise-unaware method with shallow AI for diagnosis of bearing inner race faults with acoustic sensing. The diagram would represent the baseline method by removing the shallow AI and the RMS feature.

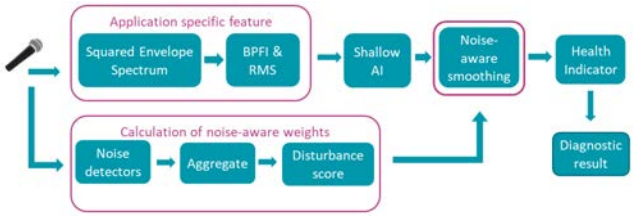

Figure 5. Diagram of noise-aware smoothing for diagnosis of bearing inner race faults with acoustic sensing.

The simplest strategy to enhance the diagnostic performance using the BPFI feature is to introduce a smoothing step. This method, with the choice of a median filter for smoothing, is what we consider our baseline for comparing the performance of diagnostic methods in this paper.

A more refined step is to introduce a shallow AI model before smoothing. In our case, this shallow AI is a two-layer fully connected neural network (NN) whose input features are the BPFI feature ξ_{BPFI} and the RMS value of the microphone signal. Both methods do not take the presence of acoustic noise explicitly into account, so we refer to them as noise-unaware methods. In particular, the BPFI and RMS features are very poor informants on the presence of background noise, hence the shallow AI can learn very little about rejecting undesired disturbances.

Figure 4 displays a diagram representing noise-unaware diagnosis with shallow AI and smoothing. The same diagram would represent the baseline method by removing the RMS feature and the shallow AI block.

3. Methods for robust acoustic bearing fault diagnosis

In this section we describe the two data-driven methods that we propose to increase robustness to noise in acoustic bearing fault diagnosis. As explained in Section 2, background noise introduces unreliability in the form of a high amount of false positives. The goal becomes therefore to reduce these false positives while retaining as much of the true positives as possible.

3.1. Noise-aware smoothing

Noise-aware smoothing aims to refine the health indicator calculated from the BPFI feature by taking into account the noise level present at each interval of time. To achieve this, a weighted median filter is applied to the raw health indicator over an interval of the last N points, where the weights are designed such that the influence of each point is inversely proportional to its noise level. A diagram of the diagnosis process including this strategy is shown in Figure 5.

The weighted median filter works as follows. If we are given a series of predictions $x_0, ..., x_t$ with noise levels $d_0, ..., d_t \in [0, 1]$, and a window size N, the noise-weighted prediction at time t would be computed as follows:

1. Assign a weight to every prediction $x_{t'}$ as $1 - d_{t'}$.
2. Sort predictions $x_{t-N}, ..., x_t$ and keep their associated weights $w_{t-N}, ..., w_t$ in that order too.
3. Compute the cumulative weight for each item $x_{t'}$, i.e. $\sum_{a=t-N}^{t'} w_a$.
4. The item where the cumulative weight exceeds half of the total weight is the weighted prediction, i.e. x'_t at time t such that $\sum_{a=t-N}^{t'} w_a \geq \frac{1}{2} \sum_{w=t-N}^{t} w_a$

Median smoothing follows the same procedure, except that all the weights are set to 1, reducing it to a regular median filter.

In order to obtain a noise level, each time interval is assigned a score that represents the likelihood that an undesired acoustic disturbance is present in it. For our case, an undesired disturbance is defined as any short-time sound that is not informative about the phenomenon being monitored, i.e., all sound events not generated by the bearing of interest itself. This excludes stationary background noise as well as disturbances that take last longer than a round of data acquisition (ten (10) seconds in our case).

This score is computed as the maximum of the output of a collection of noise detectors. These detectors are designed to indicate acoustic disturbances that can be characterized as events. This means any sounds whose presence in time, although it may be repeated, is limited. Examples include tools getting dropped, sporadic speech, various machinery turning on or off. Specifically, we implemented detectors targeting disturbances with the following characteristics:

Narrow-band disturbances: This detector indicates the presence of noise in a specific frequency band. In our experiments, the sources of this kind of disturbances were a pump and a forklift present in our laboratory.

High frequency disturbances: This detector indicates the presence loud, complex noises that have a lot of energy in high frequency bands. In our experiments, the source of this kind of disturbances was a neighboring experimental setup that kept loudly dropping off metal pipes.

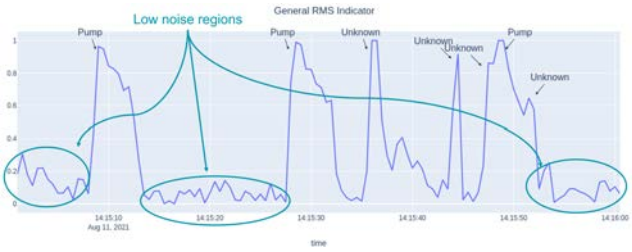

Figure 6. Example of the output of the detector for general loud disturbances. The regions circled correspond to intervals where no disturbance is detected.

General loud disturbances: A detector for loud events, designed to capture sudden changes in the root mean squared (RMS) value of the signal. This takes into account the fact that the bearings do not cause such changes at any point in their operation.

Speech disturbances: Voice Activity Detection (VAD) is a field of active research with many mature results. For this reason, we chose to utilize a VAD solution, provided by the Silero project (SileroTeam, 2021), based on a pre-trained neural network.

All detectors, except those for speech and general loud disturbances, require a characterization of the acoustic disturbances in the environment where the bearing of interest is located. An example of the output of the detector for general loud disturbances is shown in Figure 6. This detector captures some loud events that do not correspond to our known disturbance sources, marked as unknown. It also reacts to the pump activation, since it produces sudden changes in the RMS value of the signal. Capturing the same disturbance with several detectors is beneficial, as we are interested in catching as many as possible rather than determining their type. The regions of low disturbance score, that appear circled in the graph, are those given higher weight by noise-aware smoothing.

3.2. Noise awareness with deep AI and hybrid features

This method aims to utilize a deep AI model to obtain a reliable health indicator of bearing faults from acoustic information. The main idea is to introduce and train a deep AI model that uses adequately general features extracted from microphone recordings of healthy and faulty bearings. At a high level, it operates as a generalized way to clue the model in about what parts of the frequency spectrum are useful to pay attention to, and which parts are best to ignore. This model acts in combination with the very specific fault frequency features, thus integrating a data-driven technique with domain knowledge. The diagram in Figure 7 represents the diagnostic process that combines the indicators from both the BPFI feature and the deep AI-model.

The advantages of using a deep AI model are twofold. The first one is that it can learn complex patterns during the training process, leading to better diagnostic performance. The

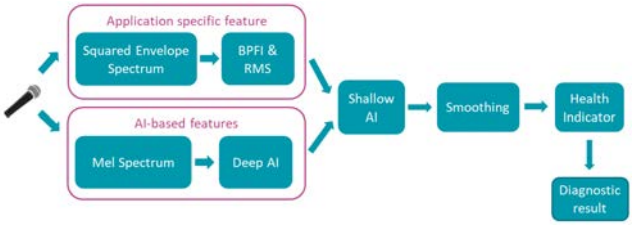

Figure 7. Diagram of deep AI-based noise awareness for diagnosis of bearing inner race faults with acoustic sensing.

second one is that, as long as sufficiently varied examples of disturbances are included during the training phase, it can learn to work with many kinds of noise sources.

The features for this method need to represent the relevant bearing fault information while being of reasonable dimensionality. For this purpose, the features we chose are the mel-spectrogram of the acoustic signal. This is a spectrogram obtained by a mel filter bank, a set of half-overlapped triangular filters equally spaced on the mel scale (Rabiner & Schafer, 2010). Since this is a logarithmic scale for frequency, the filters are narrower for low frequency bands and wider for high frequency bands.

For training, we chose a supervised approach, where we use as labels the output of anomaly detection from the accelerometer signal as ground truth. The features are normalized using their values at the start of the experiment, as the absence of normalization would be too sensitive to microphone gain and positioning.

There are several choices for the deep AI model, such as a deep neural network, a recurrent neural network, a temporal convolutional network or a transformer. In this work, our choice is a deep neural network (DNN), whose specifics are given in Section 4.3.

4. Experimental setup

The bearing datasets used in this study are collected in Flanders Make's Smart Maintenance Living Lab (Ooijevaar et al., 2019). This lab is developed as an open test and development platform and aims to support the adoption of condition monitoring technologies in the industry. It consists of seven identical drive train sub-systems. The setups are designed to perform accelerated lifetime testing of bearings and run bearings to their end-of-life. The accelerated lifetime test allows to create surface fatigue faults in bearings and monitor the fault evolution and accumulation during the (accelerated) life.

4.1. Bearing test rig and accelerated lifetime experiments

One of these experimental setups to perform the accelerated lifetime test is shown in the middle image of Figure 8. The setup comprises of a single shaft with a test bearing. The shaft is supported by a support bearing on each side. The test bear-

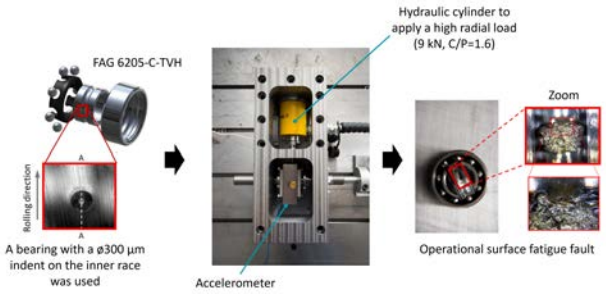

Figure 8. Illustration of the initial bearing state (left), the experimental test rig setup designed to perform accelerated life tests (middle), and the final state, a surface fatigue fault at the inner race of the bearing (right).

ing is lubricated by an internal oil bath. The setup is driven by a motor at a rotation speed up to 3000 RPM. In this work, we focus on experiments driven at 2000 RPM. Each setup is equipped with an accelerometer, temperature sensor, load sensor and speed sensor. The radial accelerations are measured at a sampling frequency of 50 kHz by an accelerometer attached to the bearing housing. The rotational speed and radial load of each setup can be controlled, such that each setup can operate at stationary and non-stationary operating conditions. An industrial Beckhoff control platform is used to acquire and store the sensor signals and to control the speed and load of each setup.

In total more than 70 bearing accelerated life tests have been performed on a FAG 6205-C-TVH deep groove ball bearing resulting in surface fatigue faults at the inner race. Two mechanisms are used to accelerate the bearing lifetime:

- A high radial load up to 9 kN (C/P = 1.6) is applied to the bearing outer ring with a hydraulic cylinder.
- Before the start of the test a small initial indentation of approximately 300 µm was created in the bearing inner race using a Rockwell C hardness tester. This indentation is used as a local stress riser and represents a local plastic deformation caused by, for instance, a contamination particle.

The accelerated life time tests are stopped as soon as 20g peak-to-peak accelerations are reached, resulting in severe rolling contact surface fatigue at the inner race (Halme & Andersson, 2009). The start and end condition of the inner race of one of the test bearing are shown in the left and right images of Figure 8.

4.2. Acoustic setup

The acoustic signals are acquired through two B&K 4189A21 microphones sampled at 50 kHz. One of them was placed under the safety cover of the bearing test setup, and the other outside of the cover, as showed in Figure 9. These microphones will be referred to respectively as *IntMic* and *ExtMic*

(a) Microphone inside the safety cover, referred to as *IntMic*.

(b) Microphone outside the safety cover, referred to as *ExtMic*.

Figure 9. Illustration of microphone positions used for the experimental recordings.

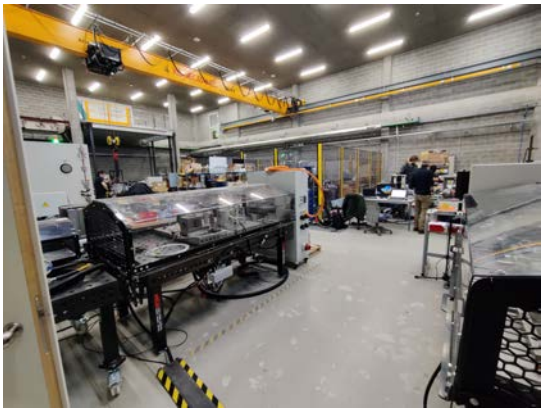

Figure 10. Illustration of the acoustic scene.

throughout the rest of the paper.

The experimental setup is situated in a large laboratory area at Flanders Make's facilities in Leuven, which has an uncontrolled and reverberant acoustic environment shown in Figure 10. It is a concrete room that contains many different kinds of setups such as drivetrains, looming machines etc., sometimes running simultaneously. There is also human activity with technicians and engineers running and maintaining the setups, or going about their daily activities. Due to the varying sizes of the setups here, sometimes small vehicles like forklifts or the crane integrated into the laboratory can also operate here. This makes the background noise potentially quite complex.

Specifically for the dataset we collected, there are a few common sources of noise that are often present, and we chose them as our focus for techniques that need us to characterize the kind of background noises that need suppressing. The most consistent, and arguably the simplest, disturbance is that coming from the hydraulic pump used to apply load on the test bearing. This pump activates roughly every minute in order to keep the pressure, and thus the load, constant. This cre-

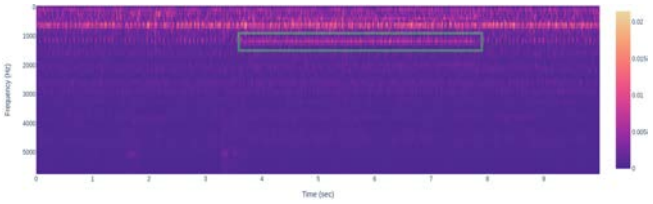

Figure 11. The spectrogram of an instance of pump activation with a faulty bearing being tested, captured by the *ExtMic* microphone. The pump activity is highlighted inside the green rectangle.

ates a very audible and consistent noise that is quite apparent in the signal, as can be readily observed in the spectrogram presented in Figure 11. The second common disturbance is a sharp, impulsive noise made by a nearby setup dropping metal pipes in a container. This happens once or twice a minute. Finally, on multiple occasions, there are people who are either walking or standing around the setup while in conversation. These are usually captured by the microphones, and constitute a third kind of disturbance we are interested in.

4.3. Processing configuration

The feature extraction is performed on segments of 10 seconds. For the BPFI feature, the tolerance of the SES peak search around the BPFI and its harmonics is set to 1.5% of the theoretical frequency (Eq. 1). The number of harmonics n_{harm} for the calculation of ξ_{BPFI} (Eq. 2) is set to 4. The mel spectrogram is calculated on 64 mel bands. The features are normalized using Z-score normalization, where the mean and standard deviation are computed on the first 30 minutes of the corresponding experiment. In experiments that lasted for more than one day, this calculation is done for each day.

Our dataset consists of two groups of run-till-failure experiments, all at 2000 RPM, where the bearing developed an inner race fault. The first group is characterized by continuous monitoring, where the sensors (accelerometer and microphones) constantly acquired data. This group contains 11 experiments, 7 of which run till failure and 4 of them ended prematurely. The second group contains 5 experiments were periodic monitoring of 1 second every 10 seconds was applied, 3 of them run till failure and 2 of them ended prematurely. This group is only used for training purposes. For cross-validation purposes, the dataset is split in three folds.

In addition to the captured data, a set of ground truth labels is also provided. It should be noted here that this labelling is not based directly on the physical state of the bearing, since it would not be available without stopping the test and dismantling the bearing, but based on analysis of the data captured by the accelerometer. Using this labelling the moment in time where the bearing starts having faulty behavior is determined. Data prior to this moment is then considered as healthy, and data afterwards is considered faulty.

For the deep AI model, we choose a deep neural network (DNN) with an input layer, three hidden layers of 32, 16 and 8 units, and an output layer.

5. Results and Discussion

In this section, we evaluate and compare the performance of both noise-aware and noise-unaware methods for bearing fault diagnosis using the microphone *ExtMic* signals, as its location outside of the safety cover of the setup is the most realistic. For clarity, we provide a summary of the methods evaluated in the following list.

1. **Noise-unaware methods**: These methods, described in Section 2.2, do not take the presence of noise explicitly into account. A diagram illustrating both methods is shown in Figure 4.
   (a) **Baseline**: The baseline method is based on the BPFI feature with median-smoothing.
   (b) **Shallow AI**: This method uses the BPFI and RMS features as input to a two-layer fully connected NN (shallow AI) and median-smoothing to achieve a diagnosis result.
2. **Noise-aware methods**: These methods aim to increase their robustness to noise, as explained in Section 3.
   (a) **Noise-aware smoothing**: The method described in Section 3.1, where the weights of the smoothing filter depend on the detected noise level. Its diagram is shown in Figure 5.
   (b) **Deep AI with hybrid features**: The method detailed in Section 3.2. It combines the BPFI and RMS features with mel spectrum features, where the latter are the input of the DNN (the deep AI model). It uses median-smoothing to obtain a diagnosis result. Its diagram is shown in Figure 7.
   (c) **Deep AI combined with noise smoothing**: This method is a combination of the two previous methods, i.e., the methods 2a and 2b.

5.1. Performance metrics

We use several metrics to assess the diagnostic performance of the proposed methods.

- **EPR**: The point on a precision vs. recall plot where these two metrics are equal. A high score indicates a high ratio of true positives with respect to both predicted positive samples and real positive samples. Expressed as a percentage.
- **ROD**: Rate of detection, the rate at which faults are detected before the safety stop, at a given precision value, equivalent to *recall*. In our case, we compute this value at 99% precision. More formally, if TP and FN denote respectively the true positive and false negative counts,

then

$$ROD = \frac{TP}{TP + FN}, \tag{3}$$

where $\frac{TP}{TP+FP} > .99$. Expressed as a percentage.

- **TOFD**: Average time of first detection in seconds, i.e, the time between the occurrence of the fault and the first time the model detects its, for a given precision value. In our case we compute this value at 99% precision, and it is only considered if the ROD is 100%. In the same way as our ground truth labels, the occurrence of the fault is defined based on accelerometer data. Note that this metric can be defined w.r.t. any source more reliable than the acoustic signal we are using. Formally, this metric is computed as

$$\frac{1}{N}\sum_{n=1}^{N} t_{fault,n} - t_{detection,n}, \tag{4}$$

where $ROD = 1.0$, $t_{detection,n}$ is the time of detection, and $t_{fault,n}$ is the time the fault occurred, both for the n-th experiment.

Regarding the TOFD metric, note that there is always some delay between the occurrence of a fault and its detection. There are two main sources of this delay. The first one is related to smoothing, and is not affected by the fact that we are running accelerated lifetime tests. This means that it would remain constant (for a given smoothing filter) even in regular testing. The second is the time gap between the fault being available to a vibration sensor versus it being available to an acoustic sensor. This delay pertains to the evolution of the fault, and therefore scales with the fault accelerations applied during the testing procedure. If we were to run regular lifetime tests, these delays would be multiplied by a corresponding factor. This means that, while the first delay is adjustable, the second delay is a consequence of the physics of the system and can only be reduced so much. It is a hard constraint on acoustic monitoring.

5.2. Performance results

The performance metrics for our evaluated methods are displayed in Table 1.

5.2.1. Performance of noise-unaware methods

It can be clearly seen that the baseline method's performance is quite poor, since its EPR is barely over 50 %, and at 99% precision it is only able to detect 14% of the faults.

The introduction of the shallow AI causes a significant jump in model performance, where it can now reach 100% ROD at a precision level of 99%, and an EPR point of 69%. However, note that the TOFD of 1520 seconds, about 25 minutes, is quite high, due to the required size of the smoothing window to reach a high precision. An example from the health indicator obtained by the shallow AI method is displayed in Figure 12, both before and after median smoothing. It can be observed that the shallow AI allows for a clear distinction of the faulty state when the fault actually develops, but it is the smoothing that removes the high amount of false positives. However, each process introduces a noticeable delay in the health indicator, which is expected to be dependent on the particular characteristics of the background noise.

Table 1. Performance results of the evaluated methods.

Method	EPR	ROD	TOFD
Baseline	55%	14%	-
Shallow AI	69%	100 %	1520 sec
Noise-aware smoothing	72%	100 %	1031 sec
Deep AI & hybrid features	79%	100 %	605 sec
Deep AI & hybrid features + noise-aware smoothing	81%	100 %	600 sec

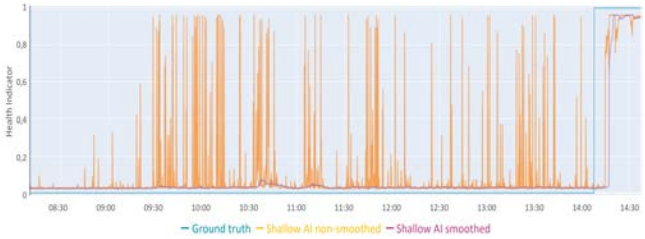

Figure 12. Example of health indicator obtained from the shallow AI method before and after median smoothing.

5.2.2. Performance of noise-aware methods

The use of noise-aware smoothing increases the EPR to 72%, maintains the ROD of 100%, and its TOFD is decreased by 33% with respect to the TOFD of the shallow AI method. This is a strict but moderate improvement over the best noise-unaware method.

The further addition of the mel spectrum features and the deep AI model causes a significant leap in performance, where the EPR point reaches 79%, and the TOFD is decreased by 42% and 60% of the TOFD values of the noise smoothing and shallow AI methods respectively. This improvement demonstrates the ability of the DNN to learn complex patterns from the mel spectrum features, and to complement the BPFI feature to achieve a better diagnostic performance. An example from the health indicator obtained by this method is displayed in Figure 13, both before and after median smoothing. It can be readily observed that before smoothing, the false positives are notably less frequent than in the example of the shallow AI method from the same experiment, shown in Figure 12. Smoothing removes these false positives, but crucially it in-

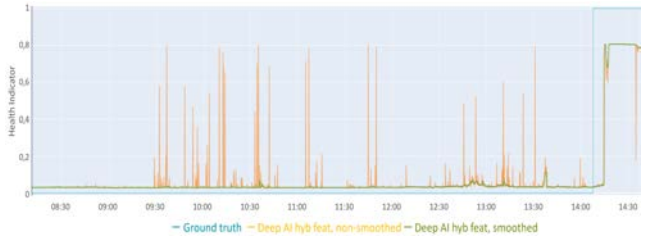

Figure 13. Example of health indicator obtained from the deep AI with hybrid features method before and after median smoothing.

Table 2. EPR points for median and noise-aware smoothing for methods 1b, 2a, 2b and 2c. Hybrid refers to the combination of BPFI and RMS with mel spectrum features.

Smoothing type	Features	
	BPFI & RMS	**Hybrid**
Median	69%	79%
Noise-aware	72%	81%

troduces less delay than in the shallow AI example. The reason is that, as the deep AI method produces fewer false positives, the smoothing window can be shorter, thus minimizing the additional delay introduced by this step.

Last of all, the combination of the two noise-aware methods, i.e., where noise-smoothing is applied to the deep AI method with hybrid features, achieves a moderate increase of the EPR until 81%, and no significant reduction in TOFD.

5.3. Effect of smoothing: noise-aware vs median

Note that the inclusion of noise-aware smoothing results in a moderate EPR improvement over the same method using median smoothing. This can be seen in Table 2, where the EPR points are arranged depending on the smoothing type and features that methods utilize. The reason is that noise-aware smoothing addresses the following issues:

- For a true increase in the anomaly score, noise-aware smoothing is typically faster to respond due to its non-even weighting.
- In case of quickly fluctuating anomaly scores, median smoothing is a lot less stable due to its inability to choose what to prioritize.

In most other cases noise-aware smoothing behaves comparably to median-smoothing, offering the same benefits. This makes noise-aware smoothing an attractive enhancement, although it comes with the additional cost of designing appropriate noise detectors for the acoustic scene where the machinery of the monitored bearings operates.

6. Conclusion

In this study, we have focused on developing robust methods for acoustic condition monitoring of inner race faults in rolling element bearings in industrial environments. This is a challenging problem due to the strong influence of background noise, which introduces a high amount of false positives and delays fault detection, resulting in poor diagnostic performance. Our two proposed noise-aware methods have different levels of complexity. The first and simplest one is noise-aware smoothing, which adapts the smoothing weights according to the detected noise levels. The second and more complex one is a deep AI model that uses mel spectrum features and acts in combination with the bearing fault frequencies to achieve a diagnostic result. These methods have been trained and tested with an accelerated bearing lifetime dataset acquired in the Flanders Make Smart Maintenance Lab, which is a reverberant environment where strong and diverse acoustic disturbances were present.

The results demonstrate significant improvements over the noise-unaware baseline, both in diagnostic performance and in detection time, using a single microphone signal. Moreover, these benefits are distinct both when the noise-aware methods are applied independently or in combination, so they can thus be chosen according to the monitoring requirements of each particular use case. In summary, we have shown that, when employing adequate strategies to increase robustness to noise, acoustic monitoring can be a cost-effective and practical alternative for vibration monitoring. Future work in this problem involves studying the influence of the training dataset size on accuracy, applying and testing our strategies to other bearing fault types, and studying the effect of data augmentation in the training of the deep AI model.

Acknowledgment

This research work was supported by Flanders Make, the strategic research centre for the manufacturing industry, and more precisely by the ACMON ICON research project. Authors would like to thank this project for funding the research presented in this paper.

ABSTRACT

This paper investigates fully automated condition monitoring of belt splices within operational belt conveyor systems, using IoT devices to predict and inform on potential belt breakage or tearing. Such events cause production stops and potentially harm workers. Belt splices are laminated belt connections subject to deterioration during operation and are usually weak spots. The proposed scheme circumvents manual inspection efforts and uses the HOSCH^{iris} DISCOVER IoT device for sensing and data acquisition. Each belt conveyor is equipped with one individual IoT device acquiring the motion signal of the scraper which is used to learn signal patterns of the pulley and the belt to identify both location and deterioration of the individual splices. Deterioration is characterized from an initial healthy condition to a severe condition of the splice to inform on the potential need for action. To assess the feasibility of the scheme, several tests are designed and performed in an industrial belt conveyor system. The results indicate that the scheme can provide valuable insights into the splice condition and its degradation.

1. INTRODUCTION

Belt conveyor systems are widely used to transport material and are an essential component in many industry sectors but are often critical assets in a production chain of bulk material, like in e.g. mining. Unexpected breakdowns of belt conveyor systems render production stops, losses, and can severely harm workers in close perimeter of such events.

The belt usually consists of several pieces, vulcanized together to achieve sufficient length. The vulcanized joints are called splices. In Figure 1, a simplified sketch of a belt conveyor is shown, and how splices could be distributed along the belt. The condition of these splices deteriorates during operation, leading to breakage or tearing. To preventively detect damage, all splices are regularly inspected. For this, the belt is run empty and at low speed to visually assess the belt surface and splices by a worker, leading to frequent downtimes in production. The quality of this manual condition assessment depends on the workers' expertise to identify issues on a moving belt, while keeping sufficiently attentive and tracking the splice locations. Such a campaign can last for several hours for longer belt conveyors, and thus human errors are not uncommon. To circumvent the problem of production losses, there is a need for monitoring solutions that work during normal operation.

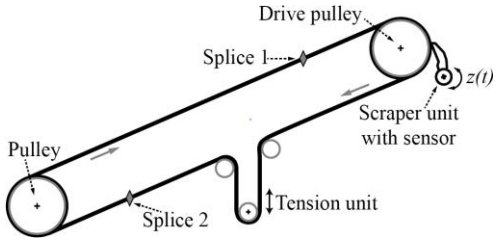

Figure 1: Sketch of the belt conveyor system with two splices and a scraper unit equipped with the sensing device generating the output $\boldsymbol{z(t)}$.

Various methods have been proposed for monitoring steel cord belt splices. Min (2010) suggests using Hall effect sensors to measure belt deformation and bending moment equations to assess the tensile force. However, concrete results validating this technique are lacking. Harrison (1985) and Kozłowski et al. (2020) propose methods based on measuring magnetic fields generated by belt reinforcement steel cords. Kozłowski, et.al. (2020) found that through a

variability analysis, the magnetic current can be compared to an estimated pattern. With this method, the cords could be monitored. Bancroft et al. (2017) used a camera and encoder to visually inspect mechanical splices and could determine the splice condition. Alport et al. (2001) developed artificial neural networks for splice monitoring using conveyor belt video footage, achieving splice identification accuracy of at least 89%. However, further development is needed for monitoring splice degradation and internal defects. Roxon Oy's HX products utilize laser scanning for surface damage and for monitoring the belt thickness that could detect splice elongation (Roxon, 2024).

The solutions discussed above require splices with steel cord reinforcement or mechanical splices that are easily visible. A camera installation or laser scanner, even though it has potential, requires the additional installation of equipment, resulting in increased maintenance costs. Moreover, the methods described above frequently lack definitive results regarding their accuracy.

The contribution of this paper is an analytics solution for condition monitoring of belt splices utilizing the displacement data from one individual belt scraper, as patented by Weimann and Kiel (2020). The benefit of this approach is that it can be used for all belt configurations, while in operation and with material on the belt. Since only the displacement of the scraper is analyzed, no additional equipment is required, making it a cost-effective solution.

The paper is structured as follows. First, a problem definition and description of the approach is given, followed by a summary of the scraper sensing solution. Next, the analytics solution is described, including belt speed estimation, transformation to distance domain, belt signature estimation, splice re-identification and degradation, and condition estimation. Thereafter, the proposed method is applied and tested in a real-life setting and the results are presented and discussed. Finally, the work is concluded.

2. Problem Definition and Approach

Splices are fixed locations on a belt which means that the individual splice locations need to be re-identified in $z(t)$, which is the displacement of the scraper (Figure 1). While $z(t)$ is time-based, the splice itself has a spatial location and structure along the belt. The problem of the condition monitoring of a splice over time is therefore to identify the passage of an individual splice at the sensor and to assess its degradation based on the signal that is acquired during the passage of the splice at the sensor. Moreover, the belt speed is not constant and needs to be treated as unknown. Using an individual IoT device combined with the scraper to measure $z(t)$ would avoid any integration of the sensing solution with the control system or IT infrastructure, making deployment easy and fast.

The approach to address the problem is as follows: The HOSCH^{iris} DISCOVER System is selected as the IoT device measuring the displacement $z(t)$ of the scraper. From the measurement and using design information of the pulley, the belt speed is estimated. Thereafter, the measurement signal $z(t)$ is transformed into the spatial or distance domain, denoted $z(d)$, where d denotes the distance that is covered. The annotated locations of the splices in the distance domain can then be re-identified in $z(d)$ requiring the detection of complete belt revolutions in the data. For every revolution of the belt, the splice locations can then be assessed, and their change can be tracked over the number of belt revolutions or time. Using the change in $z(d_i)$ for splice i at location d_i, condition indicators are derived and then mapped into actionable insights for decision making on maintenance or stopping of the belt conveyor.

Some challenges to this approach must be addressed. First, the measurement signal is affected by noise, which come from the surface structure of the belt and the pulley, but also from the scraping action to remove material from the belt. It is also not uncommon that material can get stuck between the scraper and the belt for some time which can lead to a temporary large displacement signal. How these effects will be managed is described in Section 4.

Moreover, the solution is intended to work independently of a control system or any integration into the IT infrastructure of the belt conveyor owners. The solution is therefore implemented in a cloud-based architecture as depicted in Figure 2. There, the IoT device connects with the HOSCH cloud to ingest the data and makes it accessible for the analytics in the partnering Predge cloud. All front-end functionalities are collected in HOSCH cloud, like configuration, alarming, visualization of actionable insights on the splices, and dashboards for the decision making of the user.

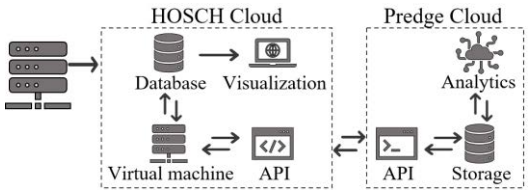

Figure 2: Cloud architecture to acquire the IoT device data, store and process it to provide actionable insights.

3. Sensing Solution

In this section, a short description is given of the sensing solution, based on the patent by Weimann et al. (2020). Figure 3 depicts a sketch of the scraper at the drive pulley on the belt, including the sensor. The pulley has a lining generating a high friction surface that is in contact with the belt. In the current setup, the high friction surface consists of three segments. The scraper is fixed to an axle where it can rotate. Connected to the scraper is a spring rod to adjust the

tension at which the scraper is in contact with the belt. The spring rod will move proportionally to the scraper. Opposite the spring rod, there is a sensor mounted to the housing which measures the distance between the sensor and a magnet attached to the end of the spring rod.

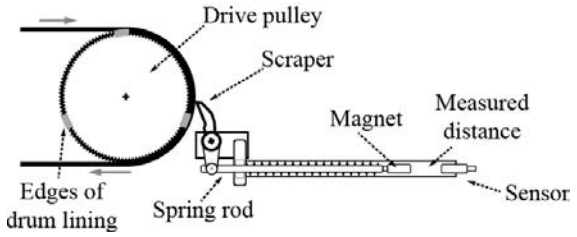

Figure 3. HOSCH HD PU pre scraper connected to the pre-tensioning spring and sensing device.

In **Error! Reference source not found.**, the raw sensor s ignal is displayed showing approximately 16 meters of the belt passing by the sensor, where the speed was increased at 12:22:07. The recurrent sinusoidal-like motion originates from the surface structure of the pulley where the drum is equipped with a lining composed of several segments. It is important to note that the pulley surface is a disturbance in the signal and may mask the belt surface changes. When the speed is increased the pulley rotational speed is increasing which leads to an increase in the frequency of the sinusoidal-like disturbance.

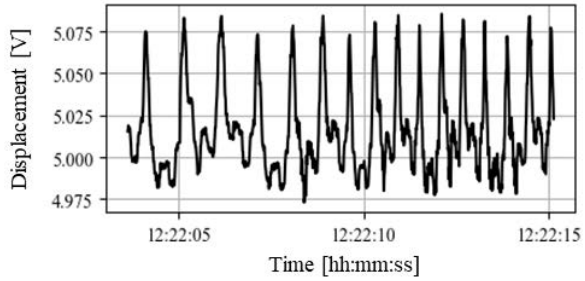

Figure 4. Raw sensor signal for a short time where the conveyor belt is run at two different speeds.

The sensor is connected to the IoT measurement system that samples the sensor signal and pre-processes it. It is thereafter locally stored and transmitted to the cloud wirelessly.

4. ANALYTICS SOLUTION

In this section the analytics solution to determine the condition of splices on a belt is presented.

4.1. Overview

The condition monitoring of splices using the scraper displacement measurement $z(t)$ requires several steps, as shown in Figure 5. One reason for this is that the splices are not as prominent in the sensor signal as the joined effect of all disturbances, like sensor noise, surface structures of pulley and belt, and displacement due to material removal from the belt. Consequently, the algorithm needs to recover the displacement that is attributed to the splices. In addition, the displacement needs to be correctly assigned to an individual splice to assess the surface change at the splice location.

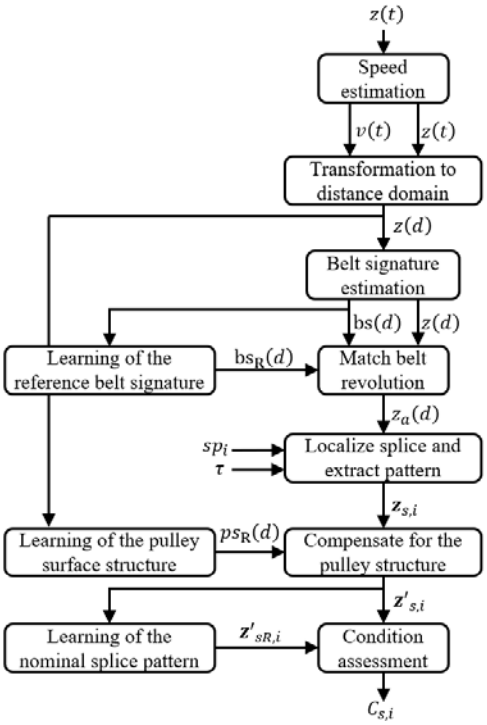

Figure 5. Block diagram for the condition monitoring of splices.

To ensure that surface changes are correctly assigned, the measured displacements need to be associated with specific locations along the belt. By estimating the belt speed from the measurement signal, transforming it into the distance domain and then identifying complete revolutions of the belt, it is possible to associate displacement measurements with specific coordinates along the belt. The identification of complete revolutions is done using an estimate for the belt surface signature, denoted $bs(d)$.

After an initial learning of a reference belt signature $bs_R(d)$, it is possible to match a complete revolution. Since splices are fixed locations sp_i along the belt with an overestimated length τ, a distance series can be extracted from the aligned raw data $z_a(d)$, reflecting the splice location, denoted $\boldsymbol{z}_{s,i}$. Since the pulley rotation and belt rotations are not aligned, the displacement induced by the pulley surface structure needs to be compensated for rendering $\boldsymbol{z}'_{s,i}$. Now the change in the surface can either be assessed in absolute terms or relative to a nominal $\boldsymbol{z}'_{sR,i}$, which is learned from data or provided by the user. The surface change can be assessed in different way and renders a condition indicator $C_{s,i}$. An advantage of this approach is that local belt damages are not confusing the association of splices to specific data series which enables the detection of new monitoring locations.

4.2. Speed estimation

To analyse the splice condition, the belt speed $v(t)$, needs to be estimated. The edges of the lining segments on the pulley introduce a distorted sinusoidal structure to the displacement data $z(t)$. This reoccurring structure in the signal is utilized when estimating the speed of the belt, by measuring the time between two registered edges and converting the time to a velocity. The displacement data $z(t)$ is split into five second batches of data $X(t)$, such that small changes in speed can be registered. $X(t)$ is now assumed to be a stationary process and can be normalized as

$$X' = \frac{X - \bar{X}}{\sigma} \tag{1}$$

where $\bar{X}$ is the mean and σ is the standard deviation of X. The normalization in (1) is done such that when computing the autocorrelation function (ACF) of the batch, there will not be any variance offset present. The ACF for a stationary process is defined as

$$r_{X'}(\tau) = \int_{-\infty}^{\infty} X'(t)X'(t+\tau)\mathrm{dt}. \tag{2}$$

The ACF in (2) is used here because of the repetitiveness of $z(t)$. The ACF will show local maxima at distances away from zero corresponding to the time it takes for the next lining segment to appear. Let i' be the solution to the following minimization problem that searches for the index in $r_{X'}(\tau)$ that corresponds to the first local maxima.

$$\begin{aligned} \text{Minimize} \quad & i \in \mathrm{dom}(r_{X'}) \\ \text{s. t.} \quad & i \geq m \\ & r_{X'}(i) \geq h \\ & \nabla r_{X'}(i) = 0 \\ & \Delta r_{X'}(i) < 0 \end{aligned} \tag{3}$$

In (3), m is a lower limit of i, h is a lower limit of $r_{X'}$ at index i and the third and fourth criterions requires i to be at a local maximum to $r_{X'}$. The solution i' to (3) is then the smallest index which satisfies all the criterions for (3). The velocity of the belt is calculated as

$$v = \frac{D}{3i'} \tag{4}$$

where D is the circumference of the pulley. The calculations in (2), (3) and (4) are done for each batch, resulting in a vector of speed estimations that will later be used for transforming the time series into a distance series.

4.3. Transformation to distance domain

If the average speed in the speed vector was greater than 0.2 m/s, $z(t)$ is transformed into a distance series, $z(d)$. The time series signal is sampled at a fixed rate at instance k independent of the belt speed. The covered distance d_k by the belt is a multiplication of the time instances t_k by the belt speed $v(t_k)$. The resulting distance dependent series $z(d_k)$ is not sampled equidistantly. By applying a linear interpolation with a fixed distance sample rate of 1 cm, an equidistant distance series is found. The benefit of transforming the time series into a distance series is that it enables the comparison of splice data regardless of the belt speed, since the position of the splices and the pulley will always be the same.

4.4. Estimating the Belt Signature

Now that the measured signal is available as a distance series, it is possible to relate a specific position on the belt with a specific point in the distance series, if the starting point of the belt in the distance series is known. It is not necessary to know an exact starting point, but it should be known where a revolution of the belt starts and ends. The belt itself has a surface structure that will produce displacements at the scraper. This displacement will occur repeatedly in the distance series. However, the distance series is affected by disturbances, like e.g. the pulley surface structure, damage to the belt and operation related disturbances. Understanding the stochastic nature of the disturbances, the sinusoidal disturbance behavior of the pulley, and assuming the belt surface is smooth a Kalman filter can be employed to estimate the belt surface and its derivative $dbs(d)$. Note that the Kalman filter is not realized in the time domain but in the distance domain.

The underlying model for the Kalman filter is defined as a sinusoidal motion which is biased by the surface signature

$$\begin{aligned} x_{k+1} &= \begin{bmatrix} 1 & d_S & 1 & 0 \\ -\omega^2 d_S & 1 & 0 & 0 \\ 0 & 0 & 1 & d_S \\ 0 & 0 & 0 & 1 \end{bmatrix} x_k + \nu_k \\ z_k &= \begin{bmatrix} 1 & 0 & 0 & 0 \end{bmatrix} x_k + \eta_k \end{aligned} \tag{5}$$

where ω is the spatial frequency of the sinusoidal-like motion induced by the pulley structure, d_S is the spatial sample rate, η and ν are normally distributed noise terms, and k denotes the sample instance. Further, the state vector is defined as

$$x = \begin{bmatrix} z & \frac{\partial z}{\partial d} & bs & \frac{\partial bs}{\partial d} \end{bmatrix}^T \tag{6}$$

The Kalman filter as described by Gustafsson (2000) is implemented using (5) as the model, initial conditions $x_0 = [z_0\ 0\ 0\ 0]^T$, and the variance of the sensor signal as R. Setting the covariance matrix Q reflecting ν and initial conditions for the state covariance matrix P, is usually difficult and dependent on the situation. Here, Q is chosen as a diagonal matrix $Q = diag(10^{-1}, 10^{-1}, 10^{-7}, 10^{-9})$ and the initial condition $P_0 = 100 \cdot Q$.

To identify belt rotations, the derivate $dbs(d)$ of $bs(d)$ is used in relation to a reference signature. Performing the estimation on several belt rotations enables the learning of a

reference signature by deriving the median of all recorded repetitions of the signature, denoted $dbs_R(d)$. Note, the reference derivative signature $dbs_R(d)$ can have an arbitrary starting point on the belt. To identify a complete revolution of the belt in the estimated signature, an optimization problem can be solved that identifies the position of $bs_R(d)$ in the currently estimated $dbs(d)$, by minimizing the deviation between the two series. The localization and identification of the splices and other points of interest (POI's) for monitoring is then solved as a lookup. The identification of the start of a belt revolution is describe here. Define

$$L' = \underset{L}{\operatorname{argmin}} \frac{1}{N}\sum_{i=0}^{N}(dbs(i+L) - dbs_R(i))^2 \quad (7)$$

where N is the number of datapoints in dbs_R. The solution L' to (7) will be an index where the reference dbs_R is the most alike dbs and will describe where a new belt rotation is taken place. By having a knowledge of the splice locations in belt reference $dbs_R(d)$, it is now possible to also localize the splice locations in $z(d_k)$.

4.5. Splice and Pulley References

Similar to having reference distance series for the belt signature, references for the splices and the pulley can be derived. Moreover, the pulley surface structure is a dominant disturbance of high magnitude and the rotation of the pulley, and the belt are only rarely aligned. Thus, one and the same position on the belt will be affected by different disturbances due to the pulley surface structure. Nevertheless, by having a pulley reference and aligning it with the recorded distance series, it is possible to remove it by subtraction from the distance series. As a result, the distance series representing the changes in the belt surface can be recovered. The remaining signal components are then $\boldsymbol{z'}_{s,i}$ and its reference $\boldsymbol{z'}_{sR,i}$. Using these two series it is possible to quantify the change in the belt surface and as a result calculate condition indices, that quantify the change over the number of revolutions of the belt.

4.6. Condition indices

The condition of the splice or any POIs on the belt can be characterized by two main parameters, the vertical displacement of the surface and the longitudinal extend of the area of change. Since the belt is composed of laminated layers of rubber and reinforcement materials, the lamination can degrade and variations in thickness can occur. Damages can also lead to lose parts or bubbles that can be filled with material. Typical condition indices include:

$$\left|\left|\boldsymbol{z'}_{s,i} - \boldsymbol{z'}_{sR,i}\right|\right|_2 \quad (8)$$

$$\max\left(|\boldsymbol{z'}_{s,i} - \boldsymbol{z'}_{sR,i}|\right) \quad (9)$$

$$\min\left(|\boldsymbol{z'}_{s,i} - \boldsymbol{z'}_{sR,i}|\right) \quad (10)$$

These indices can be tracked over time and their change can be predicted if the change is smooth over the number of revolutions of the belt. These condition indices can then be used as actionable insights for decision making on maintenance and stop of operation.

5. Results & Discussions

This section will present the results from tests that have been conducted at an industrial site. For this end, the solution was implemented in a cloud-based architecture as depicted in Figure 2. Two HOSCH[iris] DISCOVER units were installed on two belts with lengths of approximately 550 m and the splice condition monitoring scheme was adapted to the pulleys and belt. The tests were conducted to assess the speed estimation, belt signature estimation, and the condition monitoring.

For the condition monitoring specific tests were conducted, where rubber patches were glued to the belt surface. The splice areas themselves were newly vulcanized, which means they should not be estimated to a severe condition.

5.1. Speed Estimation

The estimated speed estimates were derived from the raw data signal by the algorithm. The displacement data is shown in Figure 6a where the belt starts from a stand still. The belt speed is then increased to 30%, 50%, 70%, 80%, 90%, 100%, and back to 30% of the maximum speed (3.3 m/s).

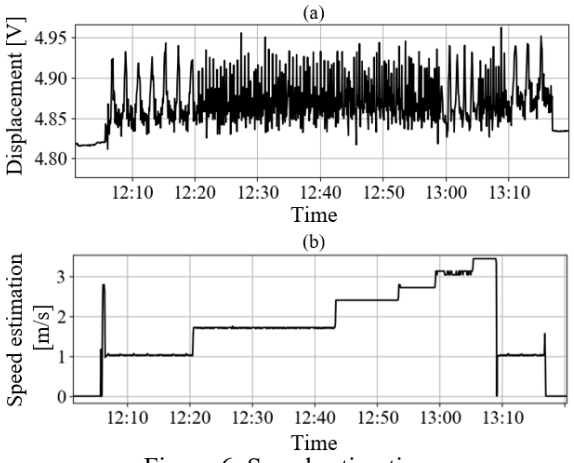

Figure 6. Speed estimation.

In Figure 6b, the estimated speed is shown. Shortly before 13:10, the speed is incorrectly estimated to be 0 m/s, which could be due to the loss of data in that time frame. There are also two spikes in the speed estimation at around 12:05 and 13:17, usually in high acceleration events when the belt is started or stopped. Using data from the control system, the speed estimation was validated rendering an error of 4% during the tests.

5.2. Belt Signature Estimation

For the belt signature estimation, no direct validation was possible, as the fine structure is estimated. Instead, the recurrence of the belt signature was used to assess the validity, by checking if the localization of the splices using the signature is correct.

In Figure 7a, a randomly picked sequence from normal operation is shown, where the displacement data is already transformed into the distance domain using the estimated speed. The estimated derivative belt signature $dbs(d)$, with its unique features can be seen in Figure 7b. The data shows two full revolutions of the belt and the noticeable similarity of the pattern before and after 60000 cm.

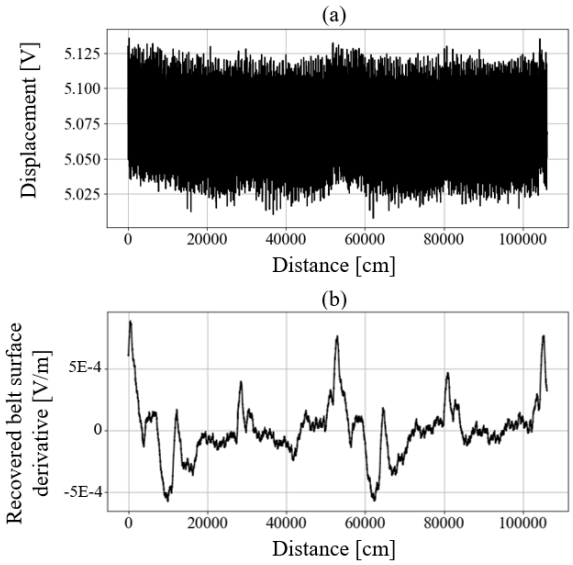

Figure 7. Transformation of displacement data to signature belt surface derivative

Using the pattern matching algorithm to align the belt rotations, the splices could be correctly localized within one meter of accuracy.

5.3. Condition monitoring of glued patches

To validate the condition assessment, artificially introduced POIs in the form of rubber patches glued to the belt surface were analyzed. For each belt, four patches of 100 x 200 x 1 mm were glued to the belt surface. The idea of the test was to track how the patches are degraded over the passages by the scraper and finally stripped from the belt surface.

To achieve this, references were created for each patch area and the already existing belt signatures and pulley references were utilized, which are generally true in the monitoring scheme. The belt conveyors were then operated as usual.

For the condition assessment of the patches the index in (9) is used and shown in Figure 8. The degradation of the patch is clearly distinguishable at about 13 belt rotations, and after about 21 rotations, it is no longer visible as it was removed from the belt by the scraper. This shows that POIs can be monitored and that changes in their behavior are estimated by in the monitoring scheme. However, the intensity of the patch degradation is not constant nor monotonically increasing each revolution and there is also some variation in the condition index.

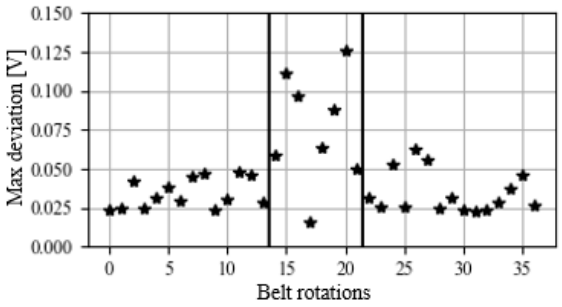

Figure 8. Maximum deviation of the belt before, while and after a patch was added.

Since the patches have sharp front edges, the collision induces an impulse on the scraper with subsequent movement. At the same time the scraper movement is sampled at a rate of 100 Hz. Depending on the alignment of the impulse with the sampling of the sensor signal and the belt speed, the maximum displacement might not be recorded, yielding a variability and error in the condition index. Nevertheless, the degradation phase of the patch is clearly captured by the scheme.

5.4. Condition monitoring of the splices

As already noted, the splices were newly vulcanized yielding a very smooth surface, which requires operation to take place over a long period of time (usually longer than a year). It was therefore expected that the splices would not generate any impact on the condition index. For the test, sequences from normal operation of the belt conveyor are used and information from inspections was collected.

Again, the maximum deviation index as given in (9) was used to assess the condition. The expectation from the test was that the index would not show any high values. In total 150 belt revolutions were assessed, which were received in batches of 10 minutes.

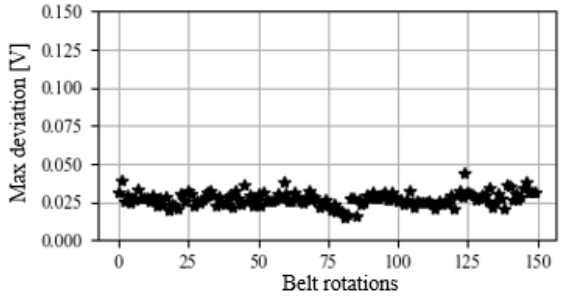

Figure 9. Maximum deviation of the belt for a splice area.

In Figure 9 it can be seen that no higher peaks are visible and that the condition index varies around a low value, which is

comparable to the lower value ranges that can be seen in Figure **8**. The inspections during the normal operation also confirmed that the splices are in good condition throughout the test period. It can therefore be concluded that the monitoring scheme is not generating false indications during normal operation and replicates the condition of the splices correctly.

6. CONCLUSION

In this work, the fully automated condition monitoring of belt splices within operational belt conveyor systems was investigated. It is shown how the belt speed can be estimated from a signal displacement signal, how a point of interest on a conveyor belt can be localized and its degradation can be monitored. For this end, typical statistical and Bayesian filtering approaches are applied together with simple learning schemes that provide data driven models of the belt, pulleys, and normal conditions of the points of interest.

Based on the conducted tests and their assessment it can also be concluded that the condition monitoring of the belt surface using the displacement signal of a single HOSCH^{iris} DISCOVER IoT device is feasible and that actionable insights on the degradation of the belt can be provided to operators and maintenance staff to ensure safe operation. The proposed solution is now online and part of the normal operation in an industrial plant.

Future work will target the collection of experience from the solution in normal operation, the benchmarking of used methods with other approaches, and assessing the effectiveness in capturing degradation events early on and in good time for decision making on operation and maintenance.

Johan Öhman is an Analytics Developer at Predge AB. He holds an MSc in Engineering Physics (2015), Luleå University of Technology, and a PhD degree in Experimental Mechanics (2020), also from Luleå University of Technology. His research interests are physics-based, and data driven modeling of industrial systems.

Vanessa Meulenberg is an Analytics Developer and Project Manager at Predge AB. She completed her BSc. in Aeronautical Engineering from Inholland University of Applied Sciences and MSc. in Composite Materials at Luleå University of Technology.

Reiner Gnauert is the Head of Digital Business Development at HOSCH Fördertechnik GmbH. He holds an MSc. in Automation Control Avionics from Hamburg University of Technology. He has a long track record in conveyor belt monitoring and a history in validation and verification in the aviation industry.

Claus Weimann is the Head of Research and Development at HOSCH Fördertechnik GmbH. He holds an MSc. in Mechanical Engineering at RWTH Aachen University. He develops new products for conveyor belts at HOSCH with a focus on scraper technology.

Wolfgang Birk is the CTO at Predge AB and Professor of Automatic Control. He holds a M.Sc. degree in Electrical Engineering from University of Saarland (1997), a Ph.D. degree in Automatic Control from Luleå University of Technology (2002), and Professor of Automatic Control (2015). He has a background in the development of condition monitoring systems, process control systems for resource efficiency as well as active safety systems in the automotive sector. His research work has led to control and monitoring solutions in several industries. In the railway sector, his main interest and expertise is the use of on-board, way-side, and track monitoring systems for condition monitoring in operation and maintenance.

Particle Filter Approach for Prognostics Using Exact Static Parameter Estimation and Consistent Prediction

ABSTRACT

Particle filters are widely used in model-based prognostics. They estimate the future health state of an asset based on measurement data and an assumed degradation dynamics. Filters are in general applied to estimate only the states given a known dynamics of the process. In model-based prognostics, the dynamics is assumed to be known in an analytical form, but the parameters vary per device and need to be learned from the measurements as well. This is especially important for the calculation of the remaining useful life (RUL), as the prediction of the future evolution is needed.

There are commonly used approaches for this: Augmenting the state space with the parameter, together with assuming them to stay constant or adding an artificial diffusive evolution to them. The Liu–West filter improves on this by modifying the artificial evolution such that mean and standard deviation of the marginal parameter distribution are kept the same. Both approaches require to choose some tuning parameters, which might be difficult in practical applications. In addition, the model parameter is often assumed frozen for the prediction part, leading to an inconsistency. We propose how a modification of the parameter evolution in case of missing measurements can solve this in both cases.

More recently algorithms for combined state estimation and exact parameter estimation have been introduced, especially the Storvik filter, based on the usage of a sufficient statistic. We analyze how this can be applied to overcome difficulties with existing approaches, avoiding the need for tuning parameters. We also extend the Storvik filter in order to deal with time-steps with missing measurements. Two formally equivalent approaches are presented. These are applicable in all cases of missing measurements, coming either from irregular data acquisition, e.g. only during maintenance or inspection, or as part of the prediction step of the RUL calculation.

We study the different methods for two simple models in order to demonstrate potential issues with existing approaches and to explore the stability of the new one based on the Storvik filter. Finally we apply it to a practical application in the area of electrical distribution systems.

1. INTRODUCTION

The most common approach for predicting the end-of-life (EOL) of a device is to model its degradation. Let x_t be a degradation variable, describing the health of the device and evolving e.g. with time t. In the simplest case, we define the (soft) failure of the device as the condition that x_t reaches a predefined critical value x_{critical} (Goebel et al., 2017; Galar, Goebel, Sandborn, & Kumar, 2021). x_t can here be either a scalar or a vector, see e.g. (Peng, Ye, & Chen, 2018). We limit ourselves to the scalar case.

The evolution of x_t is in general described by a stochastic model. We restrict ourselves here to the discrete-time case, indexed by t, and assume that the state evolves from time instance t to $t+1$ as

$$x_{t+1} \sim p(x_{t+1} \mid x_t; \theta), \tag{1}$$

where p is a suitable probability model depending on a parameter vector θ. We assume the value of θ to be specific to each individual device rather than describing the behavior of a fleet and a prior distribution $p(\theta)$ to be known.

In most cases the degradation variable x_t is not directly measurable but needs to be inferred from an observable z_t. This might be a direct measurement of x_t corrupted by measurement error or a quantity that can be indirectly associated with it. Quite generally the relation between the degradation vari-

able x_t and the observable z_t is described by

$$z_t \sim p(z_t \mid x_t; \theta), \tag{2}$$

where p is a probability model possibly also depending on the parameter vector θ.

The combination of Eqs. (1) and (2) forms a state-space model (SSM) with unknown parameter θ.

The aim of prognostics is to calculate the remaining useful life given the measurements $z_{0:t_0}$ up to the current time horizon t_0, using the predictive probability

$$p(x_t \mid z_{0:t_0}), \quad t > t_0. \tag{3}$$

Note that in Eq. (3) the parameter θ does not appear, as it has been marginalized over. The uncertainty associated with θ is therefore automatically considered. Due to the stochastic nature of the evolution and the uncertainty in the parameter, the RUL is itself a random variable. Its distribution is given by

$$\begin{aligned} \mathrm{RUL}(t \mid t_0) \sim p(t \mid \{x_{t+t_0} \geq x_{\mathrm{critical}}\} \\ \cap \{x_{t'} < x_{\mathrm{critical}} \, \forall t' < t + t_0\}). \end{aligned} \tag{4}$$

A review of the prognostics paradigm and its applications can be found, e.g., in (Si, Wang, Hu, & Zhou, 2011; Jouin, Gouriveau, Hissel, Péra, & Zerhouni, 2016; Goebel et al., 2017; Galar et al., 2021).

Determining the RUL requires a combined state and parameter estimation approach. In principle, the estimation can be obtained with any Bayesian method, e.g., a Markov Chain Monte Carlo (MCMC) approach, that determines the joint distribution $p(x_{0:t}, \theta \mid z_{0:t_0})$ of all past, present and future states and the parameter using all measurements until time t_0. In practice, this approach is not viable, since the evaluation has to be repeated each time a new measurement point is added. Hence, the method becomes computationally more demanding as time increases. A sequential approach is more appropriate, such as a sequential Monte Carlo method (SMC), see e.g. (Doucet, de Freitas, & Gordon, 2001; Chopin & Papaspiliopoulos, 2020). This requires to update the joint distribution $p(x_t, \theta \mid z_{0:t_0+1})$ at each increase of the horizon taking into account only the new measurement z_{t_0+1} and the already known joint distribution until t_0. The determination of the distribution of the state $x_{0:t_0}$, especially of only the current state x_{t_0}, is a well-studied problem for known parameter values, regularly solved with the help of particle filters. In contrast, the determination of the joint distribution of states and parameter is a more difficult one and often solved by applying some approximations.

In addition to the estimation problem for x_{t_0}, prognostics applications require the ability to make predictions. Indeed, in order to compute the RUL as in Eq. (4) one needs to calculate the future distribution for x_t for $t > t_0$, see Eq. (3). A related topic is the ability to evolve the sequential approach when measurements are sparse and obtained at irregular time intervals only. For instance, we expect measurements to be of this form, if they are obtained as part of a maintenance or inspection routine. If the time interval between measurements is long, it is beneficial to evolve the distribution of state and parameter and only keep their values at the current time. It allows to continue to evolve the distribution up to the next measurement without the need to restart from the last measurement point.

In this paper, we consider the two issues above and present:

- A critical review of the state of the art on particle based sequential methods for joint state and parameter estimation in SSMs;
- Proposals on how to extend the methods to deal with missing measurements, required especially for future predictions;
- Explore the use of the Storvik filter as an exact approach to the combined state and parameter estimation problem for prognostics applications.

The remainder of this paper is organized as follows. In Sec. 2 we briefly review the application of particle filters to SSMs. In Sec. 3 we present common approaches to perform joint state and parameter estimation, introducing also a possible way to handle missing measurements. In Sec. 4 we review the Storvik filter, an exact method for the combined state and parameter estimation, together with an extension of the method in case of missing measurements in Sec. 5. In Sec. 6 we analyze the applicability of the methods for two simple models, that are typical for prognostics applications, and in Sec. 7 we present results of the application of the Storvik filter on real data. We conclude the paper with an outcome and give potential future directions in Sec. 8.

2. THE PARTICLE FILTER FOR SSMS

The particle filter is synonymous for the SMC approach to state estimation in nonlinear SSMs. For an introduction and review see, e.g., (Doucet, Godsill, & Andrieu, 2000; Doucet et al., 2001; Chopin & Papaspiliopoulos, 2020). Neglecting the parameter θ, particle filters approximate the probability distribution of the states by an empirical distribution based on a set of N particles $\{x_t^i\}_{i=1}^N$. The approximation incorporating weights for each particle is

$$p(x_t \mid z_{0:t}) \approx \widehat{p}(x_t \mid z_{0:t}) = \sum_{i=1}^{N} w_t^i \delta_{x_t^i}(x_t),$$

where the weights $\{w_t^i\}_{i=1}^N$ are normalized to sum to one, and where $\delta_x()$ denotes the Dirac delta distribution centered in x. Particles and weights are propagated and updated according to Bayes' rule using the SSM defined by Eqs. (1) and (2).

The simplest implementation is the bootstrap particle filter, given for completeness in Algo. 1. More complex algorithms have been proposed in the literature in order to overcome the shortcomings of the bootstrap particle filter in practice. The main is the impoverishment of the particle set. This refers to the fact that without resampling most weights degenerate over time, or with resampling (as done in the bootstrap particle filter) only a few particles are retained after the resampling step.

Algorithm 1 Bootstrap particle filter

1: Initialize $\{x_0^i, w_0^i = 1/N\}_{i=1}^N$;
2: **for** $t = 1, \dots, t_0$ **do**
3: **for** $i = 1, \dots, N$ **do** ▷ Propagate
4: Sample $\widetilde{x}_t^i \sim p(x_t \mid x_{t-1}^i)$;
5: Compute $\widetilde{w}_t^i = w_{t-1}^i p(z_t \mid \widetilde{x}_t^i)$;
6: **end for**
7: Normalize $\widehat{w}_t^i = \widetilde{w}_t^i / \sum_j \widetilde{w}_t^j$, $i = 1, \dots, N$;
8: **for** $i = 1, \dots, N$ **do** ▷ Resample
9: Sample k from the set $\{1, \dots, N\}$ with weights $\{\widehat{w}_t^j\}_{j=1}^N$;
10: Set $x_t^i = \widetilde{x}_t^k, w_t^i = 1/N$;
11: **end for**
12: **end for**

In this form, the particle filter assumes the model parameter θ to be known and fixed. Therefore, it cannot be directly applied to prognostics application, as the parameter values are typically specific to each individual device. Missing measurements can be treated on the other hand trivially: If the measurement z_t is unavailable, we marginalize Eq. (2) with respect to z_t and replace $p(z_t \mid \widetilde{x}_t^i)$ by $\int p(z_t' \mid \widetilde{x}_t^i) dz_t' = 1$. In practice, this corresponds to not updating the weights (line 5 of Algorithm 1) and only sampling $\widetilde{x}_t^i$ from the distribution $p(x_t \mid x_{t-1}^i)$. Resampling is not required in this case, but could still be done, even though it might lead to unnecessary impoverishment of the particles.

3. State and parameter estimation with particle filters

Estimating sequentially both state and parameter of a model is a difficult problem. Several methods have been proposed in the literature, see, e.g., (Doucet et al., 2000, 2001). Many of these do not treat the parameter estimation sequentially, and are therefore not further discussed here. In this section, we only describe three of the most common approaches in the prognostics literature, see, e.g., (Si et al., 2011; Jouin et al., 2016).

3.1. Parameter-augmented bootstrap particle filter

The straightforward approach to state and parameter estimation consists in augmenting the state-space x_t with the parameter θ, i.e., defining a new state space $X_t = (x_t, \theta_t)$. The underlying dynamics for x_t is unchanged and is defined by Eq. (3). The parameter θ is assumed to not evolve in time, i.e., it follows the trivial dynamics

$$\theta_t = \theta_{t-1},$$

and $\theta_0 = \theta$. Together with the prior distribution $p(\theta_0) = p(\theta)$ this is equivalent to the solution of the full problem. The augmented state of the resulting SSM can then be estimated using the bootstrap particle filter. The resulting method is given in Algo. 2.

With this method, the parameter θ_t does not evolve over time. Hence, the set of possible values for it is fixed throughout the algorithm, and is equal to the initial samples θ_0^i from the prior distribution $p(\theta)$. Due to resampling, only a few distinct values of θ survive after some time (in the worst case only one). Therefore, this algorithm leads in many cases to a strong overconfidence on the parameter uncertainty, and possibly to a wrong estimate of its value. Despite this shortcoming, this approach has been proposed in (An, Choi, & Kim, 2013), even if only in a tutorial setting.

Algorithm 2 Parameter-augmented bootstrap particle filter

1: Initialize $\{x_0^i, \theta_0^i, w_0^i = 1/N\}_{i=1}^N$;
2: **for** $t = 1, \dots, t_0$ **do** ▷ Propagate
3: **for** $i = 1, \dots, N$ **do**
4: Set $\widetilde{\theta}_t^i = \theta_{t-1}^i$
5: Sample $\widetilde{x}_t^i \sim p(x_t \mid x_{t-1}^i; \widetilde{\theta}_t^i)$;
6: Compute $\widetilde{w}_t^i = w_{t-1}^i p(z_t \mid \widetilde{x}_t^i; \widetilde{\theta}_t^i)$;
7: **end for**
8: Normalize $\widehat{w}_t^i = \widetilde{w}_t^i / \sum_j \widetilde{w}_t^j$, $i = 1, \dots, N$;
9: **for** $i = 1, \dots, N$ **do** ▷ Resample
10: Sample k from the set $\{1, \dots, N\}$ with weights $\{\widehat{w}_t^j\}_{j=1}^N$;
11: Set $x_t^i = \widetilde{x}_t^k, \theta_t^i = \widetilde{\theta}_t^k, w_t^i = 1/N$;
12: **end for**
13: **end for**

3.2. Diffusive bootstrap particle filter

The main limitation of the parameter-augmented bootstrap particle filter is the impossibility to create new parameter values θ_t^i. This can be overcome by increasing their variability over time and in particular by exploring values close to the particles that survive the resampling. Since we only have information regarding the likelihood function or posterior distribution of values of state and parameter represented by some particles, some approximation is needed.

The most popular approach to create variability in the parameter consists in adding a stochastic dynamic term to its time evolution. In almost all practical cases, this dynamics takes the form of a Brownian motion, i.e.,

$$\theta_t \sim \mathcal{N}(\theta_{t-1}, \Sigma_\theta), \tag{5}$$

where Σ_θ is a suitable covariance matrix.

Whereas the motivation for the stochastic evolution of the parameter θ is purely to improve the particle filter method, it is often proposed, that it attempts to capture the mismatch between the model and the real underlying process, even if the parameter is not – in principle – changing in time. Despite this mismatch being potentially a valid point, using a stochastic dynamics for this in prognostics is difficult to justify. Indeed, the variation of the degradation variable is often rather limited and deviations will tend to be rather systematic than random. Another case made is that it allows to capture change-points of the parameter, where the time evolution changes abruptly, e.g., due to a transition to a faulty state. Such transitions are often handled better using dedicated approaches. In addition, the diffusive nature of Eq. (5) leads to past measurements being considered progressively less by the filter, leading to a larger parameter and prediction uncertainty.

On a more practical side, introducing the covariance matrix Σ_θ adds hyperparameters to the algorithm that are often difficult to tune. Unfortunately, the performance of the algorithm relies strongly on a good choice of them. If the covariance has too small elements the parameter is essentially static and the method has the same issues as in Sec. 3.1. Conversely, if Σ_θ has too large elements, the dynamics introduces overdispersion to the parameter. This second case is particularly concerning in case of missing measurements and especially in the prediction phase. Indeed, without measurements, which are the driving force constraining the parameter, the diffusive dynamics leads to a strong and purely artificial increase in uncertainty. The calculation of the RUL is most susceptible to this, as a prediction over a long time horizon is made. A hybrid approach is often employed to overcome this difficulty: The parameter is evolved using the stochastic model for the estimation phase, but is then frozen for the prediction phase. This inconsistency is listed as one of the open questions in (Jouin et al., 2016).

We propose here the introduction of an improved parameter evolution by using a time dependent covariance matrix Σ_θ in order to mitigate this issue. The time dependence is defined in the following way: the parameter is only updated when measurements are done, otherwise it remains unchanged. This corresponds formally to setting $\Sigma_\theta = 0$ for time steps without measurements. With this practical approach, we do not incur an artificial but unneeded overdispersion and still retain the better exploration of the parameter space with respect to the method of Sec. 3.1. We also remove the inconsistency in calculating the evolution in the parameter estimation and prediction phase. Despite these improvements, the diffusive bootstrap filter still strongly relies on choosing appropriately the covariance matrix to avoid either the impoverishment of the particles, or the loss of information carried by past measurements.

The diffusive bootstrap particle filter algorithm including the improvement for missing measurements is shown in Algo. 3.

Algorithm 3 Diffusive augmented bootstrap particle filter including treating of missing measurements

Initialize $\{x_0^i, \theta_0^i, w_0^i = 1/N\}_{i=1}^N$;
for $t = 1, \ldots, t_0$ **do** ▷ Propagate
  for $i = 1, \ldots, N$ **do**
    if z_t available **then**
      Sample $\widetilde{\theta}_t^i \sim p(\theta_t | \theta_{t-1}^i, \Sigma_\theta)$;
    else
      Set $\widetilde{\theta}_t^i = \theta_{t-1}^i$;
    end if
    Sample $\widetilde{x}_t^i \sim p(x_t \mid x_{t-1}^i; \widetilde{\theta}_t^i)$;
    Compute $\widetilde{w}_t^i = w_{t-1}^i p(z_t \mid \widetilde{x}_t^i; \widetilde{\theta}_t^i)$;
  end for
  Normalize $\widehat{w}_t^i = \widetilde{w}_t^i / \sum_j \widetilde{w}_t^j$, $i = 1, \ldots, N$;
  for $i = 1, \ldots, N$ **do** ▷ Resample
    Sample k from the set $\{1, \ldots, N\}$ with weights $\{\widehat{w}_t^j\}_{j=1}^N$;
    Set $x_t^i = \widetilde{x}_t^k$, $\theta_t^i = \widetilde{\theta}_t^k$, $w_t^i = 1/N$;
  end for
end for

3.3. Liu–West filter

A popular approach trying to avoid the artificial overdispersion of the parameter due to the stochastic evolution of the parameter has been proposed in (Liu & West, 2001), referred to here as "Liu–West filter". Their approach has been widely used due to two advantages: it is independent of the specific model and it is easy to implement. Examples of its use in prognostics application are e.g.(Hu, Baraldi, Di Maio, & Zio, 2015; Peng et al., 2018).

The Liu–West filter, similarly to the diffusive particle filter of Sec. 3.2, evolves the parameter in time with a stochastic process. Unlike it, the process is tuned such that the mean and covariance of the marginal parameter distribution stays invariant during the parameter update process. The overdispersion of the parameter estimation is therefore kept under control, avoiding the main drawback of the diffusive bootstrap filter.

At each time t, the parameter value for the i^{th} particle is sampled from the modified stochastic process

$$\theta_t^i \sim N(m_t^i, \Sigma_t),$$

with suitable values for m_t^i and Σ_t. To calculate these, the (weighted) mean m_t and covariance $\Sigma_{m,t}$ of the marginal distribution over all θ_{t-1}^i are determined. These are then used to get

$$m_t^i = a\theta_{t-1}^i + (1-a)m_t \tag{6}$$

and

$$\Sigma_t = (1-a^2)\Sigma_{m,t}, \tag{7}$$

In Eqs. (6) and (7), the scalar tuning parameter $a \in [0, 1]$ is used in both m_t^i and Σ_t such that the marginal distribution of the newly sampled $\{\theta_t^i\}_{i=1}^N$ have the same mean m_t and covariance Σ_t as before. In this way the overdispersion from the sampling of θ_t^i is kept at a minimum.

Two limiting cases can be seen: If the coefficient $a \to 1$ the parameter values of the particles do not move over a time step, the Liu–West filter approaches the static particle filter. Conversely if $a \to 0$ all particles have parameters drawn from a common normal distribution, independent of the individual parameter values of the particles at the previous time step. The parameter a is often chosen very close to $a \to 1$ (e.g. 0.995) or even adapted over time to cope with the improved knowledge of the parameter. The method was inspired by the analogy of the marginal parameter distribution in the diffusive update step with a kernel density estimation or a Gaussian mixture model centered around the m_t^i.

A possible implementation of the Liu–West filter is given in Algo. 4; the main difference is the modified calculation of the update of the parameter value of the particles. We give here only the simplest implementation, whereas in (Liu & West, 2001) some additional importance sampling steps are used in addition.

Algorithm 4 The Liu–West particle filter

Initialize $\{x_0^i, \theta_0^i, w_0^i = 1/N\}_{i=1}^N$;
for $t = 1, \ldots, T$ **do** ▷ Propagate
  for $i = 1, \ldots, N$ **do**

end for

The Liu–West filter often works in practice, but requires tuning of the hyperparameter a, which might be difficult to set to a reasonable value in a real application. A wrong value of a can lead, as before to an incorrect prediction.

Dealing with missing measurements can be done in two possible ways: The first one replaces $p(z_t \mid \cdots)$ by one and evolves the parameter θ_t^i in the same way as for time steps with measurements. The second one follows the proposal above and keeps the parameter fixed for that time step. This corresponds formally to choosing $a = 1$ for them.

4. STORVIK FILTER

In (Storvik, 2002; Johannes & Polson, 2006; Erol, Li, Ramsundar, & Russell, 2013) the authors propose a class of particle filter approaches that are exact with respect to the parameter distribution. Even though they slightly differ in their specific implementation, they are based on the same basic concept and we refer to them together as "Storvik filter".

The main problem with parameter estimation in SSMs, and therefore also in SMC, is the increasing number of measurement data and hidden states, which makes evolving the parameter distribution progressively harder over time. The Storvik filter assumes the existence of a finite-dimensional sufficient statistic $s(x, z)$ for the distribution of the parameter given the states $x_{0:t}$ and the measurements $z_{0:t}$. Denoting $s_t = s(x_{0:t}, z_{0:t})$, sufficiency means that

$$p(\theta \mid x_{0:t}, z_{0:t}) = p(\theta \mid s_t).$$

The value of s_t carries all the relevant information contained in the history of $x_{0:t}$ and $z_{0:t}$. In addition, the Storvik filter requires a recursive rule

$$s_t = S(s_{t-1}, x_t, z_t).$$

to update the sufficient statistic with each new state and measurement.

The existence of a sufficient statistic with a finite and fixed dimension independent of t is not guaranteed. The Fisher–Pitman–Koopman–Darmois theorem states that such a finite sufficient statistic s_t exists if and only if the distribution of θ belongs to the exponential family, see e.g. (Barankin & Maitra, 1963). This is often the case and thus guarantees a wide applicability of the Storvik filter. Especially many models use normal distributed process noise terms together with a linear dependency of the parameter, which can be addressed with this approach as discussed in (Erol et al., 2013). Extensions to distributions that are not members of the exponential family can be found in (Johannes & Polson, 2006), where the authors consider mixtures of exponential families for this case. Finally, in (Joyce & Marjoram, 2008) the authors discuss the determination of approximately sufficient statistics from data, if exact sufficient statistics are not available.

The Storvik filter is given in Algo. 5. It shares a number of similarities with the already discussed filters in that the parameter is evolved as well in each time step. The particles contain in addition to x_t^i and θ_t^i also s_t^i, which are used to sample new values of $\theta_t^i \sim p(\theta_t^i \mid s_t^i)$.

5. STORVIK FILTER WITH MISSING MEASUREMENTS

Incorporating missing measurements into the Storvik filter is not straightforward, as was in the other cases, due to the re-

Algorithm 5 The Storvik particle filter

6: Sample $\widetilde{x}_t^i \sim p(x_t \mid x_{t-1}, \theta_t^i)$;
7: Evaluate $\widetilde{w}_t^i = w_{t-1}^i p(z_t \mid \widetilde{x}_t^i, \theta_t^i)$;
8: Compute $\widetilde{s}_t^i = S(s_{t-1}^i, \widetilde{x}_t^i, z_t)$;
9: **end for**
10: Normalize $\widehat{w}_t^i = \widetilde{w}_t^i / \sum_j \widetilde{w}_t^j$, $i = 1, \ldots, N$;
11: **for** $i = 1, \ldots, N$ **do** ▷ Resample
12: Sample k from the set $\{1, \ldots, N\}$ with weights $\{\widehat{w}_t^j\}_{j=1}^N$;
13: Set $x_t^i = \widetilde{x}_t^k$, $s_t^i = \widetilde{s}_t^k$, $w_t^i = 1/N$;
14: **end for**
15: **end for**

quired update of the sufficient statistic in each step. We have identified two possible approaches:

1. Resampling the parameter at each step, despite missing measurements. We denote this choice by "U" as in "Updating".
2. Freezing the parameter to the value at the last observed time. We denote this choice by "F" as in "Frozen".

The two approaches can be shown to result from splitting the joint posterior distribution for the evolution of the state from $t+1$ to $t+k$ without measurements into

$$p(x_{t+1:t+k}, \theta) = p(\theta | s_{t+k}) p(x_{t+1:t+k}),$$

showing that the sufficient statistic needs to be updated using all $x_{t+1:t+k}$ to get the correct distribution of θ at the end. The distribution $p(x_{t+1:t+k})$ on the other hand can be decomposed in two different ways, either as

$$p(x_{t+1:t+k}) = \int p(x_{t+k}|\theta) p(x_{t+k-1}|\theta) \ldots p(x_{t+1}|\theta)\, p(\theta | x_{1:t}, z_{1:t}) d\theta$$

which corresponds to sampling one θ at the last time step with a measurement and sampling all new values of x with it, which is the "F" approach. Alternatively one can write

$$p(x_{t+1:t+k}) = \int p(x_{t+k}|x_{t+k-1}, \theta) p(\theta | s_{t+k-1}) d\theta \times p(x_{t+1:t+k-1})$$

which corresponds to updating the sufficient statistic after each step and sampling a new θ from it. This is the "U" approach. This shows that both approaches are identical in principle, but could still be more or less efficient in applications.

A possible implementation of both approaches is given in Algos. 6 and 7 for the "U" and "F" approach replacing lines 3 to 9 in Algo. 5, respectively. Please note the similarity of the two approaches to the one previously discussed.

Algorithm 6 Storvik particle filter "U" for predictions

Sample $x_t^i \sim p(x_t \mid x_{t-1}, \theta_t^i)$
Set $w_t^i = w_{t-1}^i$
Compute $s_t^i = S(s_{t-1}^i, x_t^i)$
end for

Algorithm 7 Storvik particle filter "F" for predictions

Set $\theta_t^i = \theta_{t-1}^i$ for $i = 1, \ldots, N$
for $i = 1, \ldots, N$ **do**
Sample $x_t^i \sim p(x_t \mid x_{t-1}, \theta_t^i)$
Set $w_t^i = w_{t-1}^i$
Compute $s_t^i = S(s_{t-1}^i, x_t^i)$
end for

6. Simulation study

We compare the performances of the four algorithms (parameter-augmented bootstrap particle filter, diffusive bootstrap particle filter, Liu–West filter, and Storvik filter) when applied to two simple models mimicking typical degradation dynamics. In addition we use a MCMC implementation in order to get the exact posterior distribution for all cases, using the JAGS probabilistic programming language (Plummer, 2003).

6.1. The linear model

The simplest model is the one of a Brownian motion with drift for x_t

$$x_{t+1} \sim \mathcal{N}(x_t + \alpha, \sigma_x) \tag{8}$$

together with a normal distributed measurement error

$$z_t \sim \mathcal{N}(x_t, \sigma_z) \tag{9}$$

This model is also referred to in the literature as the Whitmore model (Whitmore, 1995). For this study, we assume that only α is unknown and that σ_x and σ_z are known, so that only α and x_t need to be determined. This model falls into the class of having normal distributed process noise and being linear in the parameter. Therefore the sufficient statistic is known to be the mean and standard deviation of the distribution of the parameter α.

The prior distributions are assumed to be given as

$$p(\alpha) = \mathcal{N}(\alpha_0, \sigma_{\alpha_0}) \tag{10}$$

and

$$p(x_0) = \mathcal{N}(z_0, \sigma_{x_0}) \tag{11}$$

centered around the first measurement z_0.

To simulate the data set we have used $x_0 = 1000$, $\alpha = -8.65$, $\sigma_x = 1$, and $\sigma_z = 5$. The prior distribution parameters are $\alpha_0 = \alpha = -8.65$, $\sigma_{\alpha_0} = \sqrt{5}$ and $\sigma_{x_0} = 10$.

6.2. The stretched exponential or Weibull model

For many devices, e.g. for batteries or capacitors, the degradation process accelerates over time. The Weibull function, also known as stretched exponential, is often employed to capture this. We use a model of the form

$$x_{t+1} \sim \mathcal{N}\left(x_t - 3\alpha\left(-\ln\left(\frac{x_t}{X}\right)\right)^{1-1/3} x_t, \sigma_x\right),$$

which is chosen to follow approximately a Weibull function with shape parameter 3, but in the form of a time-independent stochastic process. The measurement model reads as before

$$z_t \sim \mathcal{N}(x_t, \sigma_z),$$

We assume the same prior distribution for α and x_0 as in Eqs. (10) and (11).

As in the linear model, the process noise is modeled as normal distributed and the dependency on the parameter is linear, even if the evolution of x_t is not. This makes the sufficient statistic to be as before the mean and standard deviation of the distribution for α.

For the simulation we have used initial condition $x_0 = 995$, maximum value $X = 1000$, $\sigma_x = 1$, $\sigma_z = 5$, and $\alpha = 1/80$. For the prior we use $\alpha_0 = \alpha = 1/80$ and $\sigma_{\alpha_0} = 6 \cdot 10^{-3}$ and where $\sigma_{x_0} = 1$ to avoid sampling impossible values $x_0 \geq X$. Parameters were chosen, such that the two models are comparable in terms of the degradation path.

For all tests we simulate 100 time steps with the measurements thinned, such that only every 5$^{\text{th}}$ time step was recorded to verify how efficiently the methods can treat missing measurement. We also stopped the estimation phase at either time horizon $t_0 = 30$ or 75 and continued with the prediction part only. The data set used, as well as the mean degradation curve for the two models are shown in Fig. 1.

6.3. Results

Figure 2 demonstrates the issues that can affect the static and the diffusive particle filters and the Liu–West filter. Measurements are available until $t_0 = 75$, after which only predictions were done. Note that we selected hyperparameters in order to exaggerate the issues. A more fine-tuned approach would lead to better agreement with the MCMC results.

With respect to the MCMC based reference result, given in Figure 2(d) we observe:

- Figures 2(a) and (b) demonstrate the underestimation and overestimation of the parameter uncertainty when using the static parameter-augmented particle filter and the diffusive particle filter, respectively.
- Figure 2(c) demonstrates that also the Liu–West filter can yield overdispersed results, even if overall less severe than for the diffusive particle filter case.

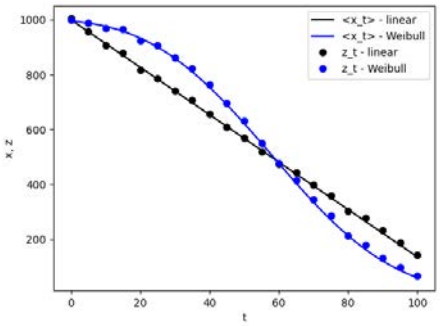

Figure 1. The mean value for x_t and the thinned measurement data z_t for the two models is shown.

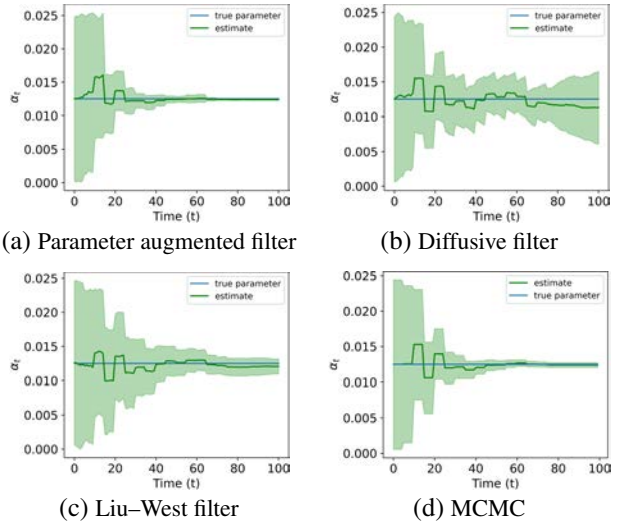
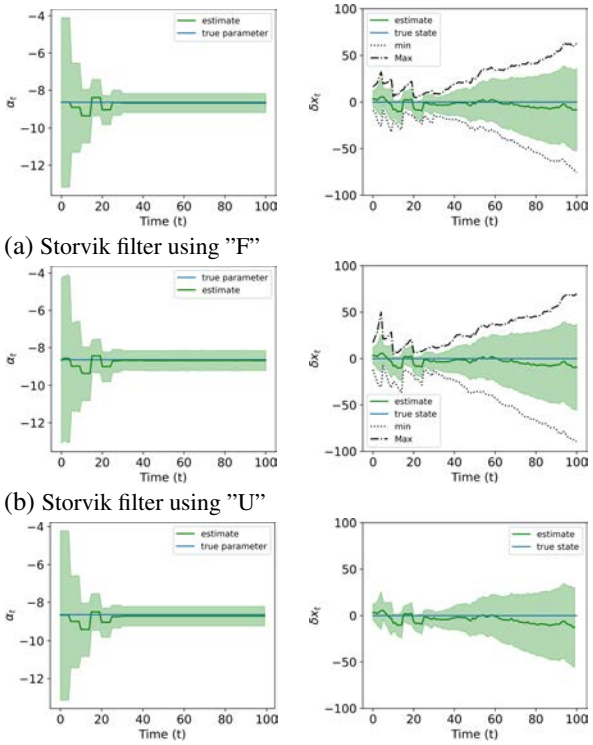


(a) Parameter augmented filter (b) Diffusive filter

(c) Liu–West filter (d) MCMC

Figure 2. Parameter estimation for the Weibull model for the three different particle filter: (a) static bootstrap, (b) diffusive, and (c) Liu–West filter. (d) gives the reference results using the MCMC approach. Mean values and uncertainty in terms of two standard deviations are given.

In Fig. 3 we give the results for the two implementations ("F" and "U") of the Storvik filter for missing measurements for the linear model, in Fig. 4 for the Weibull model. In order to focus on the performance of the two algorithm in the prediction phase, we set the time horizon to $t_0 = 30$. We observe that both implementations of the Storvik filter for missing measurements lead to results that are consistent with the MCMC result, despite (or due to) the absence of tuning hyperparameters. We also observe that the two implementations are practically indistinguishable, with the exception of a slightly more unstable behavior of the U implementation, visible in the initial time period of the Weibull model in



(a) Storvik filter using "F"

(b) Storvik filter using "U"

(c) MCMC

Figure 3. Parameter and state estimation of the linear model with the Storvik filter: Results using the two different treatments in case of missing data are compared using (a) the Frozen and (b) the Update approach. Results are compared with the reference result using the MCMC approach. On the left the evolution of the parameter estimation, on the right the difference between predicted and the true state is given. In both cases the mean and the uncertainty in terms of two standard deviation is shown.

Figure 4. Parameter estimation of the Weibull model with the Storvik filter: Results using the two different treatments in case of missing data are compared using (a) the Frozen and (b) the Update approach. Results are compared with the reference result using the MCMC approach. On the left the evolution of the parameter estimation is given showing the mean and the uncertainty in terms of two standard deviation, whereas on the right we give the full distribution for the final time step.

Fig. 4(b).

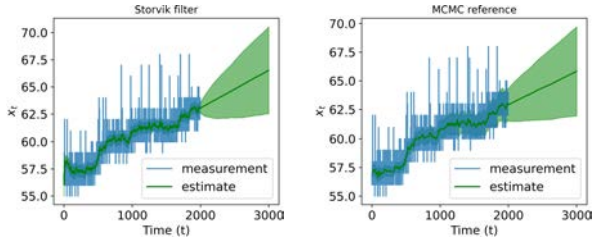
7. Application to real data with breaker opening times

In this section, we test the application of the Storvik filter against real data from an application with circuit breakers. In this case model misspecification is present and could undermine the applicability of the approach.

Circuit breakers are protection devices to interrupt short circuit currents occurring in an electric network. They are operated by mechanical mechanisms whose malfunction is one of dominant failure modes for them. The time required to open or close the contacts is the commonly monitored property. For instance, a reduction in a spring force or an increase in friction leads to an increase of this time. Hence, tracking it as a function of the number of operations enables to predict the end-of-life of these devices.

The evolution of the time x_t of the mechanical opening/closing operation is in general stochastic. Please note that t in this case typically refers to the number of operations performed instead of the time in operation. We describe it by the linear model as given in Eq. (8). The main issue with the data is that the measurement error is not following a normal distribution as assumed in Eq. (9). In fact, because of the signal processing performed during acquisition, the data is strongly quantized, as can be seen in Fig. 5(a). This was already discussed and analysed in (Hencken, 2021), which concluded that assuming normal distributed error gives reasonable results in a full analysis.

As circuit breaker often perform a larger number of operations, the use of a sequential approach will be an advantage in practice. We therefore explore here whether a particle based approach based on the Storvik filter is suitable. The model features three unknown parameters: the drift α and the two standard deviation for the process σ_x and the measurement σ_z, which leads to a more complex sufficient statistic. Following the usual normal-inverse-gamma model, the sufficient statistic consists of six variables, which are mean and standard deviation of the normal distribution of the drift α and



(a) Storvik filter (b) MCMC

Figure 5. Results of the application of the Storvik filter to the estimation of the degradation process of opening times x_t of a circuit breaker as a function of the number of oerations t. (a) shows the original data together with the state estimations and the prediction of the future evolution for the Storvik filter using the "U" method, (b) the same but for the MCMC reference approach.

the location and scale parameter of the inverse Gamma distribution for σ_x and similar for σ_z. For more details, we refer to (Storvik, 2002), where the sufficient statistic, as well as their update rules, are given.

As all measurements are available, we focus on a comparison of the basic Storvik filter without missing measurements with the exact result as given by the MCMC approach. The results of the state estimation and the expected future evolution of the two models are shown in Fig. 5. The Storvik filter is able to estimate the states quite similar to the ones found in the reference approach and in addition is able to capture the future evolution. Some slight deviations are visible, especially of the MCMC results showing a slightly larger uncertainty at the end of the measurements. But this demonstrates in a first step the possible application of the Storvik filter in real applications.

8. Conclusions and Outlook

Model-based prognostics requires joint state and parameter estimation. A sequential approach is most suitable to avoid increase in computational complexity over time. Several approaches involving particle filters and their potential issues have been discussed. We have focused also on the need of a robust treatment of time steps with missing measurements either due to irregular data acquisition or for the predictions needed for the RUL calculation. We have explored the use of the Storvik filter for prognostics application as an exact parameter estimation approach. We have shown that it can be naturally extended to incorporate missing measurements in two ways, which are similar to the ones discussed for the other particle filter approaches. Its main limitation is that it is restricted to problems allowing for the existence of a sufficient statistic. Simulations using two simple models showed the robustness and reliability of the Storvik filter, whereas we demonstrated as well, that other approaches can lead to erroneous results. We have also applied it to one real world examples, in order to test its applicability in a case, where the assumed model is not valid.

Prognostics using particle filters is an active area of research and development of real applications. The promising results with the Storvik filter should be further explored and its applicability to more complex problems, including higher dimensional state space and parameter vectors, but also to models beyond the restricted class studied here, should be explored. Finding suitable sufficient statistics in these more general models, even outside the exponential family, is another line of research to be undertaken.

ABSTRACT

This paper extends the research presented at the Prognostics and Health Management (PHM) Asia-Pacific 2023 Conference Data Challenge, focusing on a more pragmatic approach to spacecraft propulsion system health assessment. While the previous competition saw a variety of solutions, they predominantly relied on the assumption of highly stable initial hydraulic conditions – an idealization seldom met in real-world scenarios. In practical settings, factors such as operational noise, recent operational states, and ambient environmental conditions significantly disrupt this stability, rendering such solutions less feasible. Addressing this gap, our current study introduces a novel diagnostic model capable of valve faults without depending on the initial stable state of hydraulics. This approach marks a significant shift from our previous methodology, which primarily utilized similarity measures and physics-inspired features to classify health states and identify solenoid valve faults in spacecraft propulsion systems. The proposed model in this paper is validated against a diverse set of conditions, emphasizing its robustness and applicability in fluctuating real-world scenarios. Our findings demonstrate that the new model not only effectively diagnoses system health under varied and less controlled conditions but also enhances the practicality of spacecraft health management, offering a more adaptable solution in the face of operational uncertainties.

1. INTRODUCTION

Propulsion systems in spacecraft are essential for navigating through the cosmos, and their dependable and effective operation is critical. Therefore, the health management of these systems is of utmost significance. The role of Prognostics and Health Management (PHM) is central in ensuring this dependability, as it allows for the early identification and assessment of potential problems or irregularities within the propulsion mechanisms.

To promote Spacecraft PHM, the Japan Aerospace Exploration Agency (JAXA) created and released a dataset to the public (Tominaga et al., 2023), and at the same time, a data challenge was held at the PHM Asia Pacific 24 conference to facilitate the use of this data (PHMAP 2023 Secretariat, 2023). The Data Challenge required complex diagnostics such as analytical detection, classification, and regression, and many institutions took on the challenge. Despite the complexity of the problem, the top three teams of the data challenge ultimately succeeded in creating highly accurate models, and these results have been compiled and published in papers (Kato, et al., 2023) (Lee et al., 2023) (Minami & Lee, 2023). This effort was an important step in the promotion of spacecraft PHM. However, there are two major problems in adapting these models to the real world.

The first problem is the presence of non-noise regions that are unique to this data set. All of the top three teams found and used a time region in the given pressure sensor data that is completely free of noise. In this time region, all data sets with identical health conditions have the same pressure values, and the differences among Spacecraft individuals and data are zero. Specifically, the given pressure time series data is completely free of noise/variation in the initial 0.1 seconds (0 to 0.1 sec) of the 1.2 seconds. This is evidenced by the results of the data analysis (Kato, et al., 2023). This is presumably because this data set was generated by simulation. Since this specificity is considered to be different from the behavior of pressure in the real world, there is a concern that even if a high-performance model is created using only the completely noise-free portion of this data set, it will be completely useless in the real world if any noise is added, or if there is any variation in the data. To dispel this concern, it is necessary to evaluate the model using data with noise/variance.

The second problem is the use of valve open-state data. The data given are data from three iterations of valve opening and

closing, and the three proposed models use only the data from that first valve open state. However, in the valve open state, the propulsion system is not closed as a system and its pressure behavior is subject to external influences. Therefore, the pressure in the valve open state is a very complex and unpredictable behavior. Therefore, in pursuit of a robust model, state estimation is required using the pressure in the valve closed state, i.e., when the system is closed.

Because of these two major problems, the models proposed in the data challenge may not stand up to use in the real world.

To summarize the above points:

Firstly, regarding the variance-free region of the dataset:

- The spacecraft valve dataset contains an unrealistic time region that is free of variance.
- The models proposed in the data challenge use this variance-free time region, which may result in poor performance when applied to real-world data.
- To ensure the proposed models perform well in the real world, it is necessary to validate them using time regions with variance.

Next, regarding the data during valve opening and closing:

- When the valve is open, the system is open, making the sensor data complex and unpredictable. This cannot be verified until tested with real-world data.
- For building a robust model, it is preferable to use data from the closed system when the valve is closed.
- All models proposed in the data challenge are designed and trained using data from the valve-open state.
- To construct a robust model, it is necessary to design new models based on data from the valve-closed state.

To address this issue, this paper examines and evaluates the models for the PHM of spacecraft valve under the restriction that data from the variance-free portion is not used and assumes following two cases: Case 1 uses data from the valve open state, while Case 2 uses data from the valve closed state.

Model construction was examined under these scenarios to promote the construction of a more robust PHM model.

2. PROBLEM STATEMENT

The PHM Asia-Pacific 2023 Conference Data Challenge focused on Prognostics and Health Management for spacecraft propulsion systems, with the system's schematic illustrated in Figure 1. The training dataset provides 177 sets of synthetic data produced by simulations. Each set includes measurements from seven pressure sensors labeled P1 to P7, as depicted in Figure 1. These measurements were taken at a sampling rate of 1 kHz, throughout 1200 ms, and encompass three cycles of valve open-close operations, as shown in Figure 2.

The training dataset covers three distinct spacecraft, labeled #1 through #3, and it encompasses three different health conditions: normal operation, bubble anomalies, and solenoid valve faults. Solenoid valve faults could potentially occur in one of the four valves labeled SV1 through SV4, as shown in Figure 1. In the event of a fault, the solenoid valves may open anywhere from 0% to 100% of their full range. Under normal conditions, they open 100%. Note that the training data only include cases in which the valve open ratios are 0%, 25%, 50%, 75%, and 100%. The competition aims to utilize the 177 training data points to evaluate the health conditions of the 46 test data points. Half of the test data originates from spacecraft #4, which is not represented in the training set.

In this study, we focus only on the most complex task of estimating valve apertures. Two problem settings, Case 1 and Case 2, are used to validate the model for the two major problems described in the Introduction. Each is described in detail in the following sections.

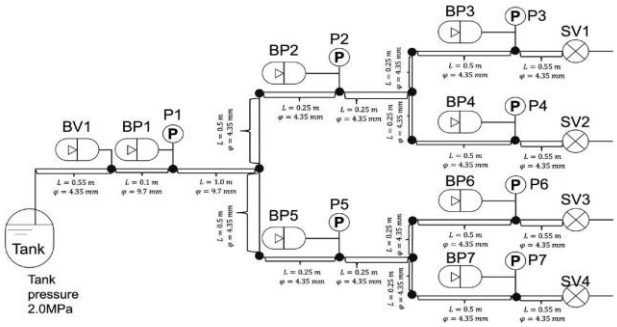

Figure 1. Schematic of experimental propulsion system

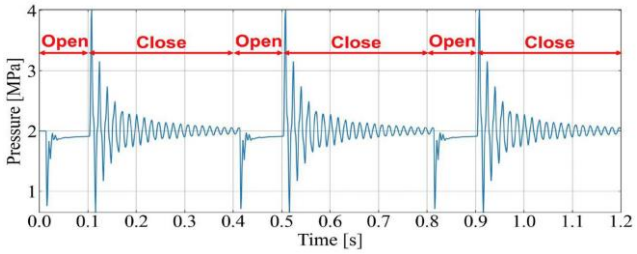

Figure 2. Typical pressure profile

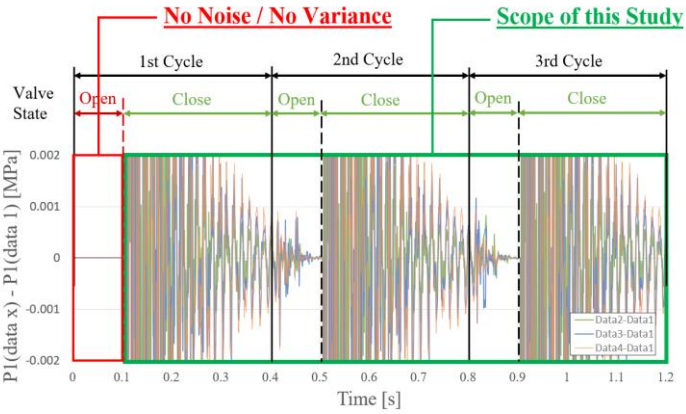

Figure 3. Pressure differences among normal data

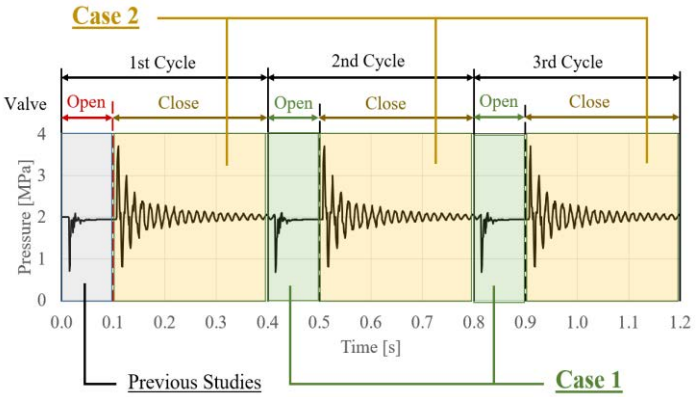

Figure 4. Data Regime

2.1. Case 1: Valve opening ratio prediction using data at valve opening with noise/variance

In Case 1, only the data of the valve open state of the second and third cycle of the valve open/close cycles is used. Specifically, as shown in the green area of Figure 4, out of the total 1.2 seconds of pressure data, only 0.4 to 0.5 seconds and 0.8 to 0.9 seconds, for a total of 0.2 seconds of data are used.

Case 1 evaluates model performance with the following metrics as well as data challenge

The evaluation metric is as follows:

$$Total\ Score = \frac{\sum_i^{Ntest} Score_i}{\sum_i^{Ntest} Score(max)_i} \quad (1)$$

Here, N_{test} is the number of test data. $Score_i$ is as follow:

$Score_i$: For the solenoid valve correctly identified as fault, prediction of the opening ratio: max (20-|truth – prediction|, 0)

For spacecraft #4, $Score_i$ are doubled, considering the difficulty. $Score(max)$ is the score if there were no prediction errors. Therefore, the total score can range from 0% to 100%.

2.2. Case 2: Valve opening ratio prediction using data at valve closed

In Case 2, only the data of the valve closed state for the 1st, 2nd, and 3rd cycles of the whole sensor data are used. Specifically, as shown in the orange area of Figure 4, out of a total of 1.2 seconds of pressure data, 0.1 to 0.4, 0.5 to 0.8, and 0.9 to 1.2 seconds of pressure data are used.

Since Case 2 is more difficult than Case 1 and it is difficult to estimate the valve opening ratio with continuous values, set the classes according to the valve opening ratio as shown in Figure 5, and set the problem as a classification problem to predict the valve opening ratio class instead of a regression problem to predict the numerical value of the valve opening ratio.

The classification models are evaluated using the following metric where TP is the total number of test data that are correctly classified.

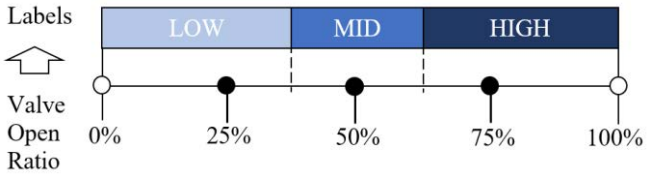

Figure 5. Labeling of valve opening ratio

$$Classification\ Accuracy = \frac{TP}{N_{test}} \quad (2)$$

3. Background: Model Selection

PHM often face the challenge of dealing with noise and variability in data, which can obscure the fundamental patterns necessary for accurate diagnosis and prediction. A common approach to address this issue is the use of filtering techniques, such as moving averages and other signal processing methods.

Simple filtering techniques, such as moving averages and other basic smoothing methods, are widely used in PHM to reduce noise and improve signal quality. For instance, Mubarak et al. (2023) demonstrated that applying a moving average filter to time series signals outperformed traditional condition monitoring methods in tasks such as Rolling Element Bearing Fault Diagnosis and Hydraulic Accumulator State Classification. Similarly, Boškoski and Urevc (2011) showed that passing vibration signals through a band-pass filter effectively removed noise, enhancing the accuracy of bearing fault detection by analyzing the envelope spectrum of the filtered signals.

However, these simple methods have significant limitations. The primary concern is their inability to distinguish between noise and useful information. As a result, essential diagnostic information may be inadvertently removed along with the noise. This is particularly problematic in scenarios like predicting valve opening degrees, where minute pressure fluctuations carry significant diagnostic value. Standard noise removal techniques are likely inappropriate here, as they can degrade model performance by losing critical diagnostic information.

To address the limitations of simple filtering, advanced techniques such as deep learning are utilized (Najafabadi et al., 2015). Deep learning models, including Convolutional Neural Networks (CNNs), Recurrent Neural Networks (RNNs), and Generative Adversarial Networks (GANs), excel in distinguishing noise from useful signals. For example, Baptista and Henriques (2022) used a one-

dimensional denoising GAN (1D-DGAN) to filter noise from turbofan engine operational data, significantly improving fault detection accuracy. Liu et al. (2018) proposed a novel bearing fault diagnosis method using an autoencoder in the form of an RNN. This method employed a Gated Recurrent Unit (GRU)-based denoising autoencoder to predict multiple vibration values of rolling bearings for the next period from the previous period. The proposed method demonstrated satisfactory performance with high robustness and classification accuracy.

While these advanced methods are effective in removing noise without losing useful information, they typically require large amounts of training data. Such extensive datasets are essential for the model to learn complex patterns and distinguish subtle differences between noise and useful signals.

In contrast, the dataset used in this study is very limited. This limitation makes the application of deep learning approaches impractical, as the model is likely to overfit the small dataset and fail to generalize to unseen data.

Given these constraints, rule-based models or simple models with fewer parameters are more suitable for this study. Therefore, this study focuses on designing and validating methods for the two cases set in the previous section, based on models proposed in the data challenge that meet these criteria. Specifically, we use the polynomial regression model based on pressure drop proposed by Minami and Lee (2023) and the similarity-based regression model proposed by Kato et al. (2023).

In Case 1, we directly utilize the existing models proposed in the data challenge to evaluate their performance in the presence of noise and variability. The primary focus is to assess whether and to what extent the performance of the previously proposed models degrades with increased variability.

In Case 2, since the models proposed in the data challenge are based on the assumption of valve open states, they cannot be used directly. This study examines the adaptation of these models' features to valve closed states. By doing so, it becomes possible to leverage the existing model structures while adapting them to new conditions.

4. METHODOLOGY AND RESULTS

In this section, the design and validation of models for two distinct cases are conducted. For both cases, a linear regression model is adopted as the benchmark method. This benchmarking methodology involves extracting nine types of basic statistics (Mean, Standard Deviation, Minimum, 25th Percentile, Median, 75th Percentile, Maximum, Skewness, Kurtosis) from each of the seven sensors. After extraction, dimensionality reduction is performed using PCA.

4.1. Case 1

In Case 1, the green area in Figure 4. Here, we examine how well the solution proposed in the data challenge maintains performance in a noisy and varied environment.

4.1.1. Methodology

As shown in Figure 1, there were two main valve opening prediction models implemented in the data challenge: one is the method that estimates the valve opening ratio by performing a polynomial fit based on the pressure drop/slope immediately after valve opening (Lee et al., 2023) (Minami & Lee, 2023). The other is the method that uses the similarity of the overall pressure during the first 0.1 seconds after the valve opens to estimate the pressure. (Kato, et al., 2023).

To adapt these proposed methods for Case 1, here, the predicted valve open ratio is calculated for each of the predictions for the 2nd cycle data (0.4 to 0.5 sec) and the 3rd cycle data (0.8 to 0.9 sec), and take the average of these is the final predicted value

4.1.2. Results

The prediction results from each model are shown in Table 1, and the calculation results of the estimation accuracy are shown in Figure 6.

Polynomial Fit's model is still able to maintain a high accuracy rate of 96%, albeit with lower accuracy, relative to previous results in the noiseless region. This suggests that the pressure drop is an important indicator that is not easily affected by noise. On the other hand, the model using Similarity shows a significant drop in accuracy, from 89% to 48%. This indicates that Similarity is susceptible to noise and has poor generalization performance when the valve is open. These results indicate that the Polynomial Fit method, which focuses on the initial pressure drop, is effective in estimating the valve opening ratio, even with noise and variation, as long as data on the valve opening state is available. On the other hand, since the data is a simulation and the number of N is small, it is necessary to verify the validity of this finding by measuring data in a setting closer to reality.

Table 1. Models and predicted valve opening ratio

Spacecraft	Case	Valve	Open Ratio [%]						
			Ground Truth	Estimation					
				Benchmark		①Polynomial		②Similarity	
				1st Cycle	**2nd, 3rd Cycle**	1st Cycle	**2nd, 3rd Cycle**	1st Cycle	**2nd, 3rd Cycle**
1	179	2	22	25	**40**	22	**22**	24	**24**
1	181	4	76	87	**72**	76	**71**	77	**79**

1	190	3	46	25	**42**	46	**46**	46	**42**
1	199	1	98	95	**100**	98	**99**	97	**96**
4	202	3	44	28	**41**	44	**44**	44	**42**
4	205	2	94	94	**90**	94	**95**	95	**37**
4	211	1	95	93	**95**	95	**95**	93	**62**
4	212	2	70	78	**82**	70	**71**	67	**16**
4	214	4	24	28	**20**	24	**25**	25	**21**

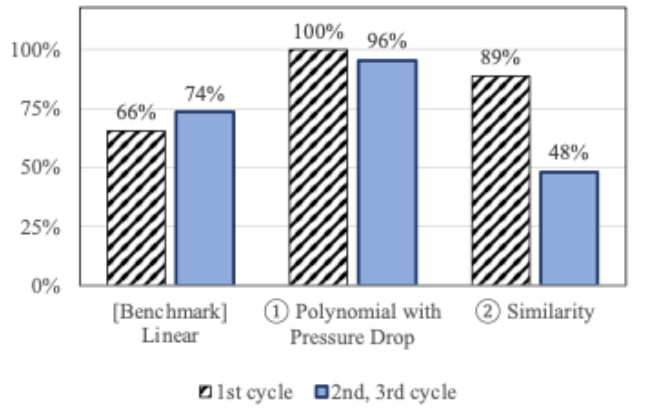

Figure 6. Regression accuracy

4.2. Case 2

In Case 2, only the data in the orange region of Figure 4 is used as a more practical but more difficult setting compared to Case 1.

4.2.1. Methodology

Unlike Case 1, the solution proposed in the data challenge cannot be used, thus a new model must be devised. Theoretically, the difference in pressure behavior with valve opening is determined only by the pressure state immediately before closing the valve, and it all returns to a constant pressure with time after closing. In other words, the difference in valve opening ratio has the greatest effect on the pressure immediately after the valve is closed, and as time passes, the difference in valve opening ratio has less effect on the pressure difference. Therefore, we devised the following two models that focus on the pressure behavior immediately after the valve is closed.

4.2.2. Method 1: Valve closing pressure surge

The first proposed model focuses on the pressure increase immediately after valve closing, similar to the focus on pressure drop in Case 1. As an example, shown in Figure 7, the pressure rise after valve closing is divided by the valve opening %, which may be used to classify the pressure rise. The label of the training data with the closest pressure based on the pressure after the specified time after the valve is closed is estimated as the label of the test data. Three models are created based on the pressure at 106 ms, 107 ms, and 108 ms after the valve was closed.

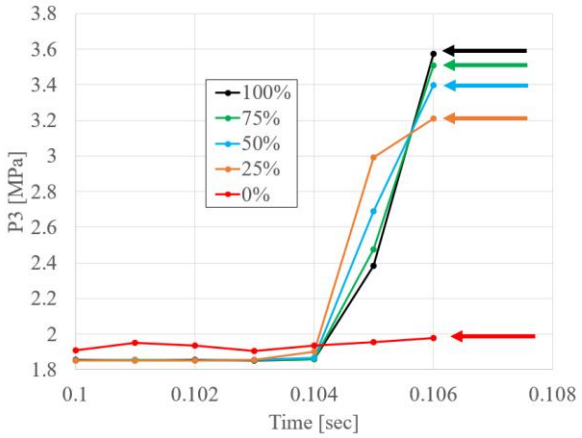

Figure 7. Example of pressure surge after valve closed (SV1)

$$Predicted\ Label = Label\left(\underset{i}{\operatorname{argmin}} \|P(train_i) - P(test)\|\right) \quad (3)$$

where training is the with training data, P is the pressure at the valve fault location, Label is the label of the training data, and Predicted Label is the label of the test data.

4.2.3. Method 2: Similarity

In this proposed model, as shown in Figure 8, the Euclidean distance is measured as the similarity of waveforms during a certain number of seconds after the start of valve closing operation, and the training data label with the highest similarity is used as the prediction label. Three models were created based on waveforms of different lengths (100 ms, 10 ms, and 5 ms).

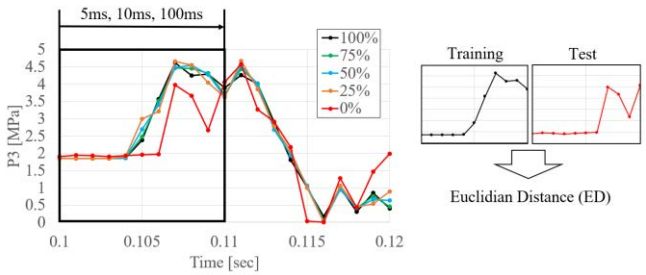

Figure 8. Similarity measurement process

$$Predicted\ Label = Label\ (\underset{i}{\text{argmin}}(\ ED(train_i, test))) \quad (4)$$

$ED(train_i, test)$ calculates the Euclidian distance of i-th training data and test data as a similarity.

4.3. Results

Table 2, Figure 9, and Figure 10 show the classification results and the results of valve opening estimation for the two models.

Table 2. Classification Results

Spacecraft	Case	Valve	Open Ratio [%]							
			Ground Truth	Estimation						
				Bench mark	①Polynomial			②Similarity		
					106 ms	107 ms	108 ms	100 ms	10 ms	5 ms
1	179	2	Low	Mid	Low	Low	Low	Low	Low	Low
1	181	4	High	High	Mid	High	High	High	High	High
1	188	1	Low	Low	Low	Low	Mid	Low	Low	Low
1	190	3	Mid	Mid	Mid	High	Mid	Mid	Mid	Mid
1	199	1	High	High	High	Mid	High	High	High	High
4	202	3	Mid	Mid	Mid	Mid	Low	High	Mid	Low
4	205	2	High	High	Low	High	Low	High	High	High
4	211	1	High	High	High	Low	Low	High	High	High
4	212	2	High	High	Low	High	Low	High	High	High
4	214	4	Low	Low	Low	Low	Low	High	Low	Low
No. of Correct Answer				9	7	7	5	8	10	9

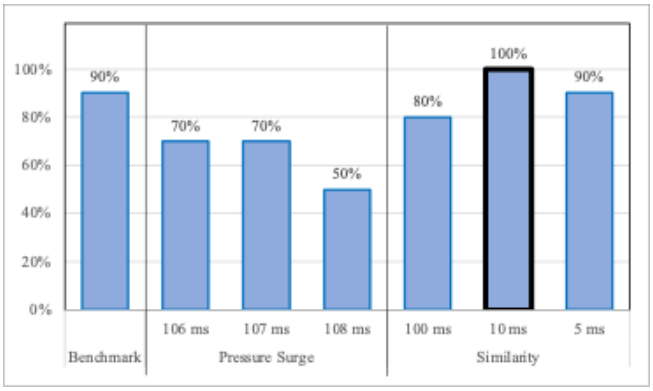

Figure 9. Classification Accuracy

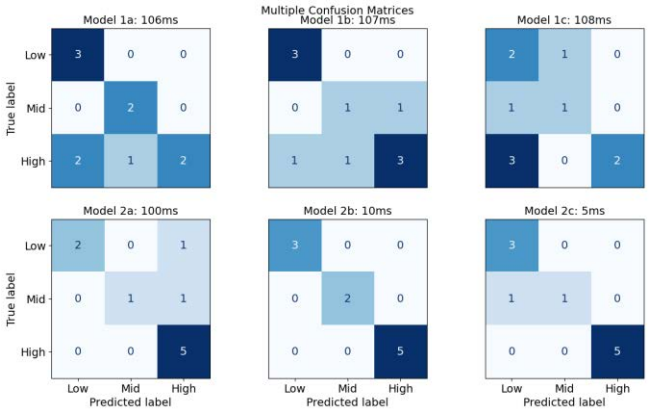

Figure 10. Confusion Matrix

The results show that Method 2 has better overall accuracy than Method 1 and the benchmarking method. The results of Method 1 show that in Case 1, high accuracy can be obtained only with pressure drop, while in Case 2, accuracy is not as good as it was, only with pressure rise. Possible reasons for this include variations in the timing of valve switching and the fact that the pressure rise is more complex than the pressure drop because it is caused by pressure propagation throughout the system.

Among the Method 2, the best accuracy was found when 10 ms waveforms were used. This suggests that there may be information useful for valve opening prediction in a specific interval. Although it is difficult to conduct a detailed analysis here due to the small amount of data, if more data were available, it would be possible to conduct an EDA and analyze the useful data areas.

From the above analysis, it is found that it is possible to use similarity to classify valve opening ratio classes and estimate intervals using only data for the closed valve state.

5. CONCLUSIONS

To construct a practical and robust spacecraft PHM model, we built and validated a valve opening prediction model with the constraint of eliminating noise/variation-free regions from the data set.

In Case 1, we verified the capability of the model proposed in the data challenge based on the valve opening data. The results showed that the regression model focusing on pressure drop had a regression accuracy of 96% even in the presence of noise and variability. On the other hand, the model using similarity was found to be only 48% accurate. This shows that the pressure drop model can produce robust results even with noise.

In Case 2, the model is built using only data from a closed system and closed valves. The model focusing on the pressure increase achieved only 70% accuracy in classification, while the model focusing on similarity achieved 100% accuracy. Further development of the model is needed to realize point estimation by regression rather than interval estimation of valve opening ratio by classification.

6. FURTHER RESEARCH

In this study, considering that system behavior generally becomes unstable when the system is open, a method that does not use the valve-open data from the dataset was proposed in Case 2. However, since the extent of instability depends on the application and the usage environment, it is necessary to collect data through experiments and verify the validity in future work.

Takanobu Minami received his B.S. and M.S. degrees in mechanical engineering from Kyoto University in 2008 and in 2011, respectively. Currently, he is pursuing his Ph.D. degree in mechanical engineering with the University of Maryland, College Park, MD, USA, and is employed as an engineer in Komatsu Ltd. His research interests include machine learning, deep learning, prognostics and health management, and industrial AI.

Dai-Yan Ji received his B.S. degree in Electronic Engineering and M.S. degree in Communications Engineering from Feng Chia University, Taiwan, in 2009 and 2012, respectively. He is currently pursuing a Ph.D. degree in Mechanical Engineering with the University of Maryland, College Park, MD, USA. He was a Research Associate at the National Central University, Taiwan, in 2017. His research interests include machine learning, prognostics, and health management.

Jay Lee is Clark Distinguished Professor and Director of the Industrial AI Center in the Mechanical Engineering Dept. of the Univ. of Maryland College Park. His research is focused on intelligent analytics of complex systems including highly-connected industrial systems including energy, manufacturing, healthcare/medical, etc. He has been working with medical school in Traumatic Brain Injury (TBI) using multi-dimension data for predictive assessment of patient in ICU with funding from NIH and NSF. Previously, he served as an Ohio Eminent Scholar, L.W. Scott Alter Chair and Univ. Distinguished Professor at Univ. of Cincinnati. He was Founding Director of National Science Foundation (NSF) Industry/University Cooperative Research Center (I/UCRC) on Intelligent Maintenance Systems during 2001-2019. IMS Center pioneered industrial Ai-augmented prognostics technologies for highly-connected industrial systems and has developed research memberships with over 100 global company since 2000 and was selected as the most economically impactful I/UCRC in the NSF Economic Impact Study Report in 2012. He is also the Founding Director of Industrial AI Center. He was on leave from UC to serve as Vice Chairman and Board Member for Foxconn Technology Group (ranked 26th in Global Fortune 500) during 2019-2021 to lead the development of Foxconn Wisconsin Science Park (~$1B investment) in Mt. Pleasant, WI. In addition, he advised Foxconn business units to successfully receive five WEF Lighthouse Factory Awards since 2019. He is a member of Global Future Council on Advanced Manufacturing and Production of the World Economics Council (WEF), a member of Board of Governors of the Manufacturing Executive Leadership Council of National Association of Manufacturers (NAM), Board of Trustees of MTConnect, as well as a senior advisor to McKinsey. Previously, he served as Director for Product Development and Manufacturing at United Technologies Research Center (now Raytheon Technologies Research Center) as well as Program Director for a number of programs at NSF. He was selected as 30 Visionaries in Smart Manufacturing in by SME in Jan. 2016 and 20 most influential professors in Smart Manufacturing in June 2020, SME Eli Whitney Productivity Award and SME/NAMRC S.M. Wu Research Implementation Award in 2022

Probabilistic Uncertainty-Aware Decision Fusion of Neural Network for Bearing Fault Diagnosis

ABSTRACT

Reliability is a central aspect of machine learning applications, especially in fault diagnosis systems, where only an accurate and reliable diagnosis system is economically justifiable, considering that any false diagnosis would lead to an increase in maintenance costs or a reduction in system efficiency. Recent advances in machine learning (ML) techniques have encouraged condition monitoring researchers to focus their efforts on finding suitable ML-based solutions for system condition assessment. However, to address the reliability issue, it is crucial to consider a larger amount of data measured by heterogeneous sensors on the system together with non-sensor information. The trend of data fusion has already started in other areas of ML application, and many of today's state-of-the-art models benefit from various types of fusion techniques to improve their accuracy. However, traditional classifiers do not provide any information about the prediction uncertainty, and they tend to show falsely high confidence when encountering low-quality data or previously unseen classes. Fusion of different data sources without considering the epistemic or aleatory uncertainty can lead to a deterioration of the result. Bayesian frameworks have traditionally been used to quantify uncertainty of systems; however, only recent advances made it possible to successfully implement Bayesian ML models.

The research methodology was investigated using the MAFAULDA dataset generated by SpectraQuest's Machinery Fault Simulator. This simulator experimentally simulated various bearing conditions, including normal operation and inner and outer ring bearing failures, at variable speeds. The dataset consists of 1951 instances measured using two triaxial accelerometers, a microphone, and a tachometer.

Diagnosis has been done via two multi label 1D Convolutional Neural Networks - each for a selected sensor - and their prediction along with their associated uncertainty quantity has been fused utilizing Bayesian model averaging. The methodology is capable of fusion of various decisions made based on different data sources and generate a unified decision with associated confidence level. Fusion process is uncertainty aware and application of 1D networks reduce the amount of data needed.

1. INTRODUCTION

1.2. Motivation behind the study

While Condition Monitoring Systems (CMS) have been extensively researched in recent years, the issue of their reliability has often been overlooked. It's crucial to recognize that CM relies on a complex system comprising sensors,

acquisition devices, data analysis techniques, and expertise. Having in mind that any system that can fail, would eventually fail highlights the importance of reliability studies on CMS. This gap in research domain has prompted the authors to investigate the reliability of CMS with the aim of increasing awareness and attracting other scientists' attention to the issue of the reliability of CMS.

The main goal of condition monitoring is to enhance the detection of failures compared to traditional methods like periodic maintenance in a cost-effective manner [1]. Therefore, addressing uncertainty in models does not imply admitting their malfunction; rather, a CMS with high uncertainty may prevent severe failures and associated costs and casualties that could be overlooked by competitor approaches. Acknowledging and addressing sources and levels of uncertainty in any diagnosis system is essential, as uncertainty is an inevitable aspect. Providing this critical information can help operators to make informed decisions and conduct thorough risk analyses.

1.1. Condition monitoring background

Condition monitoring (CM) serves as a vigilant process or a precision instrument focused on the early detection of machinery faults, failures, and wear, aiming to minimize downtimes and maintenance costs while maximizing production output. By detecting failures in their early stages, CM optimizes maintenance planning and action, thereby mitigating the risk of escalating damage and catastrophic failures. Moreover, it enhances comprehension of machinery behavior, consequently refining maintenance practices and operational efficiency [2].

CM techniques typically involve continuous measurement of machinery indicators or signals (online CM) or periodic assessments at predetermined intervals (offline CM) to detect abnormal deviations from baseline signals, distinguishing them from normal operational variations or detecting any fault signature [3].

Many examples for the development of CM can be found in literature: [4] designed and developed an integrated wireless vibration sensing tool to monitor milling equipment, employing Support Vector Machine (SVM) for analysis. [5] compared the statistical parameters of vibration signals for bearing diagnosis and suggested that signal power is the most effective criterion for diagnosis. [6] proposed an intelligent feature extraction method from vibration signals of bearing datasets to prevent human intervention for large signal analysis tasks. [7] reviewed vibration based condition monitoring of rotary machinery. [8] proposed a deep learning based gearbox fault diagnosis method that addresses data scarcity. [9] have fused multiple vibration signal into two-dimensional rectangular matrix and employed a two-dimensional convolutional neural network (2D-CNN) for bearing fault diagnosis.

Rotating machinery is a primary focus of CM research due to its challenging nature. This includes various industrial components such as rolling and journal bearings, gearboxes, shafts, blades, entire systems like wind turbines, reciprocating machines, electric motors, pumps, helicopters, fans, cam mechanisms, generators, and compressors. Various diagnostic parameters can be monitored, such as vibrations, acoustic emissions, electrical currents, flow rates, rotational speeds, pressure levels, temperature, lubrication conditions, strain, wear, and rotor-stator interactions. Vibration emerges as the predominant condition indicative of rotary machine health, as each component exhibits a unique vibration signature closely correlated with operational conditions. Faults or defects within components introduce additional dynamic forces, manifesting as vibrations within specific frequency ranges. Notable fault types detectable via vibration-based CM techniques include looseness, eccentricity, unbalance, blade defects, misalignment, bearing faults, gear damage, and shaft deformations [3].

1.2. Uncertainty in diagnosis

Uncertainty plays a significant role in human affairs, permeating everyday decisions in ordinary life. Decision-making, a fundamental capability of human beings, is essential for survival and well-being. However, decision-making is inherently challenged by uncertainty about the future. Anticipation of future events, upon which decisions are based, is inevitably subject to uncertainty. This is particularly evident in diagnostic uncertainty in engineering, where engineers often struggle to make definitive diagnoses despite extensive testing and relevant information [10].

In the realm of CM, ensuring the reliability of the diagnostic system is paramount. Indicating a fault where no fault is (a so-called false positive) can lead to unnecessary stoppages and maintenance, increasing operational costs, while false negatives risk failure and the propagation of damage. Ensuring the reliability of CMS is crucial for achieving their main goals of cost reduction and failure prevention. Considering the substantial investment necessary for implementing these techniques, only a reliable system that effectively prevents expensive failures can be justified.

To address these challenges, an uncertainty-aware fusion approach is essential. This approach involves explicitly modeling and quantifying the uncertainty associated with each source of information and the fusion process itself. By accounting for uncertainty, decision-makers can better assess the reliability and confidence level of the fused information. Moreover, an uncertainty-aware fusion approach enables the identification of potential sources of error or bias in the fusion

process, allowing for more robust and trustworthy decision-making outcomes.

Information fusion, as a methodological approach, presents a promising solution to the challenge of managing uncertainty in complex systems. By integrating diverse sources of information, including both sensory and non-sensory data, information fusion aims to enhance decision-making processes by providing a more comprehensive and accurate understanding of the observed system [11].

One of the primary advantages of information fusion is its capacity to leverage the strengths of individual sources of information while compensating for their inherent limitations. For instance, while sensory data such as vibration measurements may provide insights into the mechanical condition of a machine, non-sensory data such as operational logs or historical maintenance records can offer valuable contextual information. By combining different types of information, information fusion enables a more holistic assessment of the system's health status. However, implementing data fusion poses several challenges, particularly due to the diversity of data sources and sensor technologies involved. These challenges include issues related to data compatibility, data quality, and data integration. For instance, data collected from different sensors may vary in terms of accuracy, precision, and sampling frequency, making it challenging to effectively merge them into a cohesive dataset. Neglecting model uncertainty during fusion process can significantly impact the reliability of the fused information. Inaccurate or unreliable diagnoses from individual sources can propagate errors and inconsistencies throughout the fusion process, leading to a loss of fidelity in the final fused output. [12]

1.3. Authors contribution

The field of condition monitoring is vast, with numerous research initiatives aiming to enhance fault diagnosis techniques. This work contributes to the existing body of knowledge by introducing several approaches:

1- Multi-Label Fault Diagnosis: The authors propose a multi-label approach to fault diagnosis, enabling handling of complex fault scenarios. This methodology allows for the assignment of independent probability values to each fault class, providing a more detailed understanding of the system's health status.
2- Addressing Data Scarcity: The research addresses the common challenge of data scarcity by introducing a Custom 1D Convolutional Neural Network (CNN). 1D CNN architecture reduces the amount of data required for accurate fault diagnosis, thereby overcoming limitations associated with insufficient data availability.
3- Reliability Enhancement: The study enhances the reliability of fault diagnosis by leveraging multiple probabilistic decisions from different sensors. Through a Bayesian Model Averaging (BMA) approach, the authors combine the probabilistic outputs of various sensors, resulting in more robust and accurate diagnostic outcomes. This integration of diverse sensor data contributes to improved decision-making and system health assessment.

2. MULTILABEL PROBLEM

In traditional single-label classification, the model learns from a set of examples, each associated with a single label from a set of distinct labels. Typically, a traditional classifier utilizing a SoftMax layer assigns a probability value to each label, ensuring that the sum of probabilities across all possible labels equals one. The model then selects the label with the highest probability as the predicted label. However, this approach limits the model to predicting only one label per instance.

In contrast, in multi-label classification, the model assigns a probability value between zero and one independently to each class for a given instance. This allows for multiple labels to simultaneously have high probabilities. These classes are non-mutually exclusive and may overlap by definition. This approach was mainly used for text categorization and medical diagnosis [13]. Multi-label classification has been used by [14] to classify X-ray image via residual attention learning to diagnosis thorax disease. [15] utilized multi-label modeling for person re-identification to address the challenges of unsupervised learning, utilizing memory-based non-parametric classifier and integrates multi-label classification and single-label classification in a unified framework. [16] used attention based multi-label graph neural network to highlight the dependencies of labels in text classification.

In the context of system diagnosis and machinery fault detection, multi-label classification has not been widely investigated despite its value for identifying complex faults, especially when there's a correlation between them. By setting an appropriate threshold, the model can predict a neutral class, indicating uncertainty about the outcome, rather than forcing a specific label prediction. In contrast to single-label classification where the model assigns a probability value summing up to one across all classes, multi-label classification assigns an independent probability to each label (see Figure 1). This means that there may be cases where none of the labels have a high enough probability to cross the

threshold, indicating that the network lacks confidence in its prediction.

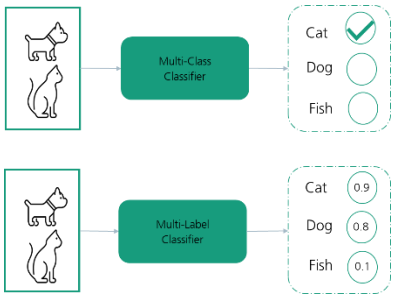

Figure 1 Label assignment in Multi-class vs Multi-label modeling

Various techniques exist for implementing a multi-label model, as shown in Figure 2. However, the details of each technique are beyond the scope of this paper, and interested readers are referred to [13, 17] for more information.

In addressing the problem, two primary approaches are commonly employed. Firstly, we can transform the problem into smaller, single-label components, allowing the use of any machine learning method to address each segment. Alternatively, we can adapt the algorithm itself to enable multi-label classification.

In the transformation approach, we can convert the problem into single-label binary classification using various methods:

- Powerset of Labels: This method decomposes the problem into all possible combinations of labels. While it provides insight into label relations, it can be computationally expensive.
- Binary Relevance: This approach compares a single label to all others or to one other label.
- Label Manipulation: We can also delete or create new labels as needed.

When implementing CNNs, different loss functions and activation layers may be required at the end of the network to accommodate multi-label classification.

3. BAYESIAN MODEL AVERAGING

In many cases, multiple models can adequately describe the distributions that generate observed data. When faced with this scenario, selecting the best model becomes crucial and is typically based on criteria such as how well the model fits the observed dataset, its predictive capabilities, or likelihood penalizations like information criteria. Once a model is selected, inferences are drawn and conclusions are made under the assumption that the selected model accurately represents the underlying truth. However, there are drawbacks to this approach. Selecting a single model can lead to overconfident inferences and riskier decisions, as it overlooks the inherent uncertainty in model selection and relies heavily on specific assumptions about the selected model. [18]

BMA provides a systematic and coherent methodology for addressing model uncertainty. It applies Bayesian inference directly to the problem of model selection, combined estimation, and prediction. BMA provides a straightforward criterion for model selection and leads to more cautious predictions. However, implementing BMA can be challenging, as it involves making various assumptions and decisions based on specific situations and contexts. [18]

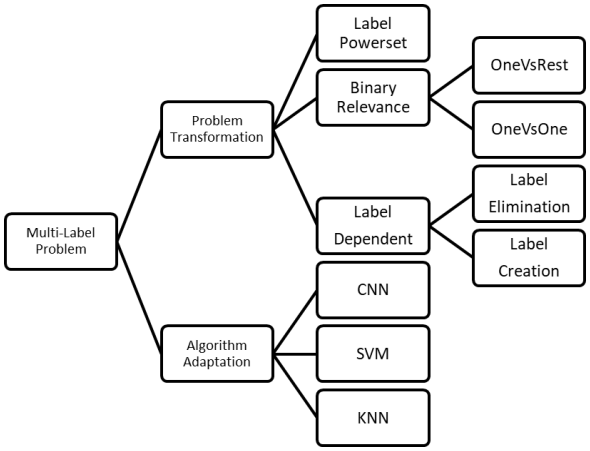

Figure 2 Overview of multi-label classification techniques

Let us consider an ensemble of models represented as $\boldsymbol{M_l}, \boldsymbol{l} = \boldsymbol{1}, \dots, \boldsymbol{K}$, and let $\boldsymbol{Y}$ represent observed data from dataset and $\boldsymbol{\theta_l}$ be parameter of the model $\boldsymbol{l}$, then likelihood function of $\boldsymbol{Y}$ given $\boldsymbol{\theta_l}$ and $\boldsymbol{M_l}$ can be written as $\boldsymbol{L(Y|\theta_l, M_l)}$. Additionally, prior probability of model parameters neglecting hyperparameters can be written as $\boldsymbol{\pi(\theta_l|M_l)}$ now, one can easily show posterior probability for model parameters as:

$$\pi(\theta_l|Y, M_l) = \frac{L(Y|\theta_l, M_l)\pi(\theta_l|M_l)}{\int L(Y|\theta_l, M_l)\pi(\theta_l|M_l)\, d\theta_l} \quad (1)$$

The denominator of (1) is called model's marginal likelihood or model evidence which represent prior distribution of all the parameter values related to model $\boldsymbol{M_l}$. Let's denote it as:

$$\pi(Y|M_l) = \int L(Y|\theta_l, M_l)\pi(\theta_l|M_l)\, d\theta_l \quad (2)$$

Bayesian model averaging introduces an additional level to this hierarchical modeling framework by incorporating a prior distribution over the entire set of models under consideration. This incorporates for the prior uncertainty regarding each model's ability to accurately represent the observed data. This is represented as a probability density function across all the models, and can be written as $\boldsymbol{\pi(M_l)}$

or $\boldsymbol{l = 1, \ldots, K}$, now we can show the posterior of model probability as:

$$\pi(M_l|Y) = \frac{\pi(Y|M_l)\pi(M_l)}{\Sigma_{l=1}^{k}\pi(Y|M_l)\pi(M_l)} \quad (3)$$

One now may re-write (3) as a ratio to a baseline model:

$$BF_{lm} = \frac{\pi(M_l|Y)}{\pi(M_m|Y)} \quad (4)$$

This can be interpreted as the relative strength of the models with respect to each other. It is clear that Eq. (3) can be expressed as the division of Eq. (4) as: [18]

$$\pi(M_l|Y) = \frac{BF_{l1}\pi(M_l)}{\Sigma_{m=1}^{k}BF_{m1}\pi(M_m)} \quad (5)$$

If $\boldsymbol{\Delta}$ is a quantity of interest, such as the utility of a course of action, then its posterior distribution can be formulated as: [19]

$$\pi(\Delta|Y) = \Sigma_{l=1}^{k}\pi(\Delta|M_l, Y)\pi(M_l|Y) \quad (6)$$

Here and on for simplicity we would address $\boldsymbol{\pi(M_l|Y)}$ term as $\boldsymbol{w_l}$. The $\boldsymbol{w_l}$s are probabilities; hence, they are nonnegative and sum up to 1. It is important to bear this in mind during their estimation. [20]

4. ESTIMATING BY LIKELIHOOD MAXIMIZATION

For convenience, we restrict attention to the situation where the conditional probability density functions (PDFs) are approximated by normal distributions. We maximize $\boldsymbol{w_k}$ by maximum likelihood from the validation/training dataset. The likelihood function is defined as the probability of the training data given the parameters to be estimated. The maximum likelihood estimator is the value of the parameter vector that maximizes the likelihood function, that is, the value of the parameter vector under which the observed data were most likely to have been observed. It is convenient to maximize the logarithm of the likelihood function (or log-likelihood function) rather than the likelihood function itself, for reasons of both algebraic simplicity and numerical stability; the same parameter value that maximizes one also maximizes the other. Estimation through likelihood maximization involves approximating the conditional PDFs here for ease of computation normal distributions has been selected. We maximize the weights $\boldsymbol{w_k}$ by maximizing the likelihood function using the validation/training dataset. The likelihood function represents the probability of observing the training data given the parameters to be estimated.

$$L(w_k|Y) = \Sigma_t \Sigma_{k=1}^{k}\, log\, \pi(\Delta|M_l, Y)\, w_k \quad (7)$$

where the summation is over values of $\boldsymbol{t}$ that index observations in the training set. [20]

5. MODEL ARCHITECTURE

5.1. Convolutional neural network

CNNs have received considerable attention and have been proven effective in various domains. One promising area for CNNs is in fault diagnosis and CM. Researchers have been increasingly using ML techniques, especially CNNs, for system diagnosis, particularly when monitoring signals such as vibration, acoustics, or temperature. [21] has utilized multi-branch residual convolutional neural network to diagnose crane gearbox with vibration signal that has been transferred to 2D images using Markov transformation field. [22] suggested an explainable CNN model that analysis cyclostationary vibration signals to diagnose wind turbine gearbox fault. [23] has proposed a light weight CNN model for bearing fault diagnosis based on Fast Fourier Transfer

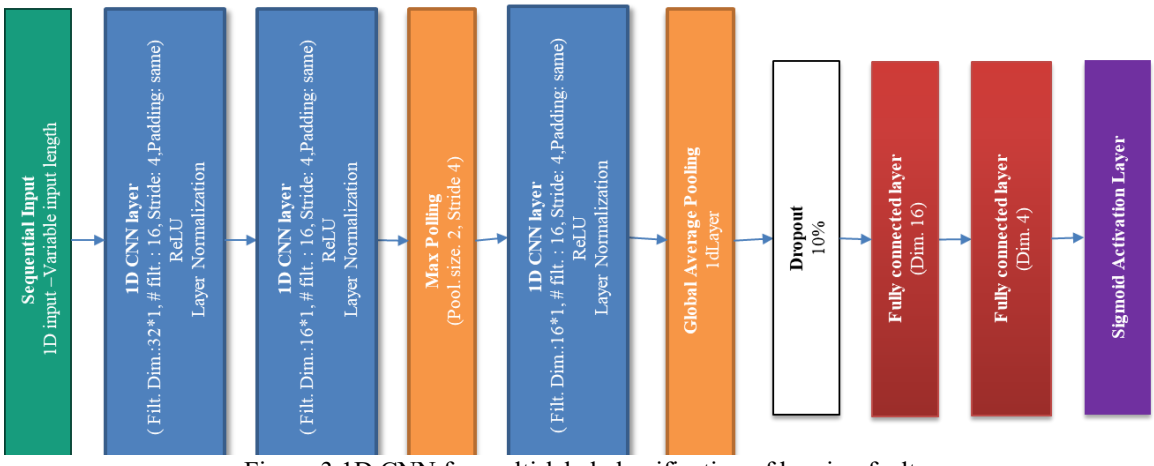

Figure 3 1D CNN for multi-label classification of bearing fault

(FFT) image coding of vibration signals. [24] has proposed a multiscale quadratic attention-embedded CNN with attention mechanisms to address the challenges associated with bearing vibration signals for fault diagnosis. [25] has fused vibration and microphone signals utilizing a 1D-CNN to enhance the accuracy of diagnosis. [26] has introduced a CNN model to diagnose bearing fault utilizing motor speed signal to remove the necessity of additional sensors.

A CNN consists of several layers, including an input layer, a convolutional layer, an activation layer, and a fully connected layer. Additional layers such as normalization and dropout are often used for generalization and to prevent overfitting. At the core of CNNs are convolutional layers, which allow us to automatically extract features from input data by mimicking how the brain's visual cortex processes images. This can be achieved by convoluting the input data with a filter, which is an n by m matrix whose elements are defined during the training phase, and moving the filter through the data at a constant step called a "stride". The convolution layer produces new images called feature maps. The feature map emphasizes the unique features of the original image. [27, 28] Although 2D CNNs have been commonly used for vibrational based diagnosis tasks, their effectiveness depends on a preprocessing step that converts the 1D signal into a 2D format. However, this preprocessing step often results in information loss and reduced diagnostic reliability. Although 1D and 2D CNNs share similar architectures, the key difference between them lies in their filter sliding mechanisms. In 1D CNNs, the filter slides vertically along the height to extract features, with the height determining the number of sample points for convolutional operations. On the other hand, 2D CNNs slide the filter both horizontally and vertically, with the height and width of the filter dictating the range of convolution operations for each step. However, 1D CNNs offer advantages over their 2D counterparts when processing 1D signals. This preference stems from several factors: [29]

- Computational complexity of 1D and 2D convolution calculations differ due to the fact that 1D CNN operates with one dimension less, resulting in significantly lower computational costs under identical conditions (same configuration, network, and hyperparameters).
- Reduced computational complexity makes 1D CNN suitable for low-cost real-time applications on smaller devices.
- Processing signals in the time domain eliminates the need for an additional step to convert a one-dimensional signal to a two-dimensional signal. This avoids adding irrelevant data and preserves the information present in the original data.

Here, we introduce a customized 1D CNN network (refer to Figure 3) along with the associated hyperparameters (see Table 1) for multi-label classification of bearing fault diagnosis. The application of 1D CNN allows us to employ shallower networks and avoids the inclusion of irrelevant information that may result from the conversion of 1D to 2D data.

By employing a sigmoid activation function at the last layer of the CNN architecture, along with a binary entropy loss function, the conventional multi-class CNN classifier has been transformed into a multi-label classifier that operates independently within each class and predicts whether the instance belongs to that class or not, as in a "one against all" strategy. This approach eliminates the need to train multiple networks for each label, thus reducing the necessity of large data and computational effort.

Table 1 Model Hyperparameters

Hyperparameter	Value
Mini batch size	25
Max epoch	50
Network selection (Early stoppage)	Minimum validation loss
optimizer	Adam
Learning rate	0.001
Loss Function	Binary cross-entropy
Padding	“Same”
Software	MATLAB

6. TEST DATASET AND PREPRATION

The methodology has been applied on the MAFAULDA dataset. The dataset consists of 1951 multivariate time-series acquired by sensors on SpectraQuest's Machinery Fault Simulator (MFS) Alignment-Balance-Vibration (ABVT). It includes six different simulated states: normal function, imbalance fault, horizontal and vertical misalignment faults, and inner and outer bearing faults. This heterogeneous dataset involves measuring acoustic and vibration signals, providing comprehensive insights into machinery behavior and fault diagnosis. Each measurement lasts for 5 seconds, with 49 measurements for normal conditions, 197 for horizontal misalignment with angles of 0.5, 1.0, 1.5, and 2.0 degrees, 301 for vertical misalignment with angles of 0.51, 0.63, 1.27, 1.40, 1.78, and 1.90 degrees, and 333 for mass imbalance of 6, 10, 15, 20, 25, 30, and 35 grams. Bearing faults have been

combined with 5, 6, 20, and 35 grams of mass imbalance to enhance the effect of the fault. The available experiment specification includes details of used equipment's, including the SpectraQuest Inc. Alignment/Balance Vibration Trainer (ABVT) Machinery Fault Simulator (MFS), Industrial IMI Sensors accelerometers, Monarch Instrument MT-190 analog tachometer, and Shure SM81 microphone. Data acquisition parameters such as sensitivity, frequency range, and measurement range are specified for each sensor. Sequences are categorized based on fault types, with details on the number of sequences per fault category, load values, and degrees of misalignment. The database is openly accessible online, with links provided at [30] for downloading the entire dataset or specific parts corresponding to different fault types. Figure 4 depicts the data preparation process for training the models. Raw vibration signals from the tangential direction of the overhang (sensor number four) and underhang (sensor number seven) accelerometers, each corresponding to a different model, are inputted along with the tachometer signal. These signals are then divided into five successive parts of one second each. The first three rotations of each one-second signal are then extracted, resulting in variable vector lengths. Following, random noise is added to reduce signal quality to signal-to-noise ratio (SNR) level of 10. The data set is then randomly divided into training (60 %), validation (20 %), and test (20 %) sets to facilitate model evaluation and validation. Additionally, reducing the data to three revolutions per second helps to evaluate the model under more realistic conditions where acquiring large datasets may not be feasible.

7. RESULT

The proposed 1D CNN was trained using the preprocessed training set (see Figure 4) of data from sensors four and seven separately. Probability acceptance threshold of 0.5 was set for each label output by the models. The models were then evaluated on the test dataset, and the performance results for the tangential overhang accelerometer signal are reported in Table 2, while those for the tangential underhang accelerometer are shown in Table 3. The corresponding confusion matrices are depicted in Figure 5 and Figure 6. Subsequently, BMA was performed on the two models, where BMA parameters were computed by maximizing the likelihood using the validation dataset. The related values are reported in Table 4. Finally, the results of the combined model via BMA, with the same probability acceptance threshold of 0.5, are shown in Table 5, along with its confusion matrix in Figure 7. Two instances from the test set have been selected and reported in Table 6 to demonstrate the step-by-step improvement of the results:

- In case A, the underhung model shows the highest probability for the outer race fault, which is an incorrect label. However, overhung and the combined model correctly identifies the fault as a cage fault.
- Case B reports an instance where the underhung model correctly identifies the label, but the overhung model fails to do so. Once again, the combined model correctly classifies the instance.

The results indicate an increase in performance of almost 5 % over the overhang accelerometer model and an increase of 8 % over the underhang accelerometer model. Considering the confusion matrix and accuracy of each class for each model, the calculated BMA parameters were as expected.

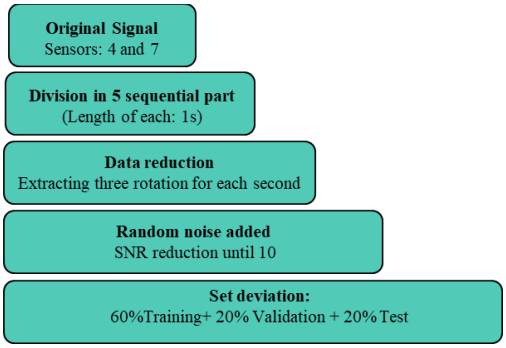

Figure 4 Data preparation scheme

Table 2 Accuracy of proposed 1D multi-label CNN for tangential Overhang accelerometer

Tangential Overhang accelerometer				
Label	Outer Race Fault	Cage Fault	Ball Fault	Healthy
Accuracy (%)	78.06	97.45	92.35	99.49
Overall Accuracy (%)			87.76

Table 6 Instances from test set

	Case A			Case B		
	Overhang	Underhung	Combined	Overhang	Underhung	Combined
Outer Race Fault	0.04	0.59	0.39	0.46	0.78	0.66
Cage Fault	1.00	0.24	0.52	0.01	0.2	0.13
Ball Fault	0.00	0.05	0.03	0.54	0.02	0.21
Healthy	0.00	0.00	0.00	0.00	0.00	0.00
True label	Cage Fault			Outer Race Fault		

8. CONCLUSION

This study introduces a multi-label approach to fault diagnosis, which facilitate the handling of complex fault scenarios by assigning an independent probability value to each class. To address the common issue of data scarcity, a Custom 1D CNN is proposed to reduce the required amount of data. Additionally, a BMA approach is employed to enhance the reliability of diagnosis by combining multiple decisions from different sensors. Evaluation of the technique on a public dataset shows a 5 to 8 % improvement in the accuracy of the combined BMA model result compared to individual models. The discussed algorithm provides an explainable process for decision fusion, emphasizing the quality of each diagnosis. BMA offers an uncertainty-aware fusion platform, where each model contributes based on its performance in the training and validation phases.

ABSTRACT

The global transition to electric power, aimed at mitigating climate change and addressing fuel shortages, has led to a rising usage of lithium-ion batteries (LIBs) in different fields, notably transportation. Despite their many benefits, LIBs pose a critical safety concern due to the potential for thermal runaway (TR), often triggered by spontaneous internal short circuit (ISC) formation. While extensive research on LIB fault diagnosis and prognosis exists, forecasting ISC formation in batteries remains unexplored. This paper presents a new methodology that combines the extended Kalman filter (EKF) algorithm for real-time estimation of ISC state with an adaptive linear regressor model for forecasting remaining useful life (RUL). This approach is designed for seamless integration into actual battery management systems, offering a computationally efficient solution. Numerical validation of the framework was conducted due to the current lack of experimental data in the literature. The significance of this work lies in its contribution to ISC prognosis, providing a practical solution to enhance battery safety.

1. INTRODUCTION

In response to the increasing environmental consciousness and the urgent need to address climate change, car manufacturers and consumers are turning towards cleaner alternatives to traditional gasoline-powered vehicles. Electric vehicles (EVs) are at the forefront of this shift, offering significant reductions in emissions that lead to cleaner air and a more sustainable planet. This movement is not just a trend; governments worldwide are actively supporting and encouraging the adoption of EVs through various policies. These include the implementation of stricter emissions regulations, mandates for zero-emission vehicles, and substantial investments in charging infrastructure.

LIBs have emerged as the go-to choice power source in EVs due to their numerous advantages, such as high energy density, powerful performance, and extended lifespan (Ding, Cano, Yu, Lu, & Chen, 2019). Despite their many benefits, LIBs are subjected to degradation phenomena (Han et al., 2019). This continuous degradation poses risks like battery failures and safety hazards, above all TR accidents (Feng, Ouyang, et al., 2018). The most common cause of TR incidents is ISC, making it imperative for the battery management system (BMS) to detect ISC formation and prevent severe ISC formation early. This is pivotal for ensuring the safe and reliable operation of EVs.

Understanding the intricate mechanism behind spontaneous ISC formation is an ongoing area of study that demands further research (Feng, Ouyang, et al., 2018). However, observations indicate that ISC formation, when not triggered by external factors like crushing or penetration, generally progresses slowly (Zhang et al., 2021). Moreover, research has shown that ISC formation predominantly impacts the electrical and thermal properties of the cell (Huang et al., 2021). This suggests that monitoring both the voltage and temperature of the cell, which are typically available in commercial BMS, could be exploited to detect and track ISC formation.

In recent years, researchers have made significant strides in developing various diagnostic algorithms aimed at detecting ISC and preventing TR. Most of these approaches are purely data-driven and aim at identifying parameter inconsistencies among single or multiple cells. These approaches utilize factors such as voltage (Hermann & Kohn, 2013), temperature (Yang, Cui, & Wang, 2019), State of Charge (SoC) (Zheng et al., 2018), and capacity (Reichl & Hrzina, 2018). However,

the subtle changes in electro-thermal signals caused by spontaneous ISC formation may not be immediately discernible within the battery dynamic responses, especially during the early stages of ISC. Additionally, signal variations due to external factors could potentially trigger false alarms. Consequently, establishing a precise threshold value presents a considerable challenge, as this value greatly affects the speed and accuracy of detection.

More advanced data-driven approaches have emerged to address these challenges, harnessing the capabilities of machine learning techniques. These approaches employ models such as deep neural networks (Cui et al., 2024) or random forest (Liu, Hao, Han, Zhou, & Li, 2023). However, since these methods rely solely on existing data, their performance is significantly limited by the scarcity of available data and the difficulties in generating new datasets.

To overcome these limitations, also model-based approaches have been developed to detect ISC. These include equivalent circuit models (ECM) (Asakura, Nakashima, Nakatsuji, & Fujikawa, 2010; Yokotani, 2014; Ikeuchi, Majima, Nakano, & KASA, 2014; Feng, Pan, He, Wang, & Ouyang, 2018), or more advanced electro-chemical models (Ma, Deng, & Wang, 2023). The basic idea of these methods is to transform the problem of ISC detection into model parameters and state estimation. The battery models are established to predict the voltage and temperature of the cells. The measured voltage or temperature of each cell is then compared with the predicted value of the model. If the residual between the two exceeds the allowable error range, it is considered that an ISC has occurred.

This work fills a crucial gap in the literature by focusing on prognosis and predicting the behavior of batteries experiencing spontaneous ISC formation. While there are existing ISC detection methods, as far as the authors are aware, no other studies have delved into predicting the evolution of ISC. What sets apart the prognostic framework introduced in this work is its dual capability: not only does it detect ISC for early warnings, but it also quantifies its severity and forecasts its future progression, enabling timely preventive measures. Moreover, the methodology emphasizes efficiency in selecting models and algorithms, considering their practical implementation in a BMS.

We build the prognostic framework upon the capabilities of the online ISC estimation algorithm proposed by the same authors in Ref. (Jia, Brancato, Giglio, & Cadini, 2024), which, unlike other ISC detection methods:

- utilizes both electrical and thermal measurements to enhance ISC detection and estimation accuracy;
- detect ISC by estimating a model parameter strictly related to the spontaneous ISC formation, allowing also to track the ISC state evolution.

This study introduces a method for predicting the battery RUL probability density function (pdf) using an adaptive linear regressor model to forecast the evolution of the ISC state until an appropriate threshold is reached. The proposed method is designed to be fully automated and can be easily integrated into a BMS for diagnosing and prognosis of spontaneous ISC formation. Moreover, the flexibility of the framework lies in its capacity to accommodate, in principle, various ISC state trajectories.

To validate our approach, we conducted a numerical case study that simulated the effects observed in measurements due to spontaneous ISC formation. This study aims to evaluate the effectiveness of our framework, given the scarcity of experimental data. Gathering such data proves challenging due to the complex nature and associated risks inherent in this phenomenon.

The paper is structured as follows: Section 2 briefly details the methods employed in developing the diagnosis and prognosis framework. In Section 3, the capabilities of the proposed method are demonstrated through a numerical case study involving a cylindrical LIB cell experiencing spontaneous ISC formation. Finally, Section 4 presents the conclusions drawn from this work and suggests potential directions for further research.

2. METHODOLOGY

2.1. Online ISC estimation algorithm

A dynamical system state comprises variables describing its condition and behavior. Non-linear dynamical systems exhibit dynamics not expressible linearly. State-space models represent system dynamics and observations using a hidden state vector $\mathbf{x}$. State equation $\mathbf{f}$ governs state vector evolution with some input $\mathbf{u}$ and some process noise $\mathbf{w}$, while observation equation $\mathbf{h}$ relates observed data, denoted with $\mathbf{y}$, to the state vector $\mathbf{x}$, some input $\mathbf{u}$ and some measurement noise $\mathbf{n}$.

The EKF estimates non-linear system states (Simon, 2006). It approximates non-linear dynamics linearly via Taylor expansion. The algorithm involves two steps: prediction, estimating the next state ($\hat{\mathbf{x}}$) and observations ($\hat{\mathbf{y}}$) with the previous state and calculating error covariance matrix ($\Sigma_{\hat{\mathbf{x}}}$); correction, updating state estimate and covariance with weighted innovation terms based on system observations. Proper initialization of the algorithm is crucial, assigning values to state vector estimate and error covariance matrix. The full algorithm is detailed in Table 1.

The electro-thermal model of a cylindrical cell described in our previous work (Jia et al., 2024), whose governing equations and parameters are summarized in Table 2 and Table 3, is discretized in time considering the following augmented state vector that includes the equivalent ISC conductance parameter G_{ISC}, expressed in Ω^{-1}, and representative of the

Table 1. Description of the extended Kalman filter algorithm.

Extended Kalman Filter Algorithm
Initialization:
Initialize state estimate $\hat{\mathbf{x}}_0^-$ and error matrix covariance $\Sigma_{\hat{\mathbf{x}}_0^-}$
Prediction Step:
Predict the state estimate:
$\hat{\mathbf{x}}_k^- = \mathbf{f}(\hat{\mathbf{x}}_{k-1}^+, \mathbf{u}_{k-1}, \bar{\mathbf{w}}_{k-1})$
Predict the observations:
$\hat{\mathbf{y}}_k = \mathbf{h}(\hat{\mathbf{x}}_{k-1}^+, \hat{\mathbf{y}}_{k-1}, \mathbf{u}_{k-1}, \bar{\mathbf{n}}_{k-1})$
Predict the error covariance matrix:
$\Sigma_{\hat{\mathbf{x}}_k^-} = A_k \Sigma_{\hat{\mathbf{x}}_{k-1}^-} A_k^T + B_k \Sigma_{\mathbf{w}} B_k^T$
Correction Step:
Compute the Kalman gain matrix:
$K_k = \Sigma_{\hat{\mathbf{x}}_k^-} C_k^T (C_k \Sigma_{\hat{\mathbf{x}}_k^-} C_k^T + D_k \Sigma_{\mathbf{n}} D_k^T)^{-1}$
Update the state estimate:
$\hat{\mathbf{x}}_k^+ = \hat{\mathbf{x}}_k^- + K_k(\mathbf{y}_k - \hat{\mathbf{y}}_k)$
Update the error covariance matrix:
$\Sigma_{\hat{\mathbf{x}}_k^+} = \Sigma_{\hat{\mathbf{x}}_k^-} - K_k(C_k \Sigma_{\hat{\mathbf{x}}_{k-1}^-} C_k^T + D_k \Sigma_{\mathbf{n}} D_k^T) K_k^T$
Where:
$A_k = \frac{\partial \mathbf{f}}{\partial \mathbf{x}}\big\|_{\hat{\mathbf{x}}_{k-1}^+, \mathbf{u}_{k-1}, \bar{\mathbf{w}}_{k-1}}$ $B_k = \frac{\partial \mathbf{f}}{\partial \mathbf{w}}\big\|_{\hat{\mathbf{x}}_{k-1}^+, \mathbf{u}_{k-1}, \bar{\mathbf{w}}_{k-1}}$
$C_k = \frac{\partial \mathbf{h}}{\partial \mathbf{x}}\big\|_{\hat{\mathbf{x}}_{k-1}^+, \mathbf{u}_{k-1}, \bar{\mathbf{n}}_{k-1}}$ $D_k = \frac{\partial \mathbf{h}}{\partial \mathbf{n}}\big\|_{\hat{\mathbf{x}}_{k-1}^+, \mathbf{u}_{k-1}, \bar{\mathbf{n}}_{k-1}}$
and $\Sigma_{\mathbf{w}}, \Sigma_{\mathbf{n}}$ are the covariance matrices of the two independent, zero-mean, Gaussian processes **w** and **n**.

actual ISC state:

$$\mathbf{x} = [z,\ i_{RC_1},\ i_{RC_2}, h,\ G_{ISC},\ T]^T \tag{9}$$

where z is the dimensionless state-of-charge (SoC), i_{RC_1} and i_{RC_2} are the two polarization currents (expressed in A), and T is the surface temperature (expressed in K).

Finally, the input vector and the output vector are defined as follow:

$$\mathbf{u} = [i_t,\ v_t]^T \tag{10}$$

$$\mathbf{y} = [v_t,\ T]^T \tag{11}$$

assuming that the load current i_t, the terminal voltage v_t, and the surface temperature T are all measurable quantities.

2.2. RUL estimation via simple linear regression

A simple linear regression model describes the linear relationship between a dependent variable, y, also known as the response, and one independent variable, x, also known as the predictor. In general, a simple linear regression model can be a model of the form:

$$y_i = \beta_0 + \beta_1 x_i + \varepsilon_i,\ \ i = 1, ..., n \tag{12}$$

where n is the number of observations, y_i is the i-th response, β_0 is the model constant, β_1 is the slope of the model, ε_i is the i-th error term that captures the variability in y_i that is not explained by the linear relationship with x_i (Seber & Lee, 2012). The usual assumptions for simple linear regression modeling are: (i) the error terms ε_i are uncorrelated; (ii) the error terms ε_i have independent and identical normal distributions with mean zero and constant variance, σ_ε^2; (iii) the responses y_i are uncorrelated.

In this study, we develop an approach to predicting the evolution of ISC state using a simple linear regression model. Here, the response variable is the estimated equivalent ISC resistance, denoted as R_{ISC}, which can be calculated as $1/G_{ISC}$. This estimate is obtained from the equivalent ISC conductance while cycling the battery cell. The predictor variable in our model is the number of cycles, denoted as N. To ensure adaptability, our approach involves fitting the simple linear regression model using a robust least squares estimation algorithm (Holland & Welsch, 1977) within a sliding window of fixed size W. This means that although the number of observations analyzed remains constant at $n = W$, the actual data points y_i can vary between each query. To address the uncertainties in our predictions, once the model is fit with the latest available data points, we generate different realizations of the ISC evolution by sampling from the estimated Gaussian distribution of the error terms, $\varepsilon_i \sim N(0, \sigma_\varepsilon)$. These realizations are then truncated when they reach a predetermined threshold for the ISC state value. Through this process, we estimate the pdf of the RUL.

3. RESULTS

In this section, we validate the performance of the framework proposed in this work through a numerical study due to the scarcity of experimental data in existing literature.

3.1. Simulating spontaneous ISC formation

To maintain simplicity and ensure consistency with our methodology, we use the electro-thermal battery model described in Section 2.1 to simulate the dynamics of a real battery cell. In practice, the voltage and surface temperature signals processed by the proposed online ISC estimation algorithm are generated by this same model, hereafter referred to as "the plant". Nonetheless, we equip the plant with appropriate noise generators to capture non-modeled dynamics.

In the plant, it is assumed that the progression of degradation follows a power-law pattern over time:

$$\begin{cases} R_{ISC}(t) = R_i - (R_f - R_i) \cdot \left(\frac{t}{T_{end}}\right)^{p(T)} \\ p(T) = p_0 \cdot e^{-\frac{c}{T}} \end{cases} \tag{13}$$

Table 2. The governing equations of the electro-thermal model.

Equation name	Equation expression	
Current Kirchhoff law	$i = i_t + i_{ISC}$, with $i_{ISC} = v_t / R_{ISC}$	(1)
Voltage Kirchhoff law	$v_t = \text{OCV}(z) + M_0 \text{sign}(i) + Mh - R_1 i_{R_1} - R_2 i_{R_2} - R_0 i$	(2)
Coulomb counting	$\frac{dz}{dt} = -\frac{\eta}{Q} i$	(3)
RC circuit dynamics	$\frac{di_{RC_j}}{dt} = -\frac{1}{R_j C_j} i_{RC_j} - \frac{1}{R_j C_j} i$, with $j = 1, 2$	(4)
Hysteresis dynamics	$\frac{dh}{dt} = -\left\lvert \frac{\gamma\eta}{Q} i \right\rvert h - \left\lvert \frac{\gamma\eta}{Q} i \right\rvert \text{sign}(i)$	(5)
Electrical heat	$Q_{in} = R_0 i^2 + \frac{v_t^2}{R_{ISC}}$	(6)
Dissipated heat	$Q_{out} = h_{conv}(T - T_{amb})A$	(7)
Heat balance	$\frac{dT}{dt} = -\frac{1}{mc_m}(Q_{in} - Q_{out})$	(8)

Where i_t is the load current, v_t is the terminal voltage, z is the state of charge, i_{RC_j} are the polarization currents, h is the unitless hysteresis state, and T is the surface temperature.

Table 3. Model parameters.

Parameter name	Symbol	Value	Unit
Open-circuit voltage	OCV	$f(z)$	V
Series resistance	R_0	9.18	mΩ
1st polarization resistance	R_1	2.53	mΩ
2nd polarization resistance	R_1	21.32	mΩ
1st polarization capacitance	C_1	5116	F
2nd polarization capacitance	C_1	3582	F
Instantaneous hysteresis voltage term	M_0	0	V
Dynamic hysteresis voltage term	M	0.16	V
Coulombic efficiency	η	0.994	–
Rate of decay constant	γ	1	–
Capacity	Q	2.05	Ah
Battery cell mass	m	76	g
Specific heat capacity	c_m	1095	J/KgK
Heat transfer convection coefficient	h_{conv}	10	$\text{W/m}^2\text{K}$
Battery outer surface	A	5.3×10^{-3}	m^2
Ambient temperature	T_{amb}	298	K

Here the exponent p is a variable that changes with temperature, behaving according to an Arrhenius function; R_i is the initial ISC resistance value; R_f is the final ISC resistance value; T_{end} is the cycling time needed to evolve from R_i to R_f; p_0 and c are respectively the Arrhenius constant and rate terms. The values of these parameters are indicated in Table 4

Table 4. Degradation model parameters.

Parameter name	Symbol	Value	Unit
Initial ISC resistance value	R_i	1000	Ω
Final ISC resistance value	R_f	0.1	Ω
Cycling time from R_i to R_f	T_{end}	1200	h
Arrhenius constant term	p_0	3278	–
Arrhenius rate term	c	3.1×10^{-3}	K

The degradation model, which also incorporates a temperature-dependent exponent, is formulated and parameterized based on the following assumptions:

- ISC persists throughout the entire lifespan of the cell, with its formation and evolution spanning hundreds of hours or more (Zhang et al., 2021);
- As ISC progresses, the internal temperature of the cell increases, leading to complex chemical reactions involving electrode materials, electrolyte, and separator (Feng, Ouyang, et al., 2018);
- Most of these chemical reactions are exothermic, accelerating the TR occurrence. When the temperature overcomes a critical point, various degradation phenomena occur, such as solid-electrolyte interphase layer decomposition, anode-electrolyte reactions, electrolyte breakdown, separator meltdown, and cathode failure. All these phenomena contribute to further increasing the internal temperature of the cell, ultimately triggering TR (Feng, Ouyang, et al., 2018).

The way the degradation sub-model described by Eq. (13) relates to the electro-thermal cell model summarized by the equations in Table 2 is graphically illustrated in Figure 1. This model is simulated by cycling the plant using a dynamic stress test current cycle and constant charging. The resulting ISC state evolution is illustrated at the top of Figure 2, where the

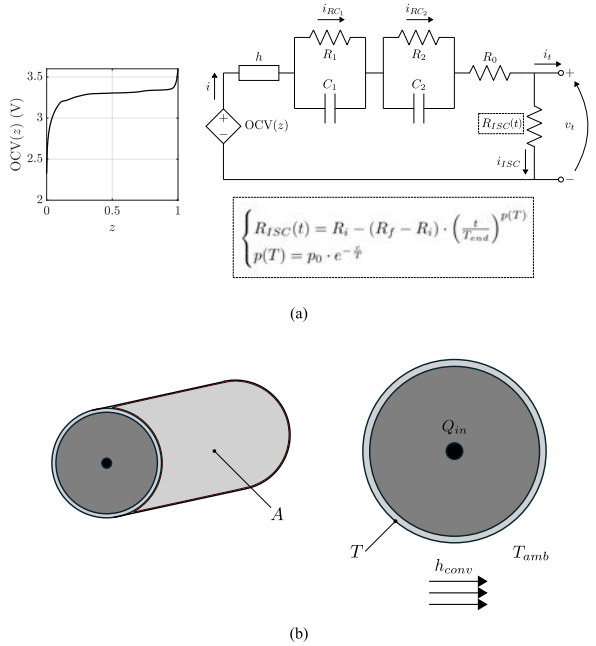

Figure 1. Electro-thermal battery cell model subjected to spontaneous ISC degradation model evolution. (a) Electrical sub-model coupled with the ISC degradation model. (b) Thermal sub-model.

x-axis has been scaled to cycles and the y-axis has been log-scaled to enhance visibility.

During the simulation, some important health-related quantities, i.e., the maximum temperature, T_{max}, and the discharging time, t_{dis}, measured across one cycle, have also been recorded along with the voltage and temperature measurements. These quantities are shown at the bottom of Figure 2. These quantities are, in fact, strongly correlated with the severity of the ISC. The observed trends agree with those expected for spontaneous ISC formation, as referenced in (Feng, Pan, et al., 2018). Figure 2 further outlines three distinct regions with dotted lines that correspond to the ISC severity state in the plant. These states are defined based on the observed effects on the aforementioned health-related quantities: in the soft ISC region, these quantities exhibit minimal changes; in the moderate ISC region, these changes become more noticeable; in the severe ISC region, the changes are extremely significant.

3.2. Prognosis

To save memory space and computational costs, we only store the data points of the Gaussian posterior pdf estimate of the ISC state obtained from the EKF at the end of each cycle. This decision is made considering that the ISC state is not expected to change significantly within a single working cycle. Although the online ISC estimation algorithm is designed to acquire and store data every second, we prioritize saving only

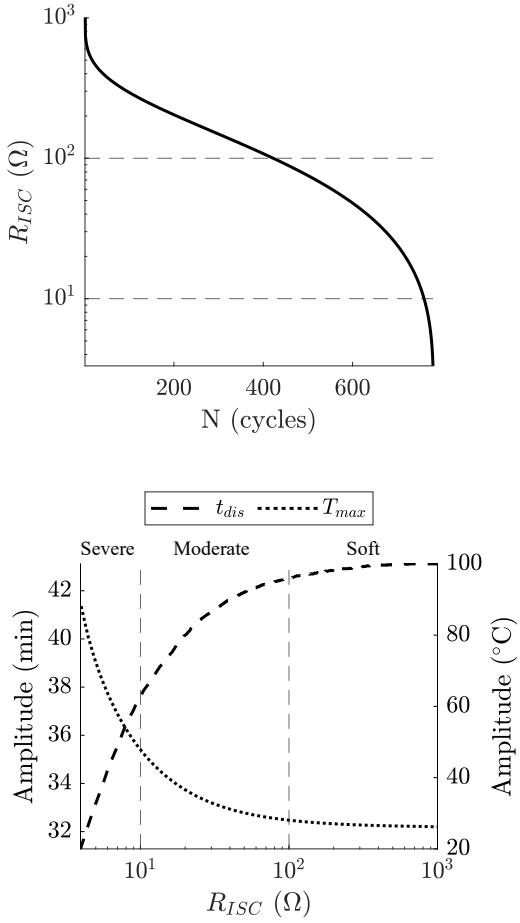

Figure 2. Top: ISC state evolution in the plant during cycling. Bottom: evolution of the maximum temperature T_{max} and the discharging time t_{dis} measured across one cycle.

these specific data points to local memory.

When enough data is available in the local memory, the user can request the prognosis. In this study, we define the prognosis triggering point as when the estimated ISC state enters the moderate ISC region, specifically when $\hat{R}_{ISC} \leq 100\Omega$, as indicated at the top of Figure 3. Additionally, we use a sliding window size W of 50 data points to ensure the linear regressor model captures the local trend behavior. This can be seen in the bottom part of Figure 3, which illustrates the linear regression at the prognosis query $N = 520$ cycles.

After fitting the parameters of the linear regressor model, the RUL pdf is computed. This is done by moving forward in time with the fitted model, sampling different realizations of the error terms from the estimated Gaussian distribution,

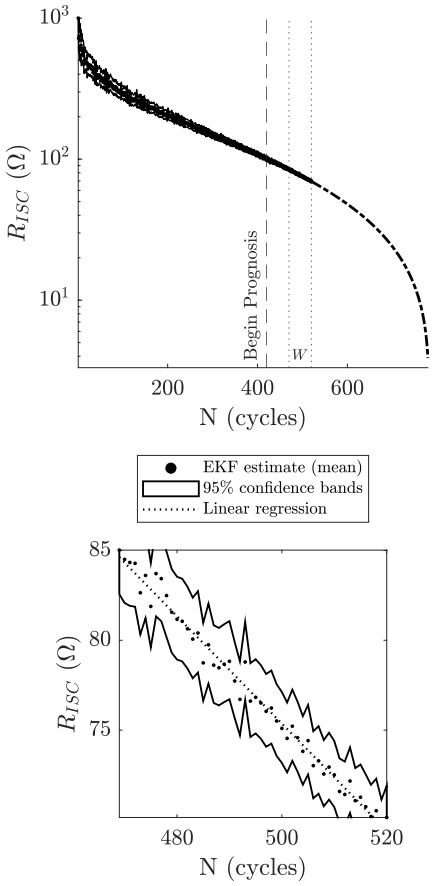

Figure 3. Top: Example of prognosis query when $N = 520$ cycles, outlining the sliding window W. Bottom: Linear regression on the latest available data points in the sliding window.

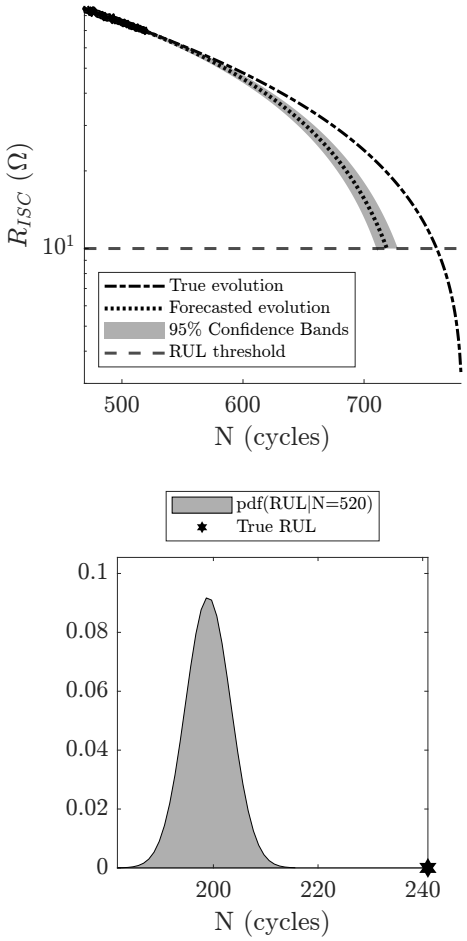

Figure 4. Top: predicted ISC state trajectory when $N = 520$ cycles. Bottom: corresponding RUL pdf estimation.

$\varepsilon_i \sim N(0, \sigma_\varepsilon)$, to account for modeling uncertainties. The prediction is then truncated up to a threshold value of 10 Ω to prevent the system from entering the severe ISC region. This process, at the prognosis query $N = 520$ cycles, is illustrated in Figure 4.

By repeating this process at different prognosis queries the RUL pdf prediction evolution is obtained, as shown in Figure 5, and compared with the actual RUL evolution of the plant. The results demonstrate the satisfactory performances obtained with the proposed method. The estimated RUL steadily converges to the true RUL value. However, the results consistently suggest that the true RUL is far outside the 95% confidence interval. This is because the linear regressor model can well approximate the local degradation behavior with good accuracy. However, the latter changes as ISC progresses due to the aforementioned exothermic electrochemical reactions, which are accounted for with the degradation model described in Eq. (13) considering an Arrhenius-like term. Furthermore, the confidence bounds narrow progressively as the prognosis steps advance, due to the increased accuracy of the EKF estimation as the ISC state becomes more severe, as also can be appreciated on top of Figure 3. This, in turn, leads to a smaller variance of the residuals with the estimated linear regressor at a later prognosis query, when the ISC state is more severe.

4. CONCLUSION

This work presents a prognosis framework for spontaneous ISC formation. The proposed framework leverages the potentialities of an EKF algorithm to online estimate and track the evolution of the equivalent ISC resistance value, which is a quantity representative of the actual ISC state of the battery cell. At appropriate instants, some of the estimated ISC resistance values are saved to local memory. The stored data are then processed for prognosis. When enough data are stored,

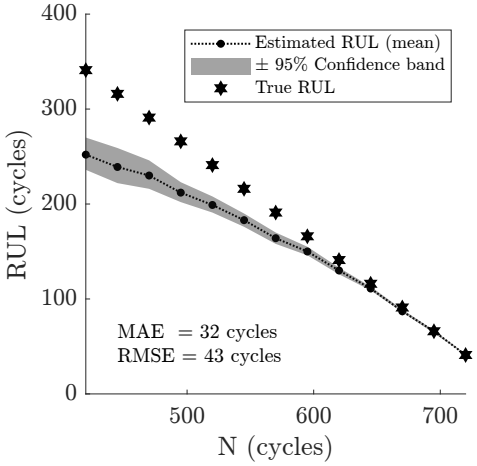

Figure 5. Comparison between true RUL evolution and predicted RUL evolution.

the user can request the prognosis algorithm to predict the battery RUL pdf. This is done by employing a linear regressor model for the prediction and a Monte Carlo simulation for quantifying the uncertainties involved. This work establishes a first step toward effective spontaneous ISC formation prognosis. Due to the lack of experimental data in the literature, the proposed approach has been validated numerically with synthetic measurements that aim to accurately reproduce the expected effects ISC has on the electrical and thermal characteristics of the cell. Furthermore, a degradation model that reasonably reproduces the expected evolution of ISC has been constructed based on certain assumptions that may not be fulfilled with real experimental data. Nevertheless, the framework proposed could in principle accommodate different degradation trajectories. Consequently, to further validate the approach, future studies will apply the methodology to real experimental data on spontaneous ISC formation as soon as the latter is available. On top of that, the method could be improved by using more sophisticated regressor models, such as ARIMA or NARX models, to improve the RUL prediction performance for a cell subjected to spontaneous ISC formation.

ABSTRACT

This paper investigates the remaining useful lifetime (RUL) estimation of bearings under dynamic, i.e., time-varying, operating conditions (OC). Unlike conventional studies that assume constant OC in bearing accelerated life tests, we introduce a dataset with time-varying OC during run-to-failure experiments, simulating real-world scenarios. We explore data-driven approaches to identify the transition point from a healthy to an unhealthy state and estimate the RUL. Additionally, we examine strategies for integrating OC information to enhance RUL estimations. These methodologies are evaluated through numerical experiments using various machine learning algorithms.

1. INTRODUCTION

Rolling element bearings are extensively used in industrial applications, such as wind turbines, electric motors, and generators. These bearings account for the largest percentage of failures in rotating machinery (Alewine & Chen, 2010) and about 40%-50% of all motor faults (Sharma et al., 2015). Failure of bearings may result in expensive downtime, increased maintenance costs due to failures propagating to other parts, and catastrophic effects if they support critical equipment. Predictive maintenance can be employed to increase the efficiency and reliability of bearings and technical systems in general, as it prevents unexpected failures and maximizes their availability. Predictive maintenance builds on prognostics, which involves the accurate estimation of the remaining useful lifetime (RUL) of technical systems or components, such as bearings.

For developing RUL estimation methods for bearings, existing datasets often focus on accelerated life tests conducted under constant operating conditions (OC) (Lee et al., 2007). In some cases where varying OC were taken into account, the OC only change between different run-to-failure experiments but remain constant within each experiment (Nectoux et al., 2012; Wang et al., 2018). However, this approach falls short of accurately simulating real-world scenarios where bearings may experience time-varying conditions throughout their operational life. Some research has been conducted on time-varying conditions. For example, Du et al. (2022) propose extracting features from the angular domain and RUL prediction based on the unscented particle filter. However, their proposed methodology was evaluated on ball bearing run-to-failure experiments, considering only varying rotating speed in the range [1450, 1550] rpm. Furthermore, the time point of degradation onset was manually determined. N. Li et al. (2019) propose a so-called "two-factor" state-space model based on a Wiener process, where the underlying degradation process is modeled in the state transition function, and the influence of the varying condition on the measured signal is captured in the measurement function of the proposed model. However, the proposed methodology builds on the assumption that the OC are known a priori and follow a known pattern. Furthermore, their methodology was evaluated on ball bearings subjected to cyclic varying speed conditions, taking up two speed values, namely 2200 rpm and 2600 rpm.

To address the presented limitation of existing studies and enhance the relevance to practical applications, we introduce a new dataset of bearing run-to-failure experiments, in which OC can dynamically vary over time, such as in a non-periodic and stochastic manner. Thus presenting new challenges for RUL estimation, as the vibration data not only reflects bearing degradation but is also influenced by changes in OC. Table 1 provides an overview of the existing datasets and their comparison to ours.

Table 1. Comparison between the publicly available datasets and our dataset.

	IMS (Lee et al., 2007)	Pronostia (Nectoux et al., 2012)	XJTU-SY (Wang et al., 2018)	LDM (Aimiyekagbon, 2024)
Bearing type	Roller bearing	Ball bearing	Ball bearing	Ball bearing
Rotating speed [rpm]	2000	1500, 1650, 1800	2100, 2250, 2400	$[1500, 3600]$
Static load [kN]	26.7	4, 4.2, 5	10, 11, 12	$[1.5, 4]$
Dynamic load amplitude [kN]	✗	✗	✗	$[0.5, 1.7]$
Dynamic load type	✗	✗	✗	Sinusoidal and Gaussian noise

Data-driven techniques for estimating the RUL involve establishing a mapping between available information, mainly vibration data, and the RUL. Typically, the initial step is to extract features from vibration data, given its high-dimensional nature and lack of a discernible trend for RUL estimation. Features are typically extracted in the time-, frequency-, and time-frequency-domain. While finding the best feature representation lies beyond the scope of this paper, we primarily adopt the Fast Fourier Transform (FFT) to obtain a frequency-domain representation of the vibration signal. Furthermore, to address the challenge of high dimensionality, we employ a methodology akin to that proposed in (Ren et al., 2018; von Hahn & Mechefske, 2022). This involves segmenting the resulting FFT signal into distinct frequency buckets and subsequently identifying the maximum value within each bucket.

It has been observed that the behavior of bearings does not exhibit a consistent trend from the beginning to the failure time. Instead, a typical scenario involves an initial phase of normal behavior followed by an abrupt shift at some point during the lifespan, indicating the initiation of degradation. These points, marking the transition from a healthy to an unhealthy state, are referred to as transition times. While existing approaches use various engineering techniques to detect these transition times (X. Li et al., 2019), this study employs a 2-means clustering technique on extracted features to define the transition time as the moment when the cluster of a bearing changes with respect to its initial cluster. After identifying the transition time, the subsequent data points can be used to train a RUL estimator model.

The dataset consisting of all features after the transition times, along with their corresponding RUL labels, can be fed into any supervised machine learning or deep learning model for fitting an RUL estimator. The challenge of estimating the RUL under dynamic OC is addressed through various approaches in the literature. Huang et al. (2019) incorporate the OC as an additional input in their deep network model. Fu et al. (2021) and Javanmardi & Hüllermeier (2023) suggest normalizing data according to OC. F. Li et al. (2020) integrate several algorithms into one model and select an optimal algorithm set for different OC to minimize their impact. Numerous studies address this problem by employing transfer learning or domain adaptation to handle the distribution shift between the training (source) and testing (target) domains (Mao et al., 2019; Fan et al., 2020; da Costa et al., 2020; Ding, Jia, Miao, & Huang, 2021; Ding, Jia, & Cao, 2021; Zhang et al., 2021). Ding et al. (2022) consider multi-source adaptation to manage the presence of subdomains in the source caused by multiple OC. To this end, we consider three distinct approaches in this study:

- Firstly, we train a regressor using only the previously attained features without taking the OC into account. This approach serves as a baseline for the subsequent two methods.
- Secondly, we employ the OC to normalize the features, aiming to mitigate its impact on the overall feature set.
- Thirdly, we concatenate the OC with the previously attained features, thereby incorporating them as additional features.

In the following sections, we first formalize the problem statement along with the details of all steps, from feature extraction to transition time determination and RUL estimation. Later, we elaborate on the data generation process and present comprehensive numerical results for the proposed approaches.

2. Problem Statement

Consider a dataset containing N instances of bearing run-to-failure data. Each bearing i in the dataset with a lifetime of T_i is represented as a time series $\mathbf{Z}_i := \left\{z_1^{(i)}, z_2^{(i)}, \ldots, z_{T_i}^{(i)}\right\}$. Here, $z_t^{(i)} := \left(v_t^{(i)}, o_t^{(i)}\right)$, where $o_t^{(i)} \in \mathbb{R}^{d_o}$ contains information about the operating and environmental conditions during the t^{th} measurement cycle, and $v_t^{(i)} \in \mathbb{R}^{d_v}$ represents the vibration signal collected during that measurement. For all $t \in [T_i] := \{1, \ldots, T_i\}$, the RUL $y_t^{(i)}$ of instance i at time t can be computed as follows:

$$y_t^{(i)} = T_i - t\,. \tag{1}$$

2.1. Feature Extraction from the Vibration Data

The vibration signal in the time domain $v_t^{(i)}$ is often high-dimensional, making it unsuitable for direct integration into a machine learning framework. In this study, we employ discrete Fourier transform to convert the signal into its frequency spectrum. This transformation results in $V_t^{(i)}$, a signal with the same dimensionality as the original time signal. Next, we partition the signal into m equally sized buckets $B_1, \ldots, B_m$ (with B_1 corresponding to the lowest frequency bucket and B_m to the highest) and simply extract the maximum ampli-

tude within each bucket to construct the m-dimensional frequency domain features $X_t^{(i)}$, i.e.,

$$X_t^{(i)} = \left(\max_{j_1 \in B_1} V_t^{(i)}(j_1), \ldots, \max_{j_m \in B_m} V_t^{(i)}(j_m) \right), \quad (2)$$

where $V_t^{(i)}(k)$ represents the k^{th} component of the signal $V_t^{(i)}$. Having access to this new feature, in the literature also known as the Spectrum-Principal-Energy-Vector (Ren et al., 2018), resolves the challenge posed by the high dimensionality of the initial vibration signal.

2.2. Transition Time Determination

K-means clustering is an unsupervised machine learning algorithm that clusters similar data points based on their proximity in the feature space. The algorithm initializes K cluster centroids and assigns each data point to the nearest centroid, recalculating the centroid of each cluster based on the mean of the assigned data points until convergence. The goal is to minimize the sum of squared distances between each data point and its assigned centroid. Here, we merely want to divide data points into a healthy or unhealthy cluster, thus K=2. We assume that each bearing starts in a healthy state, and hence, the cluster of the first point is considered healthy. A change in the cluster in the subsequent times is considered the beginning of the degradation. Once trained on the training data, the algorithm can be used in an online fashion for each test data instance to detect its changepoint promptly and initiate RUL prediction.

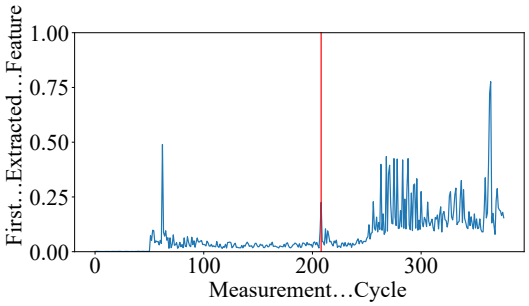
Following the extraction of low-dimensional features $X_t^{(i)}$ from the vibration data, we can utilize a 2-means clustering algorithm to assign a cluster label $\delta_t^{(i)} \in \{0, 1\}$ to each measurement time t for every bearing i. Subsequently, we define $t_{\text{TT}}^{(i)}$, the *transition time*, as the moment when the cluster of the i^{th} bearing differs from its initial cluster. Formally, this is expressed as

$$t_{\text{TT}}^{(i)} = \min \left\{ t : t \in [1 + T_c, T_i] \text{ and } \delta_t^{(i)} \neq \delta_1^{(i)} \right\}, \quad (3)$$

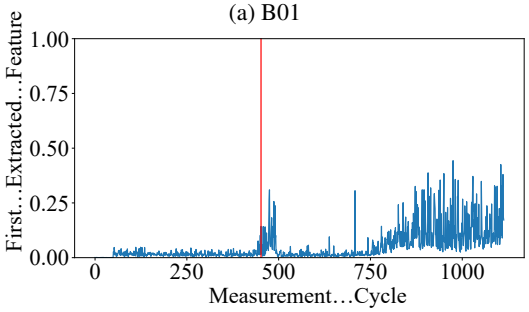
where T_c serves as a hyperparameter, representing the tolerance level. It signifies that a change in the cluster occurring earlier than T_c is not considered in the transition time calculation. The transition times for two bearing experiments are exemplarily depicted in Figure 1. Once the transition times are determined, we can define healthy and unhealthy datasets as follows:

$$\mathcal{D}_{\text{healthy}} = \left\{ (X_t^{(i)}, o_t^{(i)}, y_t^{(i)}) : i \in [N], t < t_{\text{TT}}^{(i)} \right\}, \quad (4)$$

$$\mathcal{D}_{\text{unhealthy}} = \left\{ (X_t^{(i)}, o_t^{(i)}, y_t^{(i)}) : i \in [N], t \geq t_{\text{TT}}^{(i)} \right\}. \quad (5)$$



(a) B01



(b) B04

Figure 1. The first extracted feature (blue) plotted for two bearings alongside their determined transition times (red). Here T_c is set to 150.

2.3. RUL Estimation

After extracting features from the vibration data and determining transition times, the next step is to estimate the RUL of the bearing. The primary focus of this paper is to leverage machine learning algorithms for that purpose. From a machine learning perspective, the problem is framed as a supervised regression setting—finding a mapping from the feature space to the RUL space. However, we have yet to explore how to benefit from OC information. In this context, we consider three distinct scenarios as outlined below and depicted in the flowchart in Figure 2.

- **Scenario 1 (disregarding OC):** In this scenario, OC information is neglected, and training proceeds without considering such contextual data.
- **Scenario 2 (OC for feature scaling):** This approach involves utilizing OC information for data/feature normalization. The methodology employs PCA to reduce the dimensionality of OC data from d_o to 1. Subsequently, a uniform discretization method is applied to bin the resulting one-dimensional feature into B bins. Next, inspired by a prior study (Javanmardi & Hüllermeier, 2023), the data in each bin is normalized to the $[0, 1]$ interval using B distinct MinMax scalers, aiming to mitigate the impact of diverse OC indirectly.
- **Scenario 3 (OC as additional features):** In this method, OC information is treated as an additional set of features, thereby augmenting the feature space. The objective is to

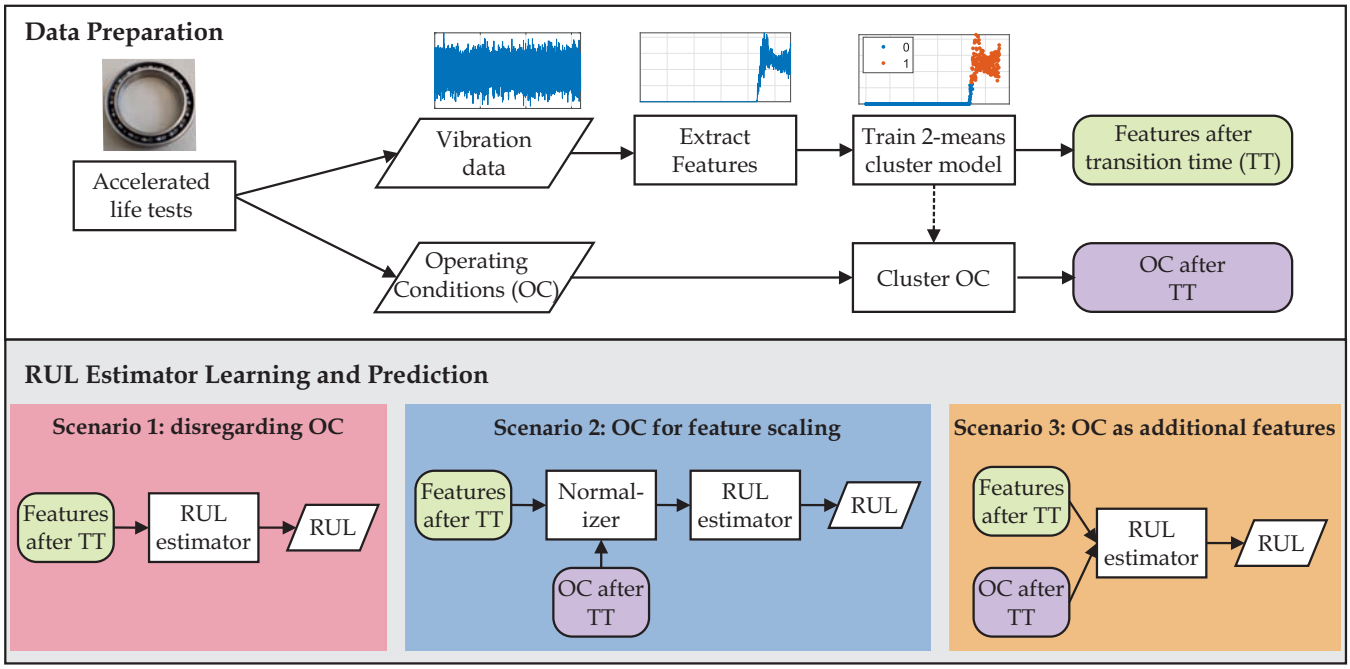


Figure 2. Flow chart of the proposed method.

enable the machine learning model to identify and consider interactions between OC and vibration features during the RUL estimation process.

Note that any machine learning or deep learning model can be used as the underlying RUL estimator for the three proposed scenarios. In this paper, we focus on traditional machine learning models, such as gradient boosting (GB) and random forest (RF).

3. Case Study

The experimental dataset, which consists of accelerated life tests of ball bearings subjected to time-varying conditions, is gathered at the Chair of Dynamics and Mechatronics (LDM) at Paderborn University. The specifications of the test bearing allow an experiment with valuable condition monitoring data to take several hours. Specifically, the 61806-2RS rolling element bearing with a basic static load rating $C_0 = 3.15\,\mathrm{kN}$ and a dynamic load rating $C = 4.00\,\mathrm{kN}$ have a basic rating life L_{10} of approximately five hours while considering a constant equivalent load of 4.50 kN, a rotating speed of 2500 rpm and other factors not been considered, such as lubrication.

The bearing test rig with its components is captured in Figure 3(a). The test bearing within its housing (3) is mounted on a shaft. The shaft is coupled with the driving motor (1) via a jaw coupling (2) and supported by two spherical roller bearings (8) within their housing. A static pre-load is exerted on the bearing via a lever structure (5), which is attached to the bearing housing. To this end, the compression spring, mounted on the lever structure, is compressed by the linear actuator (10). A dynamic load is superimposed on the static pre-load by means of an electrodynamic shaker (7), which is connected to the test bearing housing via a stinger (9).

The input signals, namely the exerted forces and shaft rotating speed, are measured synchronously with vibration and temperature as condition monitoring data. Three one-directional accelerometers (4) measure the vibration of the bearing indirectly. Two accelerometers (A and C) measure the vibration horizontally from the housing, and one (B) measures vertically from the lever structure, as illustrated in Figure 3(b). The ambient temperature and bearing temperature are measured with Pt100 resistance thermometers. The bearing temperature is measured indirectly from its housing at the positions (T1 and T2) depicted in Figure 3(b). Measurements were acquired at a sampling duration of 1.6 s and a measurement interval of approximately 12 s. The temperature signals are measured with a sampling rate of 10 Hz. To facilitate high-frequency analysis, vibration data were sampled at 128 kHz for experiments till B09 and due to data storage issues at 64 kHz for experiments from B10. This lower sampling frequency is theoretically sufficient for analysis in the frequency range of interest up to 32 kHz.

During an experiment, the test bearing is subjected to dynamic load superimposed on a static pre-load. To accommodate different dynamic load types, the dynamic load is sinusoidal with a constant frequency of 2 Hz for some experiments. The amplitude of the sinusoidal load is stationary per measurement and takes on a random value from a station-

(b) Accelerometer and temperature placement on the test bearing housing without the shaft
(c) A dismantled test bearing with a surface defect on the inner ring raceway and spalls on a rolling element.

ary uniform distribution within a predefined interval between measurements. For other experiments, the dynamic load is Gaussian white noise with a maximum excitation frequency of 200 Hz and truncated to remain within a predefined interval between measurements. A measurement of the dynamic load types is exemplarily shown in Figure 4. The shaft rotating speed is also set to be constant per measurement and takes on a random value from a stationary uniform distribution within a predefined interval between measurements. The predefined range of values per experiment can be found in Table 2.

To avoid failure of other components, except the test bearing, an experiment ends when the test bearing fails. Bearing failure is determined by two predetermined failure threshold criteria. If one threshold is exceeded, the experiment is stopped. On the assumption that the test bearing is in a normal state, without previous loading history, and the ranges of speed and force are restrained, the first criterion builds on the equivalent energy content of the vibration data and is formulated as:

$$F_{vibration} = O \cdot \frac{1}{m} \sum_{t=1}^{m} \text{RMS}\left(v_t^{(i)}(1), \ldots, v_t^{(i)}(n)\right), \quad (6)$$

where $F_{vibration}$ denotes the vibration threshold value, $O = 8$ is a predetermined constant value, m is the number of vibration signals to consider, and $v_t^{(i)}(k)$ represents the k^{th} index of a vibration signal $v_t^{(i)}$ of length n. For the provided experiments, this threshold value lies approximately between 6 g and 10 g. Since improper lubrication of the bearing raceway leads to increased friction and subsequently to increased temperature, the second criterion builds on the bearing temperature. According to the data sheet and to avoid melting the bearing seal made up of nitrile butadiene rubber (NBR), the threshold value, based on the bearing housing temperature $F_{temperature}$, is set as 110 °C.

In this paper, 17 run-to-failure experiments are utilized, with the temperature threshold value $F_{temperature}$ being exceeded for four experiments (B03, B07, B08, and B15) and the vibration threshold value $F_{vibration}$ for others. The failure types are not predetermined, but several single or combined failure types, such as an outer ring raceway defect or rolling element fault combined with an inner ring raceway defect, could occur during an experiment. Figure 3(c) is an image of a dismantled test bearing with spalls on a rolling element and an inner ring raceway defect after an experiment (B06). Due to the proximity to the bearing and for brevity, only the horizontal accelerometer (labeled A) is exemplarily considered in the following analysis. Also, three-dimensional OC information is considered, including peak dynamic load [N], mean absolute static load [N], and mean absolute rotating speed [rpm].

3.1. Numerical Experiments

We set the bucket size for feature extraction at 20. To conduct fair experiments, we repeat the proposed methods 17 times, reserving one bearing for testing each time while using the data of the remaining bearings for training. Without loss of generality, take the j^{th} bearing as the test bearing. The training and test data are defined as follows:

$$\mathcal{D}^{\text{train}} = \left\{ (X_t^{(i)}, o_t^{(i)}, y_t^{(i)}) : i \in [N] \setminus \{j\}, t \in [T_i] \right\}, \quad (7)$$

$$\mathcal{D}^{\text{test}} = \left\{ (X_t^{(j)}, o_t^{(j)}, y_t^{(j)}) : t \in [T_j] \right\}. \quad (8)$$

We then define X_{train} as the collection of features from all bearings in the training data. This data is normalized and fed into the 2-means clustering algorithm. We found out that utilizing only the first ten features is sufficient for clustering, yielding stable transition times. For the sake of fair comparison, the same transition times are used in all three RUL estimation scenarios. The resulting transition points lead to the creation of a new training dataset, which consists of only the data after the transition times, aka *unhealthy* points:

$$\mathcal{D}^{\text{train}}_{\text{unhealthy}} = \left\{ \left(X_t^{(i)}, o_t^{(i)}, \tilde{y}_t^{(i)} \right) : i \in [N] \setminus \{j\}, t \geq t_{\text{TT}}^{(i)} \right\}, \quad (9)$$

where

$$\tilde{y}_t^{(i)} = \frac{T_i - t}{T_i - t_{\text{TT}}^{(i)}} \times 100\% \quad (10)$$

is the RUL percentage after the transition time.

Different RUL estimation scenarios require different input data, as illustrated in Figure 2. The details are provided as follows.

- Scenario 1: For this approach, we simply use the training data in the form

$$\left\{ \left(X_t^{(i)}, \tilde{y}_t^{(i)} \right) : i \in [N] \setminus \{j\}, t \geq t_{\text{TT}}^{(i)} \right\} . \quad (11)$$

- Scenario 2: Here, we utilize the training OC for PCA and divide its one-dimensional output space into 20 bins. This way, each $o_t^{(i)} \in \mathbb{R}^3$ is replaced with its discretized counterpart $\tilde{o}_t^{(i)} \in [20]$. Next, for each region $r \in [20]$, a distinct normalizer MinMax_r is applied to the features with the same operating region, i.e.,

$$X_{\text{train}}^r := \left\{ X_t^{(i)} : i \in [N] \setminus \{j\}, t \geq t_{\text{TT}}^{(i)}, \tilde{o}_t^{(i)} = r \right\} . \quad (12)$$

  Let $\tilde{X}_t^{(i)} := \text{MinMax}_{\tilde{o}_t^{(i)}}(X_t^{(i)})$ be the normalized counterpart of $X_t^{(i)}$. The training data for this method can be written as

$$\left\{ (\tilde{X}_t^{(i)}, \tilde{y}_t^{(i)}) : i \in [N] \setminus \{j\}, t \geq t_{\text{TT}}^{(i)} \right\} . \quad (13)$$

- Scenario 3: We simply concatenate feature vectors and OC to create 23-dimensional features. The training data would be in the form

$$\left\{ \left([X_t^{(i)}; o_t^{(i)}], \ \tilde{y}_t^{(i)} \right) : i \in [N] \setminus \{j\}, t \geq t_{\text{TT}}^{(i)} \right\} . \quad (14)$$

We made the data, as well as all the implementations, publicly available on Zenodo[1] and GitHub[2] to encourage further development of RUL estimation models in dynamic operating conditions.

3.2. Results and Discussion

We employed GB and RF as models for estimating RUL. For each test bearing, separate models were trained for every estimation scenario. Figure 5 compares the performance of the three RUL estimation scenarios for two different bearings. To mitigate random effects, model training was repeated ten times for each test bearing and each scenario, using ten different random seeds for both GB and RF, and the resulting average mean absolute error (MAE) is reported in Table 3. Notably, the standard deviation of the MAE values was negligible and, therefore, not included in the table. The best MAE value for each bearing scenario is highlighted in bold.

The findings showcased in Table 3 shed light on the potential benefits of integrating OC information in the context of RUL estimation. Both learning models exhibited a decrease in MAE for more than 50% of the bearings when OC details were taken into account (scenarios 2 and 3 combined), with

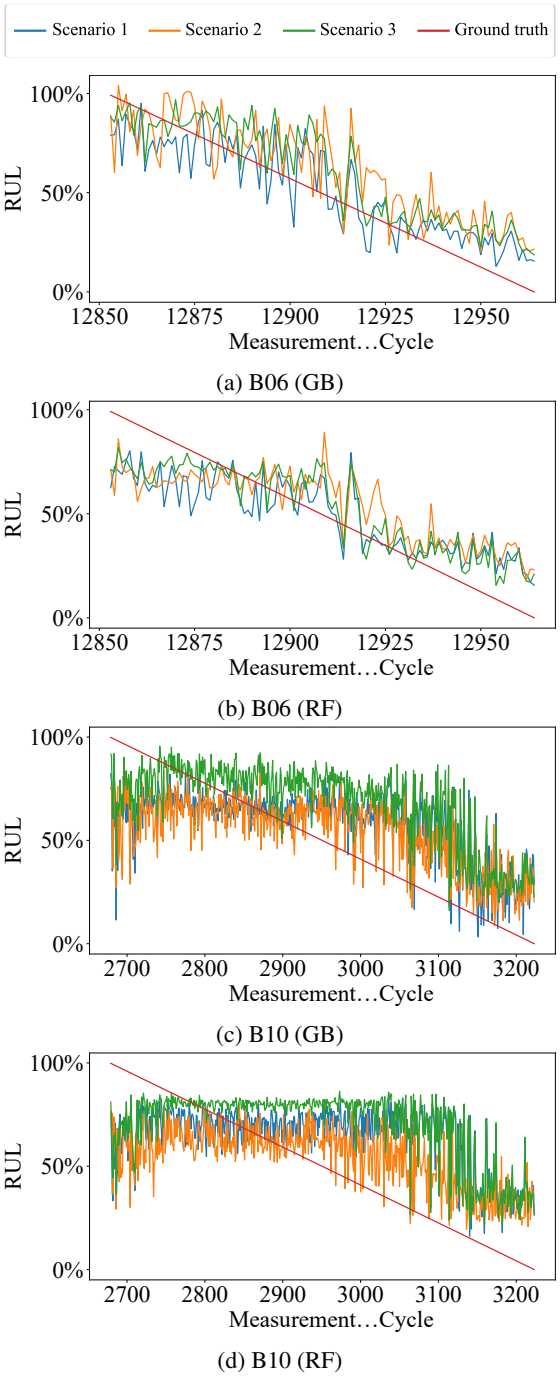

Figure 5. RUL estimation performance comparison for three scenarios.

RF benefiting more compared to GB. It should be noted that preprocessing steps, such as feature extraction and transition time identification, can also affect the final outcomes. Despite this, the primary focus here is to compare the performance of different scenarios under fixed preprocessing steps.

4. Summary and Outlook

To address the limitation of existing studies and enhance the relevance to practical applications, a new ball bearing run-to-failure dataset, considering time-varying operating conditions (OC), is introduced. Specifically, during an experiment, the test bearing is subjected to a sinusoidal load or Gaussian white noise superimposed on a static pre-load. Furthermore, the rotating speed takes on a random value from a stationary uniform distribution within a predefined interval between measurements. Owing to the degradation path of the ball bearings, a 2-means clustering algorithm is employed to partition the features extracted from raw vibration data into two states, namely healthy and unhealthy states. To estimate the remaining useful lifetime (RUL) for the unhealthy state, even under such time-varying OC, three different scenarios are considered, namely, **Scenario 1**, where the measured OC are disregarded, **Scenario 2**, where the OC are employed for feature scaling, and **Scenario 3**, where the OC serve as auxiliary features. Different machine learning techniques, such as gradient boosting and random forest, are employed as the RUL estimator for each scenario. The results of the presented case study suggest that the usefulness of incorporating OC information depends on the individual case: in some scenarios, it is clearly advantageous, and in others, it does not yield significant benefits.

As a future work, one may delve deeper into other ways of incorporating OC information into RUL estimation. For instance, a hybrid model consisting of a physics-based model and a machine learning model can be an interesting extension. The physics-based model could capture the relationship between the varying OC and the system state, while the machine learning model could capture the relationship between the measured system parameters and the RUL. Moreover, more advanced learning algorithms, such as deep learning techniques, along with tools from domain adaptation and transfer learning, can be employed on this dataset to determine whether they can enhance the results.

ABSTRACT

For complex systems, the number of residual candidates generated by Structural Analysis could be in the order of tens of thousands, and implementing all candidates is infeasible. This paper addresses the residual generator candidate selection problem from a state-observer perspective. First, the most suitable candidates to derive state-observers are selected based on two criteria related to the state-space form and a low number of equations. Then, a novel algorithm finds the minimal subset of residual generator candidates capable of detecting and isolating all faults. A procedure is introduced to compare the fault sensitivity of the selected candidates. This residual selection method is applied to the multi-engine propulsion cluster of a reusable launcher to illustrate its benefits.

1. INTRODUCTION

A classical model-based approach for fault detection and isolation usually comprises two main steps: the residual generation and the residual evaluation (Simani et al., 2003). The first step relies on the mathematical model of the system to generate signals, called residuals, that contain fault information. Then, the presence of the faults is inferred by a residual evaluation method. Structural Analysis (SA) has been proven to be a powerful tool for developing model-based fault diagnosis systems (Escobet, Bregon, Pulido, & Puig, 2019). It is a graph-based tool that uses the model equations to build a structural model. From the structural model, efficient algorithms (Krysander, Åslund, & Nyberg, 2007) can be applied to find residual generator candidates automatically. However, the number of candidates increases exponentially with the number of sensors. For large-scale systems, the number of residual generator candidates can be in the order of tens of thousands. This brings a new problem to be solved: the selection of the best subset of residuals that meets both fault detectability and isolability requirements.

The residual selection problem is addressed in (Svärd, Nyberg, & Frisk, 2013) where algorithms are proposed to find a minimal subset of residuals to meet the isolability constraints. In (Jung & Frisk, 2018), the residual selection problem is solved using convex optimization. In this case, the optimization problem depends on recorded data to find the minimal and most effective subset of residuals. In (Jung & Sundström, 2017), the residual selection problem is addressed by combining the fault sensitivity information of the residuals with machine learning methods. However, in all of those works, the fault isolability constraint used is very restrictive, leading to sub-optimal solutions with more residuals than necessary to isolate all faults.

Here, it is proposed to use a different fault isolability constraint based on the fault signature. This less restrictive constraint is able to lead to an optimal subset of residuals with minimal cardinality. Such an isolability constraint based on the fault signature has been used previously in (Zhang & Rizzoni, 2017) for residual selection. However, the objective was to find a subset of residuals that would produce the most "unique" fault signature for robustness purposes.

This paper proposes a new algorithm to find the minimal subset of residual generators able to detect and isolate predefined faults. The algorithm is adapted for an observer-based residual generation technique. State observers are more robust to modeling errors and parameter uncertainty when compared with other model-based residual generation techniques, such as Sequential Residual Generation (Isermann, 2005). The idea is to select the residual generator candidates based on

two main criteria: the candidates that can be easily written into the state-space form and the residual generators with the lowest number of equations. The state-space form is required to implement the majority of observers, such as the Kalman filter (Kalman, 1960) or Luenberger observers (Luenberger, 1964). It is preferred to have fewer equations because each one has a degree of uncertainty and modeling errors.

Depending on the number of residual generator candidates, it is possible to find many subsets of residuals with minimal cardinality. In order to choose the most suitable residuals in terms of fault sensitivity, a procedure based on the equations of the residual generator candidates is proposed. It quantifies the impact that a fault will have on the measured variables.

The main contributions of this paper are as follows. First, an algorithm to find the minimal subset of residuals to detect and isolate all faults. Second, a procedure based on the equations of the residual generators is proposed to compare the sensitivity of the residuals for one specific fault. The paper is organized as follows. In Section 2, basic notions of model-based diagnosis are recalled. In Section 3, the minimal residual selection problem is described and an algorithm to solve this problem is proposed in Section 4. Section 5 describes the procedure that uses the residual generator equations to compare the sensitivity of two residual generator candidates for a given fault. In Section 6, the proposed algorithm is applied in a multi-engine propulsion cluster of a reusable launcher. Conclusions are presented in Section 7.

2. Preliminaries on Model-Based Diagnosis

This section recalls some model-based diagnosis notions needed to formulate the residual selection problem formally introduced in (Svärd et al., 2013). Those notions are used to define necessary conditions to meet detectability and isolability constraints. Consider a model defined as

$$M = (E, X, Z, F) \tag{1}$$

where E is the vector of n_e system equations, X the vector of unknown variables in $\mathbb{R}^{n_x}$, Z the vector of known variables in $\mathbb{R}^{n_z}$ and F the vector of fault variables in $\mathbb{R}^{n_f}$. It is assumed that each fault $f \in F$ affects only one equation $e \in E$. This basic assumption is not as limiting as it may initially appear, as the equation e affected by the fault can propagate its effect through other equations. If a fault affects simultaneously more than one equation in the system, the system may be poorly modeled. Given the model (1), an ideal residual generator is defined as

Definition 2.1 (Ideal residual generator) *Consider a model M such as* (1)*. A system R with input Z and output r is a residual generator for M, and r is a residual if $f = 0$ implies $r = 0$ for all $f \in F$.*

In reality, residuals slightly deviate from zero even when no fault is present in the system due to unmodeled dynamics such as measurement noise and parameter uncertainty. One important property of residuals is their fault sensitivity, which defines the subset of faults that will affect this residual:

Definition 2.2 (Fault sensitivity) *Let R_i be a residual generator for model M. Then R_i is sensitive to fault $f \in F$ if $f \neq 0$ implies $r_i \neq 0$.*

With a set of residual generators $R \supseteq R_i, i \in \mathbb{N}$, the fault signature S_f of a fault f can be defined. The fault signature describes the subset of residuals that are sensitive to this fault:

Definition 2.3 (Fault signature) *For a set of residual generators R, the fault signature S_f of a fault f contains all the residuals $R_f \subseteq R$ sensitive to f.*

Using the fault signature, the fault isolability can be defined. If the fault has a unique signature, i.e., a unique subset of residuals is sensitive to it, the fault can be isolated from the others.

Definition 2.4 (Fault signature isolability) *A fault f is isolable using a set of residual generators R if its fault signature S_f is unique when compared to the other fault signatures.*

3. Minimal Residual Selection Problem

The minimal residual selection problem is formally defined as an optimization problem. Considering all residual generators available R_{all} to detect and isolate n_f faults, the objective is to find a minimal subset of R_{all} that respects the fault signature isolability property presented in def. 2.4, i.e., that generates unique fault signatures S_i for each fault $f_i, i = 1, 2..., n_f$. The optimization problem is formulated as

$$\begin{aligned} \min_{R \subseteq R_{all}} \quad & |R| \\ \text{s.t.} \quad & S = \{S_1, S_2, ..., S_{n_f}\}_{\neq} \\ & S \neq 0 \end{aligned} \tag{2}$$

where $|R|$ is the cardinality of the subset R. An equivalent optimization problem, using the fault signature, is introduced in (Zhang & Rizzoni, 2017), but a solution to this problem is not addressed.

The fault signature isolability concept is a key notion of finding the minimal subset of residuals to isolate all the faults. In previous works, such as (Svärd et al., 2013) and (Jung & Frisk, 2018), a different fault isolability definition was used. For instance, a fault $f_i \in F$ is considered to be isolable from another fault $f_j \in f$ if there exists a residual $R_k \in R$ that is sensitive to f_i but not to f_j. Due to the fact that the isolability is defined by pair of two faults, to isolate n_f faults, it is necessary to meet $\frac{n_f!}{(n_f-2)!}$ isolability requirements. This notion of isolability is thus more restrictive compared to the proposed definition 2.4.

The difference between the two notions of fault isolability

is illustrated on the following simple example. Consider a set of three residual generators and three faults with different sensitivities defined in Tab. 1. The symbol $*$ indicates that a given residual r_i is sensitive to a fault f_j.

$$R_{all} = \{r_1, r_2, r_3\} \quad F = \{f_1, f_2, f_3\}. \tag{3}$$

Table 1. Fault signature matrix.

	r_1	r_2	r_3
f_1	0	$*$	$*$
f_2	$*$	$*$	0
f_3	$*$	0	$*$

To isolate all three faults using the fault isolability requirements employed in previous works, the set of residuals should respect six different constraints:

$$\begin{aligned} &c_1 : f_1 \times f_2 \;\; c_2 : f_1 \times f_3 \;\; c_3 : f_2 \times f_1 \\ &c_4 : f_2 \times f_3 \;\; c_5 : f_3 \times f_1 \;\; c_6 : f_3 \times f_2 \end{aligned} \tag{4}$$

where $f_i \times f_j$ denotes a constraint that requires a residual sensitive to f_i but not to f_j.

Analysing the fault signature from Tab. 1, all three residuals are thus required to meet the six fault isolability constraints. However, it is possible to find smaller subsets of R_{all} capable of detecting and isolating all faults (3) using the fault signature isolability concept. The number of isolability constraints is then divided by two:

$$c_1 : S_1 \neq S_2 \;\; c_2 : S_1 \neq S_3 \;\; c_3 : S_2 \neq S_3. \tag{5}$$

It can be checked that any pair of residuals generates a unique fault signature for each fault, respecting the constraints 5, and is, therefore, a solution to the optimization problem (2).

4. Minimal Residual Selection Algorithm

A new algorithm to solve the optimization problem (2) is proposed. First, the minimal number of residuals needed to isolate n_f faults is calculated. Assuming that each residual r_i has only two states: $r_i = 0$ when $F_i = 0$ and $r_i \neq 0$ when $F_i \neq 0$, where F_i is the vector of faults that affects r_i. The lowest number of residuals n_{min} necessary to isolate n_f faults must follow the inequality:

$$2^{n_{min}} \geq n_f + 1. \tag{6}$$

It must be highlighted that n_{min} represents the theoretical lowest number of residuals necessary to generate n_f different fault signatures. The existence of such subset will depend on the sensitivity of each residual.

For instance, to isolate the three faults from Eq. (3), at least two residuals are required to generate three different fault signatures, considering that the fault signature $(0, 0)$ is excluded because it is equivalent to the fault-free state. For comparison, the solution proposed in (Jung & Frisk, 2018) based on optimization finds a subset of six residuals to isolate four faults.

The main idea behind the proposed algorithm consists in taking all possible combinations of n_{min} at a time of residual generators in R and checking if this subset of R generates a different fault signature for each residual. Assuming that the total number of residual generators is n_R, the number of all possible combinations is defined as

$$n_c = \frac{n_R!}{(n_R - n_{min})! n_{min}!} \tag{7}$$

From Eq. (7), if the number of residual generators is too big, it would be impossible to test the isolability properties of all possible subsets of R. For example, to isolate thirty faults ($n_f = 30$) using sixty residual generators ($n_R = 60$), it is necessary to have at least five residuals ($n_{min} = 5$), and there are more than five million possible combinations of residuals to be tested ($n_c > 5 \times 10^6$).

To restrict the number of residual generators, two new concepts are introduced:

- **Detectability class:** for each fault $f \in F$, list every residual sensitive to this fault $R_{df} \in R_{all}$;
- **Undetectability class:** for each fault $f \in F$, list every residual that is not sensitive to this fault $R_{uf} \in R_{all}$.

The idea is to select the most suitable residual generator for each detectability and undetectability class. The criterion for selecting that residual generator will depend on the residual generator method. In this work, the observer-based residual generation method is used. Two criteria are defined to choose the most suitable residual generator from a state-observer point of view:

1. Choose the residual generators composed of Ordinary Differential Equations (ODEs) or Differential Algebraic system of Equations (DAE) of index 1.
2. Select the residual generators with minimal "state cardinality," which means the residual with a minimal number of equations, which is equivalent to the state dimension of the corresponding observer.

The first criterion is related to the observer theory, which is mostly based on ODE systems. DAE systems of index one are also included because they can be easily transformed into an ODE by taking the derivative of the algebraic equations (Campbell, Linh, & Petzold, 2008).

The second criterion is related to model uncertainty. Each equation has a level of uncertainty due to modeling errors. It is thus suitable to choose the residuals with fewer equations to minimize the combined level of uncertainty.

Finally, the union of all residuals that meet both criteria for each detectability and undetectability class is used to test all possible combinations to verify the fault isolability requirements. The formal description of the process to find the minimal subset of residual generators is described in Algorithm 1. It can be divided into two main loops. The first loop takes the set of residual generator R and filters it using the two criteria defined above. The isolability properties of the filtered subset of residuals R_f are inspected. If the isolability properties are not met, a flag to relax the filtering constraints ($rCons$) is activated. The second loop tests all possible subsets of R_f based on the minimal number of residuals (n_{min}) needed. If no subset of R_f containing n_{min} residuals is capable of detecting and isolating the faults F, the minimum number of residuals n_{min} is increased, and the search restarts. The procedure returns a list R_{min} containing all subsets with n_{min} residuals that can detect and isolate all faults. The other procedures used in Algorithm 1 are described below.

- DETECTABILITYCLASS(R, F) for each fault $f \in F$, lists all residuals from R that are sensitive to this fault. Returns n_f subsets of residuals corresponding to each fault.
- UNDETECTABILITYCLASS(R, F) for each fault $f \in F$, lists all residuals from R that are not sensitive to this fault. Returns n_f subsets of residuals corresponding to each fault.
- FILTERRESIDUALS($d, u, rCons$) for each detectability class d and undetectability class u, filter the residuals considering cardinality and equations structure criteria. If the flag $rCons$ is activated, the cardinality criteria are relaxed. Returns the list of residuals R_f that fits all filtering criteria.
- CHECKISOLABILITY(R, F) checks if a group of residuals R generates unique fault signatures for each fault $f \in F$. Returns 1 if true and 0 if false.
- COMPUTESUBSETS(R, n_{min}) compute all possible combinations of residuals from R separated into groups of n_{min} residuals. Returns a list containing all possible combinations.

Algorithm 1 Residual Selection Algorithm

Inputs: Set of residual generators R, List of faults F
Output: Subsets of R with minimal cardinality R_{min}

```
procedure RESIDUALSELECTION(R,F)
    d ← DETECTABILITYCLASS(R,F)
    u ← UNDETECTABILITYCLASS(R,F)
    rCons ← 0
    isol ← 0
    while isol = 0 do
        R_f ← FILTERRESIDUALS(d, u, rCons)
        if CHECKISOLABILITY(R_f,F) then
            isol ← 1
        else
            rCons ← rCons + 1
    n_min ← COMPUTENUMMINRES(F)
    while R_min = ∅ do
        R_S ← COMPUTESUBSETS(R_f,n_min)
        k ← 0
        for all R_i ∈ R_S do
            if CHECKISOLABILITY(R_i, F) then
                R_min(k) ← R_i
                k ← k + 1
            if R_min = ∅ then
                n_min ← n_min + 1
    return R_min
```

5. RESIDUAL EVALUATION PROBLEM

The Algorithm 1 presented in Sec. 4 returns all possible combinations of residuals with minimal cardinality capable of isolating the predefined faults. In example (3), there are three different pairs or residuals that could be used to isolate the faults. A method to compare the residual generators is presented here. The objective is to quantitatively measure whether one residual is more sensitive than another.

Assuming that state observers will generate the residual by measuring the difference between the output estimated by the state observer $\hat{y}$ and the measured output y, the idea is to quantify the "innovation" that the fault will have on the measured states of the residual generator. Taking y_{bf} as the measured output before fault and y_{af} the measured output after fault, the innovation is defined as

$$In = y_{bf} - y_{af}. \tag{8}$$

In theory, the innovation brought by the fault is important to better the sensitivity of the residual generator to this fault. This procedure is illustrated on the same simple example used in (3). Consider a linear time-invariant system composed of a chain of integrators:

$$\begin{aligned} &e_1 : \dot{x_1} = k_1 x_2 \;\; e_2 : \dot{x_2} = k_2 x_3 \;\; e_3 : \dot{x_3} = k_3(u + f_3) \\ &e_4 : y_1 = x_1 + f_1 \;\; e_5 : y_2 = x_2 + f_2 \;\; e_6 : y_3 = x_3 \end{aligned} \tag{9}$$

where the unknown variables are $x = \{x_1, x_2, x_3\}^T$, the outputs are $y = \{y_1, y_2, y_3\}^T$, the input is u, the fault vector is $F = \{f_1, f_2, f_3\}^T$, and $k_i, i \in [1, 3]$ are known constants.

Thee residual generators candidates can be extracted from (9) using structural analysis, where three MSOs are computed and taken as residual generators. They are composed of the following equations

$$\begin{aligned} &r_1 = \{e_2, e_3, e_5\} \;\; r_2 = \{e_1, e_4, e_5, e_6\} \\ &r_3 = \{e_1, e_3, e_4, e_6\} \end{aligned} \tag{10}$$

the fault signature of the residuals (10) are illustrated in Tab. 1. It has been shown previously that any pair of (10) is enough to isolate the three faults. However, the impact of the faults is different for each residual.

For instance, let us compare the sensitivity of r_1 and r_2 when f_2 is injected using the procedure described above. For r_1, the relation between the fault f_2 and the output is direct because the output of r_1 is y_2. For r_2, the measurement of y_2 is first used to estimate $\dot{x}_1$, which is then used to estimate the output y_1. The innovation brought by f_2 in r_1 and r_2 can be summarized as

$$In_{r_1,f_2} = f_2 \quad In_{r_2,f_2} = k_1 f_2. \tag{11}$$

If the known constant k_1 is bigger than one, this empirical analysis indicates that r_2 will be more sensitive to r_1 to detect f_2. Repeating this analysis to the other faults and residuals, an efficient subset of residual generators concerning fault sensitivity can be found.

6. Application Example

The algorithm presented in Section 4 is used to find a list of minimal subsets of residuals capable of detecting and isolating a predefined list of faults in a multi-engine propulsion cluster of a reusable launcher.

6.1. Multi-Engine Propulsion Cluster Description

The propulsion cluster considered here is composed of three main parts: propellant tanks, feeding lines, and liquid-propellant rocket engines. The tanks are where the propellant is stored, and the feeding lines connect the propellant tanks with the rocket engines, where the thrust is generated. The propulsion cluster considered is composed of three rocket engines. The rocket engines use liquid oxygen (LOX) and liquid hydrogen H_2 as propellants (Pérez Roca, 2020). A simplified scheme of the LOX part of the multi-engine cluster is illustrated in Fig. 1. The feeding lines architecture with one main line splitting into secondary lines is optimal for minimum mass and pressure drop values (Miquel, 2020).

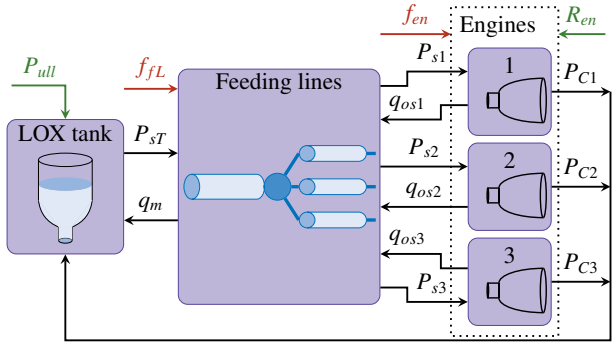

Figure 1. Multi-engine propulsion cluster scheme

The cluster operation can be summarized as follows: the rocket must follow a predefined trajectory. The trajectory is converted into thrust reference (R_{en}) and then given to the engines. Each engine has its control law that uses the control valves to meet the references. The valve position defines how much mass flow (q_{oi}) is used by the engine and, therefore, defines the mass flow that goes out of the tank through the feeding lines. The outlet pressure of the feeding lines (P_{si}) is imposed as the input pressure of the engines. P_{si} also depends on the tank's outlet pressure P_{sT}. The tank's outlet pressure is defined by the tank's ullage pressure (P_{ull}) and the rocket acceleration a_L. The acceleration depends on the thrust generated by each motor, which is directly related to the engines' combustion chamber pressure P_{Ci}. The index $\cdot_i \in \{1,2,3\}$ denotes the respective rocket engines.

The state vector is composed of the following variables

$$\begin{aligned} x = \{&P_{sT}, P_m, P_{si}, q_m, q_{si}, q_{GHi}, q_{CHi}, q_{THi}, q_{TOi}, \\ &P_{Ci}, P_{Gi}, P_{THi}, P_{TOi}, \omega_{Hi}, q_{GOi}, q_{COi}, \omega_{Oi}\}^T \end{aligned} \tag{12}$$

where P_{sT} is the output pressure of the LOX tank, P_m/q_m are the output pressure/mass flow of the main line, P_{si}/q_{si} are the output pressure/mass flow of the i-th secondary line, q_{GHi}/q_{GOi} are the gas generator H_2/LOX mass flow, q_{CHi}/q_{COi} are the combustion chamber H_2/LOX mass flow, q_{THi}/q_{TOi} are the turbine H_2/LOX mass flow, P_{Ci}/P_{Gi} are the combustion chamber/gas generator pressure, P_{THi}/P_{TOi} are the H_2/LOX turbine intake pressure, and ω_{Hi}/ω_{Oi} are the H_2/LOX pump rotating speed.

The vector of known variables z is composed of input variables u and output measurements y, $z = \{u, y\}$

$$\begin{aligned} u &= \{V_{GOi}, V_{GHi}, V_{COi}, V_{CHi}, V_{Zi}\} \\ y &= \{P_H, P_{ull}, P_m, P_{si}, P_{Ci}, P_{Gi}, \omega_{Hi}, \omega_{Oi}, \\ &\quad RMC_i, RMG_i\}^T \end{aligned} \tag{13}$$

where VG_{Hi}/V_{GOi} are the gas generator H_2/LOX control valves, V_{CHi}/V_{COi} are the combustion chamber H_2/LOX control valves, V_{Zi} is the valve that directs the gas generated by the gas generator to the turbines, P_H is the outlet pressure of the H_2 line, P_{ull} is the ullage pressure at the LOX tank, and RMC_i/RMG_i are the combustion chamber/gas generator mixture ratios.

The mixture ratios are the relation between the LOX and H_2 mass flows:

$$RMC_i = \frac{q_{COi}}{q_{CHi}} \quad RMG_i = \frac{q_{GOi}}{q_{GHi}}. \tag{14}$$

The fault vector f is composed of the following faults:

$$f = \{f_{qCOi},\ f_{VCHi},\ f_{VGHi},\ f_{\omega Hi},\ f_{RMCi}\}^T \tag{15}$$

where f_{qCOi} is a external LOX leakage in the combustion chamber, f_{VGHi} is a blockage in V_{GHi}, f_{VCHi} is a blockage in V_{CHi}, and $f_{\omega Hi}/f_{RMC}$ are bias faults in the sensors of ω_{Hi}/RMC_i respectively.

All the equations that describe the relations between states, inputs, and faults are listed in Appendix 7.

Considering that each engine is identical, only the measurements and faults from engine one are considered to simplify the implementation of the algorithm and avoid unnecessary computational. However, all results obtained for engine one can be automatically extended to the other two engines.

The first step is to find all residual generator candidates R. This step is performed using the Fault Diagnosis Toolbox (Frisk, Krysander, & Jung, 2017). In total, considering the equations and measurements of only engine one, the system is composed of fifty-three equations, and the degree of redundancy is eight. The residual generator candidates are obtained by computing all the Minimally Structurally Overdetermined (MSO) sets. Each MSO is a subsystem with a degree of redundancy one, i.e. it has one more equation than the number of unknown variables. All MSOs can be solved independently and are, therefore, residual generator candidates.

6.2. Algorithm implementation

The computation of all residual generators results in 24433 candidates that can possibly be used to detect and isolate five faults. From (6), at least three residuals are used to detect and isolate five faults.

The first loop of Algorithm 1 finds a subset of 16 residuals that meet both cardinality and state-observer criteria.

$$\begin{aligned} R_f = \{&r_{166}, r_{167}, r_{170}, r_{710}, r_{711}, r_{713}, r_{1000}, r_{1001}, \\ &r_{1006}, r_{1085}, r_{1320}, r_{1321}, r_{1326}, r_{1408}, r_{1593}, r_{1838}, \}. \end{aligned} \tag{16}$$

The fault sensitivity of the selected residuals is expressed in Table 2. It shows that the selected residuals 16 are enough to detect and isolate all faults considered.

The second loop of Algorithm 1 takes the selected residuals R_f from equation (16) and tests all possible combinations using the minimum number of residuals and selects the combination that generates unique fault signatures for each fault. In the first iteration of the loop, the minimum number of residual generators is three, and from (6), there are 560 possible combinations to be tested. However, there are no subsets of three residuals capable of isolating all faults. In the second iteration, the minimum number of residuals is increased by one, resulting in 1820 possible combinations of four residuals. The Algorithm 1 returns 40 combinations, each one containing four residuals from (16) that can isolate all faults. For comparison, the algorithm proposed in (Svärd et al., 2013) returns a subset of at least seven residuals to isolate the same five faults.

Two possible subsets of residuals are chosen for further analysis:

Table 2. Fault signature matrix.

	f_{VGH1}	f_{VCH1}	f_{qCOi}	$f_{\omega Hi}$	f_{RMCi}
r_{166}	0	0	0	$*$	0

$$\begin{aligned} R_1 &= \{r_{166}, r_{170}, r_{713}, r_{1001}\} \\ R_2 &= \{r_{166}, r_{170}, r_{713}, r_{1321}\} \end{aligned} \tag{17}$$

both subsets in (17) have almost the same structure; the only difference is the last residual generator. To compare those residual generators, the empirical residual evaluation method presented in Section 5 is used. The residuals are composed of the following variables:

- r_{1001}

$$\begin{aligned} x_{1001} &= \{q_{GO1}, q_{CH1}, \omega_{H1}\} \\ z_{1001} &= \{P_{s1}, P_H, P_{G1}, P_{C1}, RMC_1, RMG_1, \\ &\quad \omega_{O1}, \omega_{H1}, V_{CH1}, , V_{GO1}\} \end{aligned} \tag{18}$$

- r_{1321}

$$\begin{aligned} x_{1321} &= \{q_{GH1}, q_{CO1}, \omega_{H1}\} \\ z_{1321} &= \{P_{s1}, P_H, P_{G1}, P_{C1}, RMC_1, RMG_1, \\ &\quad \omega_{O1}, \omega_{H1}, V_{CO1}, , V_{GH1}\} \end{aligned} \tag{19}$$

the residuals have a very similar structure, having three states and the same output ω_H. One difference is when the fault f_{RMC1} is injected. In r_{1001}, RMC_1 is used to estimate q_{CO1}, on the other hand, in r_{1321}, RMC_1 is used to estimate q_{CH1}. When fault f_{RMC1} is injected, the estimation of the mass flows will be given by

$$\begin{aligned} r_{1001}: &\quad q_{CO1} = (RMC_1 + f_{RMC1}) q_{CH1} \\ r_{1321}: &\quad q_{HC1} = \frac{q_{CO1}}{RMC_1 + f_{RMC1}}. \end{aligned} \tag{20}$$

For residual r_{1321}, the influence of f_{RMC1} is directly observed in the output ω_{H1} because the evolution of ω_{H1} depends on q_{HC1}. Residual r_{1001} is not directly influenced be-

cause q_{CO1} is not used to estimate ω_{H1}. The fault f_{RMC1} will first impact the state q_{GO1} which then will influence the estimation of q_{GH1} and affects ω_{H1}. During those steps, the fault magnitude f_{RMC1} is divided by a constant bigger than one, attenuating the effect of the fault in the output. This makes the residual r_{1321} more suitable to detect f_{RMC1}. The same analysis can be extended to faults f_{qCO1} and $f_{\omega O1}$, where the magnitude of the faults is attenuated before affecting the output of residual r_{1001}.

6.3. Simulation results

To test the performance of the residuals (17) in simulation, an Unscented Kalman Filter (UKF) was calculated for each residual. This state estimator can deal with any type of nonlinearities and gives accurate estimations up to the third order of Taylor expansion (Wan & Van Der Merwe, 2000). The unscented transformation parameters were set at the default values, which gives an optimal solution for Gaussian distributions, with $\alpha = 0.001$, $\kappa = 0$, and $\mathcal{B} = 2$. The multi-engine cluster model was implemented using Simulink, and measurement noise was added. It is a white noise with zero mean, and the standard deviation varies according to the sensor specifications. For the rotational frequency of the turbopumps ω_{Oi}, ω_{Hi}, the Standard Deviation (SD) is 0.1% the rotational frequency when the engine at its nominal operating point. For the low-pressure values (P_{si}, P_H, P_{ull}), the SD is 0.1%, the nominal pressure value. For the high pressures (P_{Gi}, P_{Ci}) the SD is 0.2% the nominal value. The mixture ratios RMC_i and RMG_i have a standard deviation of 0.3%, the nominal value. The measurement noise covariance matrix $\mathcal{R}$ of the UKF was defined according to the standard deviations. The model parameters are considered perfectly modeled, so the process noise covariance matrix $\mathcal{Q}$ is proportionally defined ten times smaller than $\mathcal{R}$. To simulate the behavior of the system in closed-loop when a fault is injected, three PIDs were designed for each engine using the classical configuration (Pérez Roca, 2020). The PIDs use the valves to control the outputs $y_{PID} = [RMC_i, RMG_i, P_{Ci}]$. The closed loop system has a settling time to the step response of two seconds without overshooting.

Five faults are simulated in rocket engine 1, and each fault stays active for two seconds. The fault injection time and parameters are presented in Tab. 3.

The residuals generated by the UKFs are the difference between the output estimated by the state observer and the measured output, they are illustrated in Fig. 2. The UKF calculated from residual generator r_{166} is denoted UKF_{166}, etc.

From Fig. 2, the theoretical fault signature matrix of the residuals defined in Table 2 is observed in simulation. The exception is residual r_{1001} where the faults f_{qCO}, f_{wO} and f_{RMC} are attenuated by the residual's equations, and the impact of those faults cannot be seen when measurement noise is added. From simulation results, it is confirmed that the subset R_2 from (17) is more suitable for fault detection and isolation due to the higher sensitivity of r_{1321} when compared with r_{1001}.

Table 3. Fault parameters

Fault	Time	Effect
f_{VGH1}	12s-14s	Blockage 50% V_{GH1}
f_{VCH1}	16s-18s	Blockage 10% V_{CH1}
f_{qC1}	20s-22s	LOX Leak. of 0.8% nominal q_{CO1}
f_{wO1}	24s-26s	Bias of 1% nominal ω_{O1} value
f_{RMC1}	28s-30s	Bias of 5% nominal RMC_1 value

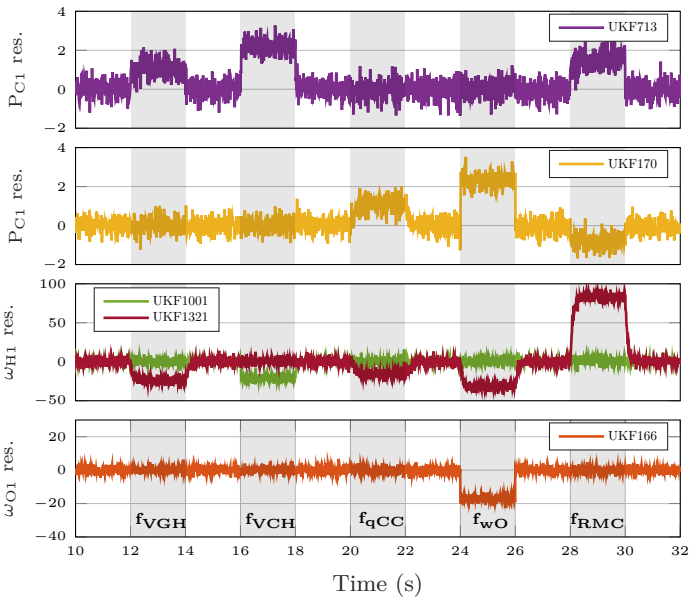

Figure 2. Residuals

7. Conclusion

A novel algorithm to find all possible subsets of residual generator candidates capable of detecting and isolating all faults with minimal cardinality has been presented. The minimal cardinality is achieved using a less restrictive isolability constraint based on the fault signature. Since the algorithm cannot be applied to a large number of residual generator candidates due to combinatorial explosion, two criteria to decrease the number of residual candidates were established. Those criteria take into account the residual generator method based on state observers, i.e. the reduced sensitivity to uncertainty when the number of state equations is minimal per residual. A procedure was presented to evaluate the selected residuals and compare the subsets with minimal cardinality returned by the algorithm. The proposed methods were applied in a model of a multi-engine propulsion cluster where five different faults

were considered. From 24433 residual generator candidates, the algorithm found 40 subsets, each one containing four different residual generators, that were capable of detecting and isolating the five faults. Two of those subsets of residual generators were implemented using Unscented Kalman Filter. Simulation results showed that the subsets can be used to detect and isolate all faults, and as a result the effectiveness of the proposed selection algorithm and quantitative sensitivity evaluation.

APPENDIX

The Liquid-Propellant Rocket Engine models are all derived from (Pérez Roca, 2020). All variables used in the equations that are not states (12), inputs and outputs (13) or faults (15) are known constants. Only the equations of the oxygen side are presented. The equations of the hydrogen side have the same structure. The only difference is the index $._O$ is replaced by $._H$ on the hydrogen side. The effect of the faults in the dynamic equations of the cluster is highlighted in red.

The pressure at the output of the oxygen turbopump P_{pOi} is given using manufacturer data:

$$P_{pOi} = \left(\frac{ap_O}{\rho_O} + R_{OGC}\right)(q_{COi} + q_{GOi})^2 + bp_O(q_{COi} + q_{GOi})\omega_{Oi} + cp_O\rho_O\omega_{Oi}^2. \quad (21)$$

The evolution of the oxygen mass flow that enters the combustion chamber q_{COi} and the gas generator q_{GOi} are derived from conservation of the momentum equation:

$$\dot{q}_{GOi} = \frac{1}{I_{GO}}\left[P_{si} + P_{pOi} - P_{Gi} - \left(\frac{1}{2\rho_O(V_{GOi} + f_{VGOi})^2} + R_{OG} + R_{OGC}\right) q_{GOi}^2\right] \quad (22)$$

q_{COi} has the same structure, where the subscript $._G$ is replaced by $._C$.

The hot gases mass flows are given by

$$\dot{q}_{THi} = \frac{1}{I_{TH}}\left(P_{Gi} - P_{THi}\right) - ky_{TH}R_{outG}\frac{T_G}{P_{Gi}}q_{THi}^2 \quad (23)$$

$$\dot{q}_{TOi} = \frac{1}{I_{TO}}(P_{Gi} - P_{TOi}) - Zr_iR_{outGG}\frac{T_G}{P_{Gi}}q_{TOi}^2 \quad (24)$$

where Zr_i is the equivalent resistive coefficient of the valve. The combustion chamber pressure P_{Ci} evolution can be approximated by first order Taylor expansion

$$\dot{P}_{Ci} = k1_C(q_{CHi} + q_{COi} - f_{qCOi}) - k2_C\sqrt{T_C}P_{Ci}. \quad (25)$$

The oxygen turbine pressure P_{TOi} is defined as

$$\dot{P}_{TOi} = k1_{TO}T_Gq_{TOi} - k2_{TO}\sqrt{T_G}P_{TOi}. \quad (26)$$

Finally, the rotational speed's evolution is given by manufacturer data

$$\dot{\omega}_{Oi} = \frac{1}{J_O}[T_{TOi} - \frac{ac_O}{\rho_O}(q_{COi} + q_{GOi})^2 - bc_O(q_{COi} + q_{GOi})\omega_{Oi} - cc_O\rho_O\omega_{Oi}^2] \quad (27)$$

where the motor torque T_{TOi} is given by $T_{TOi} = ST.W_i$ with ST the specific torque and W_i the work provided by the turbine pressure P_{TOi}.

For the feeding lines model, the evolution of the mass flow q and outlet pressure P in one rigid pipe, considering the effects of the fluid inertia, dynamic compressibility and neglecting the fluid thermal expansion, can be described by the momentum and mass balance equations:

$$\begin{aligned}\dot{q} &= \frac{S}{L}\left(P_{in} - P - \frac{f_rL}{2\rho S^2D}q^2\right)\\ \dot{P} &= \frac{\alpha^2}{V}(q - q_o)\end{aligned} \quad (28)$$

this pair of equations must be repeated for each pipe to model the feeding lines illustrated in Fig. 1.

The governing equations of pressurization of a propellant tank are obtained from (Majumdar & Steadman, 2001). The output pressure of the tank is defined as

$$P_{sT} = P_{ull} + \rho_O[a_L + g\cos(b)]H_d \quad (29)$$

Considering that a cylinder can approximate the shape of the tank, the gravitational head H_d is defined as

$$H_d = \frac{V_{LOX}}{\pi r^2}, \quad V_{LOX} = V_{LOX_0} - \frac{\int_0^t qm\,dt}{\rho_0} \quad (30)$$

The rocket's acceleration a_L can be approximated by a bivariate quadratic function total thrust T generated by the engines and the mass of the rocket m_R:

$$a_L = k_{1a} + k_{2a}T + k_{3a}m_R + k_{4a}Tm_R + k_{5a}m_R^2 \quad (31)$$

Finally, the mass of the rocket m_R can be calculated as:

$$m_R = m_{R_0} - \int qm\,dt - \int q_H\,dt \quad (32)$$

where $q_H = q_{CH} + q_{GH}$ is the total hydrogen mass flow used by the three engines, and m_{R_0} is the initial mass of the rocket.

Robust Remaining Useful Life Prediction Using Jacobian Feature Regression-Based Model Adaptation

Prasham Sheth[1] and Indranil Roychoudhury[1]

ABSTRACT

The accurate and robust prediction of remaining useful life (RUL) is critical for enabling the proactive mitigation of fault effects rather than reacting to them. For RUL prediction, one must model nominal and faulty system behaviors and how different faults progress over time. Complex data-driven machine learning (ML) models may capture both nominal and fault progression by updating the model parameters at different stages. As new data are observed, these model parameters can be updated to keep the system model always accurate. However, complete retraining of these models is both data- and computation-intensive and unsuitable for dynamic, fast-changing environments requiring quick recalibration. This calls for efficiently adapting the model to new operating conditions or the system's current state. One such efficient way to recalibrate model parameters to newly observed data using Jacobian feature regression (JFR) is presented in Forgione, Muni, Piga, and Gallieri (2023), where a recurrent neural network (RNN) models the current behavior of the dynamic system. Then, any subsequent deviation of observed measurements and the RNN model is attributed to an "unacceptable degradation of the nominal model performance." To update the RNN model, Forgione et al. (2023) propose augmenting the current model with additive correction terms learned by implementing JFR on observed "perturbed system" data. In this paper, we propose an automated *online* framework to adapt the model efficiently to always reflect the system's current state and use it for accurate RUL prediction and select JFR as one such adaptation technique. We extend the implementation of JFR-based model adaptation to hybrid models and demonstrate JFR to be more sustainable than the other retraining methods. Finally, we showcase the application of this approach to the oil and gas industry. A testbed that simulates a digital synthetic oilfield is used to show the effectiveness of this adaptation-based RUL prediction technique.

1. INTRODUCTION

1.1. Motivation

The accurate and robust prediction of remaining useful life (RUL) is one of the most critical functions of prognostics and health monitoring for assets. RUL is the time before a system can no longer function nominally. Knowing how much useful time a system has can help prevent having to react to such a failure and plan steps to mitigate its effects, e.g., planning maintenance and repair, thereby supporting the seamless operation of the facility.

Predicting RUL is a well-explored problem and can be implemented using (1) *model-based* or science-based approaches, (2) *data-driven* approaches that use available data but completely agnostic of scientific domain knowledge, or (3) *hybrid* approaches that combine scientific theory with available data. For accurate RUL prediction, a model must capture the nominal behavior of the system as well as the progressively degraded behavior. In model-based approaches, multiple models can be developed for nominal and degraded system behavior for different possible faults. A single, sufficiently complex data-driven or hybrid model may capture both nominal and degraded system behavior. One approach to building a single model is to periodically update or adapt the model to new system observations so as to reflect reality accurately. Many possible ways are available in the literature that enable this updating or adaptation of the model, such as retraining of machine learning (ML) models, recalibration of model parameters based on some initially collected field data, and so on. However, many of these approaches are computationally expensive, have intense data requirements, and are unsuitable for dynamic, fast-changing environments that need quick recalibration requirements.

1.2. Related Work and Their Challenges

Wang, Zhao, and Addepalli (2020) provide a well-structured summary of the increasing interest in using deep-learning approaches, such as autoencoders, deep belief networks, recur-

rent neural networks (RNNs), and convolutional neural networks for RUL prediction. The authors present conventional model-based as well as hybrid RUL prediction approaches and provide an excellent summary of the scope of the research development undertaken regarding RUL prediction.

To highlight a few works that focus on predicting RUL, Lei et al. (2016) propose an approach that contains two modules: (1) indicator construction, which fuses the information from multiple features and constructs a health indicator that they referred to as weighted minimum quantization error to correlate the machinery degradation, and (2) RUL prediction block that uses a particle-filtering-based algorithm. Ma and Mao (2021) propose a convolution-based long short-term memory (CLSTM) for predicting the RUL of bearings. By showcasing the ability of the CLSTM architecture to predict RUL effectively, they validate the effectiveness of using the spatial and temporal features. Y. Zhang, Xiong, He, and Liu (2017) showcase the use of an LSTM-RNN based method for predicting the RUL of lithium-ion batteries, highlighting the approach's capability to capture the long-term dependencies of capacity degradation in batteries.

A major challenge of the existing RUL prediction approaches is that they are system-state-dependent; i.e., their effectiveness in predicting RUL accurately is hinged on the assumption that the system model accurately reflects the current and future (degraded) system states. However, collecting data representing the system in all possible scenarios is impossible for many systems in real life, especially when these systems are never allowed to degrade sufficiently. The data collection process for such a wide range of possibilities is also extremely expensive. Therefore, the availability of training data for such models is a big bottleneck, and as soon as the system goes into a level of degradation that is not represented in the data, the chances of the model effectively predicting RUL degrades exponentially. In such scenarios, having a dynamic model that adapts based on the system's state becomes necessary. Researchers have focused on developing different approaches by using techniques such as transfer learning, domain adaptation, and modeling the degradation process. This does not represent the exhaustive list of techniques but just highlights the major approaches being explored.

Transfer learning is one technique for adapting the model to use the previous learnings to improve generalization about the new task. In the case of the RUL prediction, the task remains the same but differs as the underlying data distribution changes; hence, the model has to be "transferred" to this new set of data points that belong to the new distribution. The change in distribution, as mentioned earlier, could result from different operating conditions or different states of the system because of the degradation or upgrades to the equipment of the system. *Domain adaptation* falls within the umbrella of transfer learning, wherein the main focus is to help the model adapt from one or more sources of domains to a target domain. Ding, Ding, Zhao, Cao, and Jia (2022) introduce a multisource domain adaptation network for RUL prediction of bearing under varying conditions. Their domain adaptation strategy functions in two stages where the domain-specific distribution is integrated with regressor adaptation. A fusion of LSTM and domain adversarial neural networks (DANN) to extract temporal information from the time-series data and learn the domain-invariant features, thereby successfully addressing the challenge of distribution shifts in data domains resulting from the different states of the systems is proposed in da Costa, Akçay, Zhang, and Kaymak (2020). Si, Hu, Chen, and Wang (2011) present an approach to predict RUL using a Wiener process with a nonlinear and time-dependant drift coefficient. It, in particular, involves designing a state-space model and using Bayesian filtering to update the drifting function parameter. The method is significant because of its potential application in online prediction, which is one of the critical requirements for such an RUL prediction framework. With different dynamics of the underlying system, determining the frequency of the updates is a critical task. L. Liu, Guo, Liu, and Peng (2019) introduce a data-driven framework for RUL prediction that integrates sensory anomaly detection and data recovery and improve RUL prediction by detecting sensory anomalies, recovering data, and using this recovered data for more accurate predictions. Huang, Xu, Wang, and Sun (2015) focus on addressing nonlinear degradation trajectories and heterogeneity in practical systems. They combine a nonlinear Wiener process with an adaptive drift feature. Y. Zhang, Yang, Xiu, Li, and Liu (2021) present an integrated technique that combines the Wiener process for degradation modeling and an LSTM network for forecasting degradation increments by learning the long-term dependencies of the offline degradation model and online observed degradation. Cheng et al. (2023) focus on predicting the RUL of the machinery under varying working conditions. Their proposed approach uses dynamic domain adaptation by integrating dynamic distribution and adversarial adaptation networks to predict RUL effectively. Pan, Li, and Wang (2022) propose combining LSTM and particle filter to predict the RUL for lithium-ion batteries under different stress conditions. They particularly leveraged transfer learning to update the LSTM model to ensure generalizability and then particle filter to capture the uncertainty. Siahpour, Li, and Lee (2022) introduce consistency-based regularization into the DANN training process. Consistency-based regularization helps to remove the negative impact of missing information. Sun et al. (2019) present a deep transfer learning network based on spare autoencoder. They incorporate three strategies — weight transfer, feature transfer learning, and weight update — to improve adaptability and prediction accuracy. Also, they showcased the network's capability to be trained on one tool and then being transferred to another tool under operation for online RUL prediction. The use of

bi-directional LSTM (BLSTM) neural networks and transfer learning for RUL estimation is explored in A. Zhang et al. (2018). They address the challenges of insufficient failure progression samples in data-driven prognostics by training the model on different but related datasets and then fine-tuning it with the real target domain dataset. J. Liu, Saxena, Goebel, Saha, and Wang (2010) present an adaptive recurrent neural network (ARNN) model for predicting the RUL of lithium-ion batteries. The model employs a dynamic state forecasting approach using a neural network architecture that adapts by optimizing the model's weights using the recursive Levenberg-Marquardt method.

1.3. Proposed Solution and Contributions

A better way to recalibrate model parameters to match model predictions to the newly observed data using Jacobian feature regression (JFR) is presented in Forgione et al. (2023). An RNN is used to model the dynamic system using available measurements. Then, as the system dynamics change, it causes the nominal model to be inaccurate for predicting the observed measurements in the presence of the perturbed system dynamics. The core idea of their approach is to adapt an existing RNN model, which was trained on data from a nominal system, to perturbed system dynamics, not by retraining the model from scratch, but by including an additive correction term to the nominal model's output. This correction term is designed to account for the discrepancies between the nominal system and the perturbed system. In other words, as an "unacceptable degradation of the nominal model performance" occurs, Forgione et al. (2023) propose a transfer learning approach to improve the performance of the nominal model in the presence of perturbed system dynamics, where the nominal model is augmented with additive correction terms that are trained on observed perturbed system data. These correction terms are learned through JFR "defined in terms of the features spanned by the model's Jacobian concerning its nominal parameters." Efficient model adaptation is achieved by using the JFR in the feature space defined by the Jacobian of the model with respect to its nominal parameters. Forgione et al. (2023) also propose a non-parametric view that uses the Gaussian process. This could be useful to provide flexibility and efficiency for very large networks or when only a few data points are available.

The contributions of this work are significant because they offer a more efficient and effective way to keep data-driven and hybrid models accurate when applied to dynamical systems that experience changes over time. We address some of the challenges described in Section 1.2 by building upon the method introduced in Forgione et al. (2023) as follows:

1. We present an automated approach to use adaptation techniques for predicting RUL while ensuring system-state-dependency of the models. Although JFR is used as the model-adaptation technique in this paper, JFR can be replaced by any other model-adaptation algorithm without any loss of generalizability.
2. We extend the implementation of JFR-based model adaptation to hybrid models that combine physics and data-driven models. This is important (and even necessary) as the representation of systems using data-driven models can become a bottleneck if the training data are limited, and there could be no guarantee that the data-driven models follows the physics of the system behaviors in all possible scenarios.
3. We highlight the lower carbon footprint of the JFR-based adaptation technique instead of retraining the model completely using the standard transfer learning.
4. We modify the offline adaptation approach into an online adaptation approach, which becomes critical to the PHM systems, especially in RUL prediction. To enable online adaptation, we use the anomaly detection output in order to trigger the model-adaptation.
5. Finally, we also discuss the application of our JFR-based model adaptation approach to assets relevant to the oil and gas industry. In particular, we discuss the results of applying the technique to a testbed that simulates a digital synthetic oilfield.

1.4. Organization

The remainder of this paper is organized as follows. Section 2 formulates the RUL prediction problem, and our approach to solve this. Section 3 includes the experimental setup and results, and finally, Section 4 concludes the paper and provides directions for future work.

2. Problem Setup and Approach

To set up the problem, let us denote a system by S, that typically takes in some inputs from discrete timesteps 1 to k, i.e., $\mathbf{x}_{1:k}$, and has measured outputs $\mathbf{y}_{1:k}$. Let us assume that M denotes a model representing this system S that takes in the same inputs $\mathbf{x}_{1:k}$ and outputs simulated measurements denoted by $\hat{\mathbf{y}}_{1:k}$. Due to differences between a model and reality, such as modeling error, and measurement noise, $\mathbf{y}_{1:k}$ and $\hat{\mathbf{y}}_{1:k}$ are seldom exactly the same, but a "good" model M would generate $\hat{\mathbf{y}}_{1:k}$ that is very close to the real outputs $\mathbf{y}_{1:k}$. We define a *threshold function* $T : \hat{\mathbf{y}}_\kappa \rightarrow \{\texttt{true}, \texttt{false}\}$ that partitions the operational state of the system into nonfailure and failure states based on observed measurements, such that $T(\mathbf{y}_\kappa)$ returns `true` when the system is in a failure state, and `false` otherwise. If the time of prediction is denoted by k_P, then typically, we define end-of-life (EOL) predicted at time k_p as $EOL(k_P) = \inf\{k' : k' \geq k_P \text{ and } T(\hat{\mathbf{y}}_k)\}$, and RUL at time k_P is defined as $RUL(k_P) = EOL(k_P) - k_P$. To make EOL and RUL predictions, the model M is fed hypothesized future inputs $\mathbf{x}_{k_P:\infty}$, also denoted by $\mathbf{x}_{future}$.

The model M can be defined/trained using model-based, data-

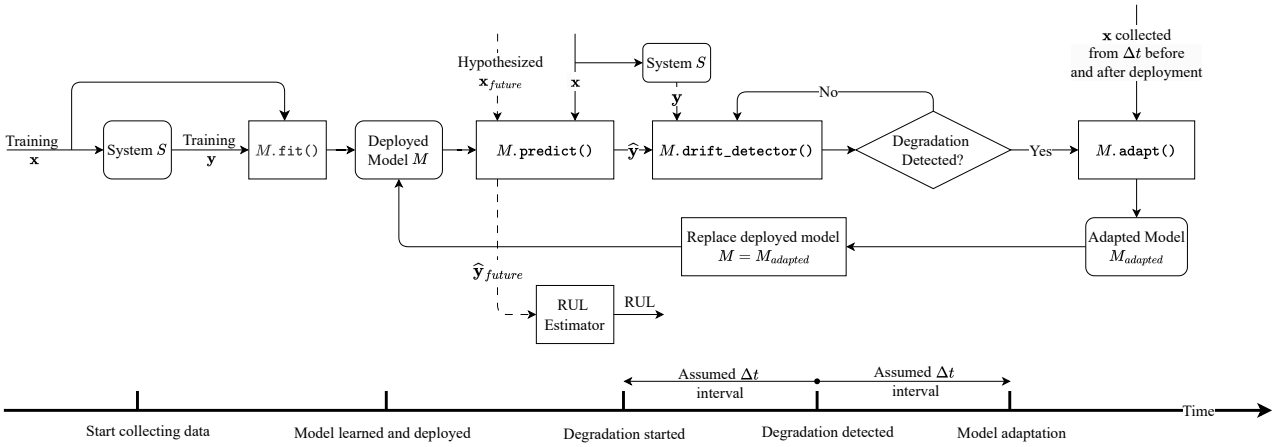

Figure 1. The workflow describing how the adaptation technique could adapt the model trained in the controlled setting (nominal model) to predict RUL after the degradation in the system is detected.

driven, or hybrid (model-based + data-driven) approaches. We use standard techniques to train or build such a model M and train it to the input-output signals using the $M.\texttt{fit()}$ algorithm. Typically nominal $\mathbf{x}$ and $\mathbf{y}$ combinations can be used to build M. Once the model is trained, it is deployed, and the $M.\texttt{predict()}$ algorithm passes new $\mathbf{x}$ through M to generate new predicted $\mathbf{y}$. $M.\texttt{predict()}$, when fed with hypothesized future inputs $\hat{\mathbf{x}}_{future}$, can predict estimated future outputs $\hat{\mathbf{y}}_{future}$ which is then fed to the RUL Estimator which passes $\hat{\mathbf{y}}_{future}$ through a threshold function T to compute the RUL of the system.

Now, ideally, if there is no degradation in the system, the M model would forever be able to correctly predict the future observations of the system. However, this is never the case as all engineered systems eventually encounter some sort of degradation or failure. Also, there is no guarantee that the operating conditions will remain constant throughout the system's life. One way to adapt to this changing system dynamics would be to retrain the model for every new pair of $\mathbf{x}$ and $\mathbf{y}$; however, that process is computationally wasteful. Hence, to intelligently call the model update, we develop and deploy an $M.\texttt{drift\_detector()}$ algorithm that compares the predictions from M, and the sensors obtained from the real system to see if there is a statistically significant drift between the predicted and observed sensors. If yes, then while there are many reasons for which this drift could occur, we attribute this drift to degradations in the system that are not captured by the deployed model M anymore, and the parameters of this model need to be re-calibrated or adapted to the newly observed sensors. If that is the case, then we call the $M.\texttt{adapt()}$ that helps us adapt the model to the new dynamics using the newly observed data. We denote this adapted model as $M_{adapted}$. In our case, the JFR-based model adaptation algorithm is used to adapt the model to new data observed. $M_{adapted}$ now replaces the model M, and the process continues until a significant deviation is *again* detected in the sensor readings predicted by M and the observed sensor readings from the system. Figure 1 presents an overview of the overall workflow.

As established, the data from the controlled environments could be used to configure and train different models that represent the system. Over time, as the system's behavior changes, the model becomes stale and its predictions are inconsistent with the system's behavior. As the system operates in real life, different measurements are collected and stored in some database. Using the designed approach, there are two choices for model adaptation.

Condition-Based Model Adaptation (CBMA): The data are continuously collected from the deployment environment in this setting. The model and the system are constantly monitored, and any kind of deviations are detected and tagged. If the deviation is above the threshold, all the past information collected before the deviation happens is used for adapting the model. It is an offline adaptation technique as not all the incoming information is directly used for adaptation. Rather the adaptation is triggered based on the output of anomaly detection. From an implementation perspective, for condition-based model adaptation, we use data from a window comprising of Δt time steps *before and after* the time at which degradation was detected, where Δt is a design choice. The timeline at the bottom of Figure 1 visually depicts this.

Continuous Model Adaptation (CMA): In this scheme of adaptation, there is no dependency on the anomaly detection process. As and when a new measurement is recorded it is used for adapting the model. This helps in the continuous utilization of the incoming information.

While both CBMA and CMA methods enable the efficient use of the incoming data to update the model continuously,

these two model adaptation methods have their pros and cons. Specifically, CMA requires high computing power as the models are continuously adapted. Furthermore, observing a single outlier can result in a deviation from the model's behavior, whereas it is not a persistent thing for the physical system. On the other hand, CBMA requires dependencies on the anomaly detectors and the storage systems where the data needed for model adaptation are stored. CBMA also enables us to quantify the model's behavior change which could be reflected based on the differences between the predictions of the nominal model that is trained using the data from a controlled setting, and the predictions of the adapted model that is adapted using incoming data predictions.

Our proposed adaptation approach can be used for either CMA or CBMA. Further, we have extended the offline model adaptation approach presented in Forgione et al. (2023) to hybrid models that represent the dynamics of a system by leveraging both first-principles domain knowledge and data-driven ML approaches. Karpatne, Watkins, Read, and Kumar (2017) presents physics-guided neural networks (PGNN), one such example of a hybrid modeling approach. PGNN uses the first principles model parallel to the data-driven components (e.g., RNNs). It could be helpful to directly use the first principle model even if it is not tuned and calibrated to the best quality. Such developed hybrid models for the specific systems could be further coupled with the adaptation technique to help us have a model that is always in close alignment with the physical system. A model that is always closely aligned with the physical system enables seamless deployment of different applications such as optimization, control, forecasting, prognostics and health management, automation, and decision-making, among others.

3. Experimental Setup and Results

Digital Synthetic Oilfield Testbed Setup: Our testbed's design is particularly chosen to mimic real-life oilfields. The test bed has three DC motor pumps attached to three flowmeters. Each DC motor pump pumps the water (used in place of oil) from the well to the eventual storage. The flowmeters measure the flow exiting the pumps. We also attached a fourth flowmeter to calculate the aggregated flow from the three pumps. Single and persistent faults are injected into each of the pumps to represent the loss of efficiency. The EOL condition for each pump is defined as the state when any pump's output flow dips below 0.15 units. The controllable input in the case of each pump is the pump speed, and the output measurement from the flowmeter would be the flow rate. Since the input voltage determines the pump speed, the voltage is considered the equivalent input variable for each of the pumps. Figure 2 represents the internal structure of the DC motor pump[1].

[1] https://ctms.engin.umich.edu/CTMS/?example=MotorSpeed\&section=SystemModeling

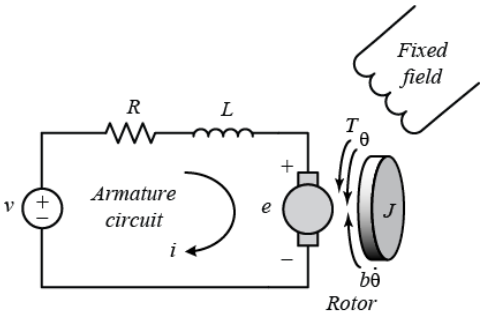

Figure 2. The electric equivalent circuit of a DC motor.

Based on the internal structure of each pump, the state-space model was designed for the testbed, considering the rotational speed and electric current as the state variables. After defining the established conditions to represent the system parameters, this state-space model for the testbed was used to simulate the operation of the three pumps in the oilfield. Equations (1a–1f) summarize the representation of this digital synthetic oilfield testbed. In this setup, (V_p for pump $p \in [1, 2, 3]$) represents the voltage and hence the controlled pump speed for each pump respectively (controllable inputs); ($y_p = \omega_p$, $p \in [1, 2, 3]$) represents the flow rate of each pump respectively (system measurements); and the hidden state variables include (ω_p, $p \in [1, 2, 3]$) that represents the angular momentum of each pump respectively, (i_p, $p \in [1, 2, 3]$) that represents the current drawn for each pump respectively. The inductance L_p, resistance R_p, and back electromotive force constant k_p for pump $p \in [1, 2, 3]$ are the system parameters.

$$\frac{d\omega_1}{dt} = \frac{1}{L_1}(V_1 - R_1 i_1 - k_1 \omega_1) \tag{1a}$$

$$\frac{di_1}{dt} = \frac{1}{J_1}(k_1 i_1 - B_1 \omega_1) \tag{1b}$$

$$\frac{d\omega_2}{dt} = \frac{1}{L_2}(V_2 - R_2 i_2 - k_2 \omega_2) \tag{1c}$$

$$\frac{di_2}{dt} = \frac{1}{J_2}(k_2 i_2 - B_2 \omega_2) \tag{1d}$$

$$\frac{d\omega_3}{dt} = \frac{1}{L_3}(V_3 - R_3 i_3 - k_3 \omega_3) \tag{1e}$$

$$\frac{di_3}{dt} = \frac{1}{J_3}(k_3 i_3 - B_3 \omega_3) \tag{1f}$$

There are multiple ways to model such systems. Neural state-space formulation is one such approach that could be used to model the system. This approach uses a couple of neural networks (NNs) to model state-transition and state-observation models. The same could be represented using Equations (2a–2b) where the function f represents the state-transition model and function g represents the state-observation model. In this neural state space formulation, once the model is trained, we

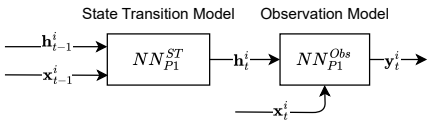

Figure 3. Schematic representation of neural state space model to model each component independently using just the inputs and hidden variable that affect it.

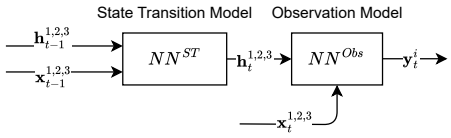

Figure 4. Schematic representation of neural state space model to model each component independently using all the inputs and hidden variables from the entire system.

utilize the forward Euler method to walk forward and make a closed-loop prediction for the next steps. Also note we are denoting the controllable inputs to the system by $\mathbf{x}$, the hidden state variables by $\mathbf{h}$, and the observed system measurements by $\mathbf{y}$. The subscript t represents the time step to which these values correspond.

$$\mathbf{h}_t = f(\mathbf{x}_{t-1}, \mathbf{h}_{t-1}) \tag{2a}$$
$$\mathbf{y}_t = g(\mathbf{x}_t, \mathbf{h}_t) \tag{2b}$$

Based on the described system for the testbed, we have a scenario where we have three pumps as the system's core components. For each of these three pumps, we have one controllable input and one measurement (output), and then internally, we have two state variables. Three major combinations were used for these different variables in our experiments. The summary and the description of why the particular selection was considered are described below.

1. One controllable input, one measurement, and three state variables: This setting enables us to represent each pump independently. Figure 3 represents this setting.
2. Three controllable inputs, one measurement, and seven state variables: In this setting, we model each pump's measurement independently but still consider all the input and underlying state variables. Figure 4 represents this setting. This enables us to consider all system dynamics together and learn the dependence of each pump's output on the entire system.
3. Three controllable inputs and three measurements: As shown in Figure 5, in this setting, we model the entire system using a single model that considers all the input variables and tries to learn the entire system by itself.

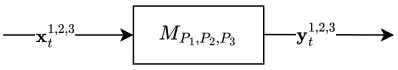

Figure 5. Schematic representation of the model when the entire system is modeled using the inputs and measurements.

In the first two settings, since we are able to use the available information for the state variables, the neural state space approach is used to model the system. There are existing approaches (e.g., Sheth, Roychoudhury, Chatar, and Celaya (2022)) that model the state-transition and state-observation function separately using two independent networks and in a joint setting where two networks are connected to each other. In this setting, these functions are represented using a NN. We also consider the measurement to be an unknown hidden state variable that needs to be estimated. In such a functional way, the state observation model becomes a passthrough function to select the state variable representing the measurement. Hence, the state-observation function could be omitted as represented in Equation 3. This particular method helps us condition the model in such a way that it has to produce the correct combination of the state variables as well as the measurement. By penalizing the wrong predictions, the model is regularized to adhere to the internal relations between state variables and the measurements. This could also be thought of as the state variables providing the regularization to the original model that is penalized for any sort of inconsistencies between the state variables and the measurement.

$$\mathbf{h}_t \cup \mathbf{y}_t = NN(\mathbf{x}_t, \mathbf{h}_{t-1}, \mathbf{y}_{t-1}) \tag{3}$$

The first two settings differ in the variables used by the NN to represent the state-space formulation. Equations 4 and 5 represent the two settings, respectively. The superscripted i represents the pump number to which different values correspond.

$$\mathbf{h}^i_t \cup \mathbf{y}^i_t = NN(\mathbf{x}^i_t, \mathbf{h}^i_{t-1}, \mathbf{y}^i_{t-1}); \quad i \in \{1,2,3\} \tag{4}$$

$$\mathbf{h}^i_t \cup \mathbf{y}^i_t = NN(\mathbf{x}^1_t, \mathbf{x}^2_t, \mathbf{x}^3_t, \mathbf{h}^1_{t-1}, \mathbf{h}^2_{t-1}, \mathbf{h}^3_{t-1}, \mathbf{y}^i_{t-1}); \quad i \in \{1,2,3\} \tag{5}$$

In the third setting, since the system is modeled as a whole, we utilize an LSTM network to model the system, and all the time dependence is captured through the LSTM network and can be represented as shown in Equation 6.

$$\mathbf{y}^1_t, \mathbf{y}^2_t, \mathbf{y}^3_t = LSTM(\mathbf{x}^1_t, \mathbf{x}^2_t, \mathbf{x}^3_t) \tag{6}$$

For all three settings, online and offline adaptation techniques have been integrated to adapt the model. Since the faults are injected independently into the pumps of the testbed, the summary table for the experimental results has four rows, one for the nominal setting and the remaining three for settings cor-

Table 1. Summary of experimental results (data-driven models). The metrics for all three pumps are shown separately under the columns for RMSE and R^2.

Scenario Number	Fault Setting	Number of Models	RMSE before Adaptation	RMSE after Adaptation	R^2 before Adaptation	R^2 after Adaptation
1	Nominal	3	[0.01, 0.01, 0.05]	-	[0.99, 0.99, 0.50]	-

	Fault in Pump 2	1	[0.01, 0.05, 0.01]	[0.01, 0.01, 0.01]	[0.96, -0.14, 0.7]	[0.99, 0.96, 0.97]
	Fault in Pump 3	1	[0.01, 0.02, 0.03]	[0.01, 0.01, 0.01]	[0.97, 0.95, 0.53]	[0.99, 0.99, 0.95]

Table 2. Summary of performance of physics-based model. The metrics for all three pumps are shown separately under the columns for RMSE and R^2.

System Setting	RMSE	R^2
Nominal	[0.04, 0.04, 0.01]	[0.81, 0.83, 0.99]

responding to the faults in three pumps, respectively.

Table 1 summarizes the results from the experiments to model the system, where each model's performance is evaluated using the root mean square error (RMSE) and R^2 metrics, where

$$\mathrm{RMSE} = \sqrt{\frac{\sum_{i=0}^{N-1}(y_i - \hat{y}_i)^2}{N}},$$

and

$$R^2 = 1 - \frac{\text{sum squared regression (SSR)}}{\text{total sum of squares (SST)}}.$$

For the sake of simplicity, the aggregated results from the online experiments are shown. Figure 6 shows the plots depicting the nominal model's prediction, predictions from the adapted model, and the actual system behavior when the fault was present in Pump 1. It also shows the threshold value, which could be used to predict RUL. Essentially, the time when the flow value for any pump goes below the threshold could be considered as the RUL for the system.

(Karpatne et al., 2017) introduced PGNN that enables us to couple the physics-based model with an NN. The core idea behind the coupling is to allow the NN to overcome the regions where the physics-based model might make errors because of the lack of generalizability introduced by the poorly estimated parameters. (Sheth et al., 2022) have successfully demonstrated the advantages of integrating the PGNN with neural state-space models. Figure 7 represents the original structure of the PGNN and Figure 8 represents the modified structure of PGNN for the neural state-space model as designed in (Sheth et al., 2022)

Inspired by these works and the ensuring need for the generalizability and scientific accuracy of the models representing the system, we have implemented all three scenarios using hybrid models that combine physics-based models with data-driven models. Since we designed the testbed, we can access the actual physics model used to collect the data. However, to mimic the scenarios we have in real life where the exact physics model is unavailable, we decided to use the functional form of the original physics model. We estimated the parameters after introducing some random noise to the recorded measurements. In doing so, we estimated the parameters of the physics model, which were not completely aligned with the underlying system model. This mimics the scenario of having a physics-based model that is not well-calibrated. Table 2 summarizes the performance of the physics-based model in the nominal setting.

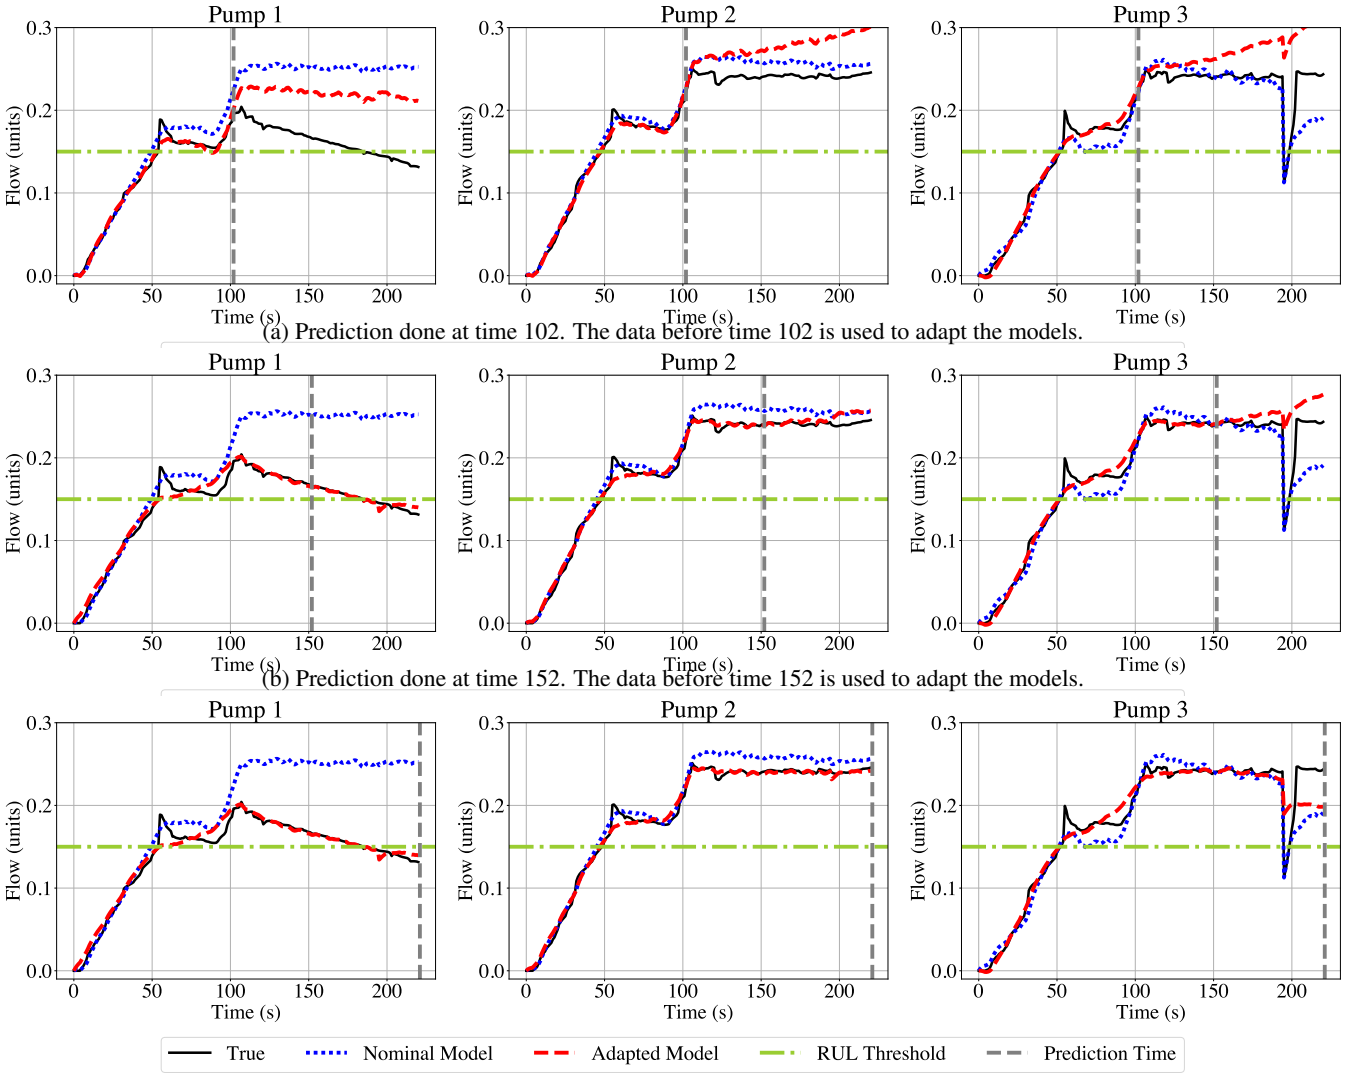
Based on the description of our neural state-space model and the PGNN architecture, there are two major ways in which the output from the physics model could be used:

1. Using the output estimate from the physics model as an input to the data-driven model. This strictly represents the PGNN architecture described in Figure 7. Figure 9 represents the same in our scenario.

2. Treating the output estimate from the physics model as one of the state-transition variables in the neural state-space formulation. This way, the output estimate from the physics model is integrated into the state-transition part of the neural state-space model. The output estimate from the physics model from the previous timestep is considered while predicting the actual output for the current timestep. Also, the model is penalized for pre-

Table 3. Summary of experimental results (physics-regularized data-driven models). The metrics for all three pumps are shown separately under the columns for RMSE and R^2.

System Setting	RMSE	RMSE after Adaptation	R^2	R^2 after adaptation
Nominal	[0.01, 0.02, 0.02]	-	[0.99, 0.94, 0.90]	-
Fault in Pump 1	[0.06, 0.02, 0.02]	[0.01, 0.01, 0.01]	[-0.71, 0.94, 0.90]	[0.98, 0.99, 0.99]
Fault in Pump 2	[0.01, 0.08, 0.02]	[0.01, 0.01, 0.01]	[0.99, -1.46, 0.90]	[0.99, 0.99, 0.99]
Fault in Pump 3	[0.01, 0.02, 0.06]	[0.01, 0.01, 0.02]	[0.99, 0.94, 0.38]	[0.99, 0.99, 0.90]



(a) Prediction done at time 102. The data before time 102 is used to adapt the models.

(b) Prediction done at time 152. The data before time 152 is used to adapt the models.

(c) Prediction done at time 221 (End of the simulation). The data before time 221 is used to adapt the models.

Figure 6. Flow estimates for the three pumps of the system representing the oilfield using the data from different timesteps to adapt the model. The blue dotted line represents the estimates from the nominal model, the red dashed line represents the estimates from the model after adaptation, and the black solid line represents the actual system behavior when the fault has been introduced in Pump 1. The green dashdot horizontal line represents the threshold that could be used to determine the RUL of the system. The vertical gray dashed line represents the present time till which the data from the system are observed.

dicting the wrong value for the output estimate from the physics model. Thus, the output estimate for the physics model works both as a signal for predicting the system's output from the model and provides a regularization effect for the model to be grounded to the physical relationships captured by the physics model. We refer to this set-

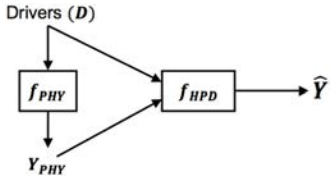


Figure 7. Structure of PGNN (Karpatne et al., 2017).

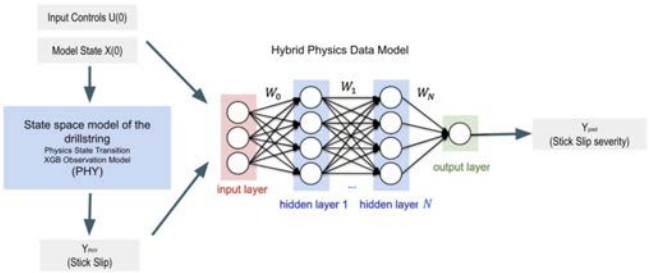

Figure 8. Schematic representation of PGNN for neural state-space model as shown in (Sheth et al., 2022).

ting as physics-regularized neural network (PRNN) and is shown in Figure 10. The predicted physics model estimate is compared with the actual physics model estimate. It is added to the loss function for training, and in the inference phase, we can ignore this output.

In our experiments, we evaluated both techniques and we coupled the physics model with the neural state-space models that we have for the second scenario. Table 3 summarizes the results from the experiments for the PRNN model corresponding to the second setup where the output of the physics model is used as a regularization condition. Figure 11 showcases the prediction estimates when the nominal version of the PRNN model is used for forward Euler simulation to generate the predictions for all timesteps in the closed loop setting and the prediction estimate for the same system state with the adapted PRNN model. Conducting experiments with PRNNs in this particular setting validates how the adaptation technique has been integrated into the neural state-space model, thus enabling the adaptation of hybrid models representing the system. Similar to the neural state-space model, the estimates of the physics-based model could be integrated into the list of controllable inputs for the LSTM model. When experiments for this particular setting were conducted, similar to the neural state-space model, positive results were obtained.

Based on the presented results in Table 1 and Figure 6, it is evident that the adaptation technique helps robustly adapt to the fault scenario. Further, it helps slightly reduce the errors due to the noise in measurements for the components without any faults, thus improving the overall prediction. Comparing the performance of the nominal model learned using the physics with the PRNN (first row of Table 2 and Table 3), it could be seen that the PRNN helps improve the performance over

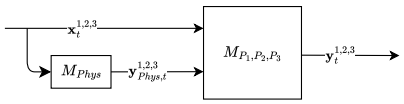

Figure 9. Schematic representation of PGNN for neural state-space model for our testbed.

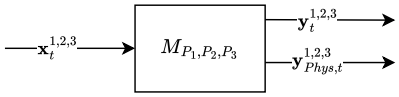

Figure 10. Schematic representation of PRNN for neural state-space model for our testbed.

the model learned just using the physics by eliminating the error resulting from the suboptimally estimated parameters from the physics-based model. Comparing the performance of the data-driven model and PRNN from Table 1 and Table 3, it could be observed that the PRNN model helps ensure the model follows the underlying physics and, hence, could help improve the performance of the data-driven model. The difference in the performance of nominal models for Pumps 1 and 2 between the data-driven model and PRNN is not significant due to the simplicity of the components. However, the improvement is evident in the case of Pump 3, which was set slightly differently to drop its performance instantaneously after 3 minutes and then behave normally again. In this case, the data-driven model's performance degrades as this noisy instance hurts the model's training. However, since the PRNN obtained the signal from the physics model, it was able to stay on track with the training process. Further, based on Table 3, and Figure 11, it is clear that the adaptation technique successfully adapts the learned PRNN model to faulty scenarios.

To estimate the amount of Carbon Dioxide (CO_2) produced by the cloud or personal computing resources used to execute the code, one may use the `Code Carbon`[2] library. It helps us track the carbon emissions for any computational process by considering the region where the machine is located, the amount of CPU and GPU consumed, the power used to run the particular process, and the overall machine's power consumption. By tracking all of this, the library can compute an estimate of the carbon intensity and energy consumption, thus resulting in the final number representing the CO_2 emissions.

Based on this library, Table 4 summarizes the power used as well as the CO_2 emissions in the process to train the model, retrain it using the standard transfer learning approach, and the adaptation of the model using the JFR method. For conducting this study, experiments were hosted to the Google Cloud Platform so as to have an accurate track of the compute resources as well as the carbon intensity. Using the local computer, the variables such as the particular power source

[2] `https://codecarbon.io/`

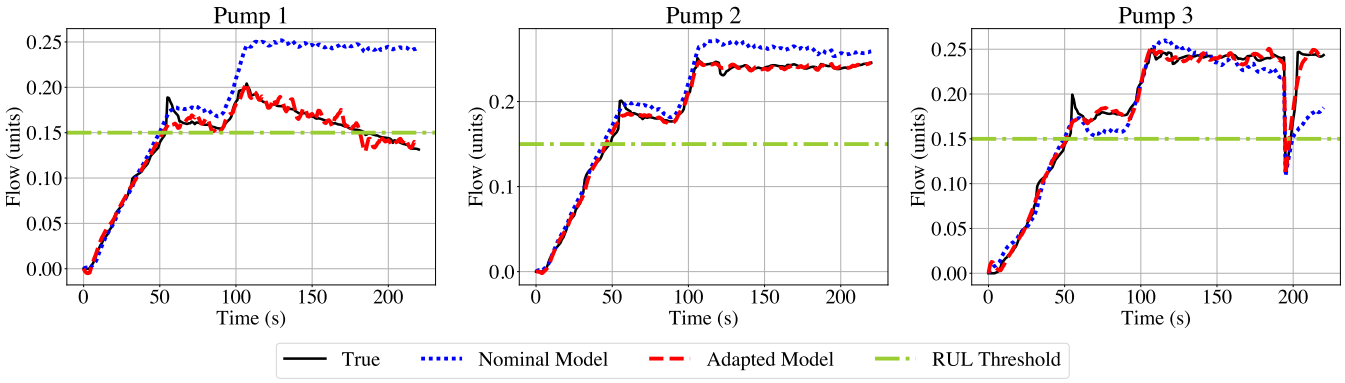

Figure 11. Flow estimates for the three pumps of the system representing the oilfield. The estimates are derived after running the forward Euler simulation on the PRNN model. The blue dotted line depicts the estimates derived using the model before adaptation (i.e.) in the nominal state. The red dashed line represents the estimates from the model after adaptation, and the black solid line represents the actual system behavior when the fault has been introduced in Pump 1. The green dashdot horizontal line represents the threshold that could be used to determine the RUL of the system.

being used and other local factors can skew the results.

Table 4. Summary of carbon emissions and power usage.

Phase	Carbon Emissions	Energy Consumed
Training	1.70×10^{-4}	2.84×10^{-3}
Retraining	1.70×10^{-4}	2.8×10^{-3}
Adaptation	1.37×10^{-6}	2.28×10^{-5}

From the results in Table 4, it is evident that the process of adaptation results in far lower levels of carbon emissions as well as less power usage. This is a clear advantage of using the adaptation technique instead of the standard retraining-based transfer learning as the carbon emissions are reduced, improving the sustainability aspects of the developed solution; the duration for which both processes are run is also much different where adaptation is approximately 10 times faster and uses far less computational resources.

4. Conclusions and Future Work

In this paper, we presented an automated online model adaptation framework for robust RUL prediction. We showcased the JFR-based adaptation technique to adapt the models representing the system for online RUL prediction and also extended this technique to adapt the hybrid ML approaches that provide robust system representation. The results indicate that this approach is much more computationally efficient than retraining a data-driven model based on standard transfer learning methods. In the future, we would like to continue modifying the algorithms to relax some of the assumptions. We would also like to extend this approach to switched hybrid systems that combine discrete modes along with continuous system dynamics in each discrete mode.

ABSTRACT

Remaining useful life (RUL) prediction of rolling element bearings is a complex task in the frame of condition monitoring which brings cost benefits to the industry by reducing unexpected downtimes and failures. Data-driven approaches based on deep learning have demonstrated exceptional performance in estimating RUL effectively. Nevertheless, challenges such as data scarcity for model training and varying operating conditions add more complexity to prognostic tasks using these methods. This study proposes a methodology for simulating the vibration signals during the degradation process of bearings in order to mitigate the need for historical data for training the models. Simulations are realized using a phenomenological model whose free parameters are adapted based on real measurements so that the simulated run-to-failure datasets are under the same influence of speed as the real dataset with almost the same degradation rate. The simulated dataset is used for model training. Moreover, the proposed methodology is able to react to the shaft speed and be flexible at the predictions when the speed of the bearing varies. The proposed model can take extra information regarding the operating speed and the sequential ordering of the measurements to be aware of the working conditions and the dynamics of the damage progression. The positive effect of the extra information is shown in the results. Model training is based on an unsupervised domain adaptation approach to reduce domain discrepancy between the simulated and real feature space. The effectiveness of the proposed method is examined according to bearing run-to-failure tests under varying operating conditions.

1. INTRODUCTION

Improving the accessibility of industrial assets is a crucial factor in boosting productivity and efficiency, leading to cost benefits for industries. This is achieved by exploiting the full life of components and avoiding premature replacements. Rolling element bearings, being the key component of rotary equipment in the industry, are prone to failures due to their frequent operation in harsh and demanding conditions, including high temperatures, heavy loads, and contaminated surroundings, which increase the possibility of unexpected failures. Failures could spread to the entire machine and lead to unplanned downtimes (Buzzoni et al., 2020; Tajiani & Vatn, 2023).

RUL estimation techniques can be employed to determine the remaining time until the failure occurs. Failure is defined as a state in which a health indicator crosses a predefined threshold such that the component is no longer able to operate in the desired way (Lei et al., 2018). Numerous methods can be employed to achieve this objective. However, data-driven approaches, particularly those based on deep learning, have recently demonstrated outstanding results due to their capability of modeling processes with high complexity like degradation process in bearings (Fink et al., 2020). The main bottleneck of using deep learning methods is the necessity of having a large amount of labeled pre-recorded run-to-failure data for training the models. This process is time-consuming, labor-intensive, and crucially, in industrial settings, failures may be infrequent, and maintenance is usually performed before failures (Arias Chao et al., 2022), which makes it hard to have a perfect dataset for training the models, since for model training, datasets should cover the whole life of bearings until the point of failure, and the degradation process is normally a long process that could take months or even years (Chen et al., 2023). Additionally, labeled data from

different bearings or machines operating under different conditions may be insufficient due to different deterioration trajectories and conditional probabilities. As a solution, leveraging simulated datasets for training deep learning models has surfaced as a practical approach to mitigate the constraints imposed by the limited availability of real labeled datasets. This approach enhances the overall performance of the models by providing a broader and more diverse set of training data (Hosseinli et al., 2023). Gryllias and Antoniadis (2012) generated artificial signals by a phenomenological model for different types of localized faults in bearings and then trained a Support Vector Machine (SVM) model using them. The real samples were then classified using the trained SVM model. Cui et al. (2020) proposed a method based on a 5-DOF dynamic model of bearings coupled with surface topography excitation to create a dictionary of many different degradation processes. Then, based on the similarity of the tested bearing and the simulated ones, the RUL of the tested bearing can be estimated based on the life label of the most matched sample. Deng et al. (2023) developed a 5-DOF dynamic model of bearings and generated a large amount of samples. Then, a particle filter-based dynamic calibration method was used to calibrate the parameters of the model based on observations. The simulated dataset was further used to train a deep learning model and estimate the RUL of real samples. Ai et al. (2023) utilized a phenomenological model to create a dataset for three types of fault: ball, inner race, and outer race for fault diagnosis. A deep learning model based on the transfer learning approach was then trained to remove the gap between the distributions of the real and simulated signals for fault classification of the real dataset.

Moreover, varying operating conditions, which can be seen in industrial cases such as wind turbines, servo motors, compressors, etc., pose another challenge for estimating the RUL of bearings. Developing a RUL prediction method that can respond to the operating conditions is of high importance since the developed models based on the assumption of steady operating conditions could not have satisfying performance under varying operating conditions (Chi et al., 2022; Liao & Tian, 2013). (Wang et al., 2021) developed a model-based method for RUL estimation by considering the joint dependency of degradation rate and time-varying operating conditions. The parameters of a system state function and an observation function were then estimated to model the degradation process of the system and predict the RUL of bearings. (Li et al., 2019) developed a state-space model for systems working under varying operating conditions. The model considered two effects of the varying operating conditions: changes in degradation rates and jumps in degradation signals. By estimating the underlying system state and the remaining time until it reaches a failure predefined threshold, the RUL of tested bearings was estimated. Zhang et al. (2022) proposed a normalization method that recalibrates the upward and downward abrupt jumps of sensor readings at the operational conditions change points. Then, the normalized sensor features and operating condition features were fed to a gated recurrent unit (GRU) to estimate the RUL of the aircraft turbofan engine dataset provided by NASA.

Motivated by the observation that the literature lacks a comprehensive exploration of RUL estimation under varying operating conditions using deep learning, in this paper, the proposed methodology consists of different steps including data simulation as a way of mitigating the influence of data scarcity and then a deep learning model based on a domain adaptation approach which gets the raw vibration signals as input as well as supplementary information on working conditions in which the signals are acquired in order to make the model aware of varying operating conditions. The rest of the paper can be summarized as follows:

1. Utilize a phenomenological model that simulates the general vibration signals of the bearings under different fault modes: ball, inner race, and outer race defects.
2. Adapt the phenomenological model based on the healthy real signals to tune the dynamic parameters of the model and also identify the effect of varying speed conditions on the amplitude of vibration signals.
3. Separate the effect of speed from the peak-to-peak health indicator so that it only indicates the degradation process which is void of the influence of speed and realizing anomaly detection based on this new health indicator (normalized peak-to-peak).
4. Realize curve-fitting on the normalized peak-to-peak after the anomaly to find out how fast the damage is progressing and then generate many synthetic run-to-failure data under the same influence of speed and damage progression as the real data to create a big training dataset for training a deep learning model.
5. Train a deep learning model according to the domain adversarial method to decrease the discrepancy between the unlabeled real data and the labeled simulated data. The deep learning model takes two additional inputs: speed information and sequence information in order to better understand the working conditions and the sequential relationship between each measurement.
6. Estimate the RUL of the real measurements using the trained deep-learning model.

In other words, the proposed methodology, as shown in Figure 1, is a digital twin (DT) that requires no historical data and is able to adapt itself to different rotating speeds, fault modes, and degradation rates of bearings.

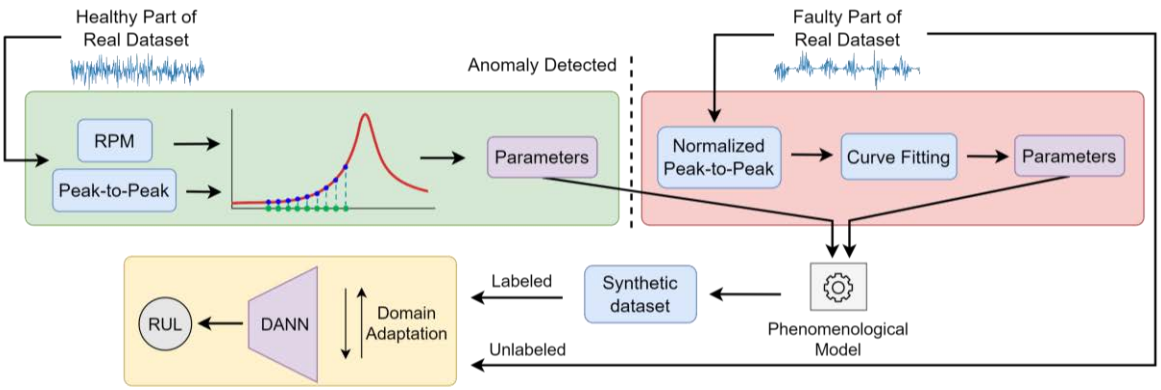

Figure 1. Pipeline of the proposed methodology

Peak-to-peak values are used here as a reference health indicator to tune the digital twin, since the EoL criterion is assumed to be defined on the peak-to-peak, and the synthetic dataset needs to be created under the same definition as the real dataset's EoL to be able to mimic historical datasets for training. Moreover, a few unlabeled real data that comes after the anomaly detection are used for unsupervised domain adaptation. They are unlabeled because their corresponding RULs are not known at this stage.

The rest of the paper is organized as follows. First, the fundamental theoretical background used in the proposed methodology is shortly introduced in Section 2. Moreover, the proposed approach to adapt the DT and predict the RUL is introduced in Section 3. Furthermore, a run-to-failure dataset captured under varying speed operating conditions is presented in Section 4, the methodology is applied, and the effectiveness of the proposed approach is demonstrated. Finally, Section 5 provides the conclusion of the paper.

2. THEORETICAL BACKGROUND

2.1. Phenomenological model

The phenomenological simulation of bearing vibration signals involves replicating the actual vibration signals of a real bearing. The simulation method achieves this by comparing the entire bearing and its supporting structure to a single-degree-of-freedom (SDOF) vibration system and introducing consecutive impulses to excite the structure, mirroring the effects of localized faults within the bearing. This approach allows for a representation that emulates the characteristics of real-world bearing vibration signals. The initial idea was proposed by McFadden and Smith (1984) and then it was improved by Antoni (2007) in order to have a more realistic spectral analysis. The simulated vibration signal can be generated by the following formula:

$$x_k(t) = S(k)\,.\,D(k)\sum_{i=-\infty}^{+\infty} h(t - iT - \tau_i)q(iT)A_i + n(t) \qquad (1)$$

where $S(k)$ and $D(k)$ are the amplitude modifiers regarding the speed and damage influence on the amplitude of the signals, respectively, for the k-th simulated signal in a degradation process. $h(t)$ is the impulse response of the equivalent SDOF system. T is the time between two consecutive impacts. i is the index of the i-th impact due to the fault, $n(t)$ accounts for the possible noise presented in the signals, and q is the amplitude modulating function due to the load distribution. A and τ are the parameters in order to take into account the randomness of the impact intensities and the moments that the impacts occur, respectively. According to (Antoni, 2007):

$$E\{\tau_i\tau_j\} = \delta_{ij}\sigma_\tau^2$$
$$E\{A_i^2\} = 1 + \delta_{ij}\sigma_A^2 \qquad (2)$$

where σ_τ and σ_A are the standard deviations, and δ_{ij} is the Kronecker symbol. The time period between two consecutive impacts depends on the rotational speed of the inner race of the bearing, and the mean value of the time interval ΔT is expressed by:

$$E\{\Delta T\} = \frac{E\{\Delta\theta\}}{2\pi f_r} \qquad (3)$$

where f_r is the inner race rotational speed and $\Delta\theta$ is the angular distance between two consecutive impacts which its mean value is expressed by:

$$E\{\Delta\theta\} = \frac{2\pi}{O_{imp}} \qquad (4)$$

where O_{imp} is the characteristic fault order, and it is defined as follows for different types of faults:

$$\begin{aligned}
&\text{Outer race} && \frac{n}{2}\left(1 - \frac{d}{D}\cos(\beta)\right)\\
&\text{Inner race} && \frac{n}{2}\left(1 + \frac{d}{D}\cos(\beta)\right)\\
&\text{Rolling element} && \frac{D}{2d}\left(1 - \left(\frac{d}{D}\cos(\beta)\right)^2\right)\\
&\text{Cage} && \frac{1}{2}\left(1 - \frac{d}{D}\cos(\beta)\right)
\end{aligned} \qquad (5)$$

where n is the number of rolling elements in the bearing, D is the pitch circle diameter, d is the bearing roller diameter and β represents the contact angle.

2.2. Domain adaptation

Acknowledging that simulated signals are derived from a simplistic model, incapable of capturing all aspects of faulty bearings or the degradation process, a distribution mismatch between real and simulated signals arises. This mismatch poses challenges in generalization when deploying trained models on real datasets. To tackle this issue, a domain adaptation method is employed to enhance generalization by transferring knowledge acquired from the source domain $\mathcal{D}_S$, where simulated signals originate, to the target domain $\mathcal{D}_T$, representing real-world datasets (Pan & Yang, 2010). This facilitates improved performance and adaptability of trained models. In this case, the marginal probability distributions of source and target domains, $P(x_S)$ and $P(x_T)$, are assumed to be different due to the simplicity of the simulations, but their conditional probability distributions, $P(y_S|x_S)$ and $P(y_T|x_T)$, are assumed to be the same due to the fact that in the preprocessing steps, the digital twin is tuned based on the real data in terms of the type of fault, the influence of speed, and the dynamic characteristics of the bearing.

This paper employs a Domain Adversarial Neural Network (DANN) to tackle the abovementioned domain shift problem. The network, illustrated in Figure 1, comprises three key components: a feature extractor G_f a domain classifier G_d, and a label predictor or regressor G_r. The feature extractor G_f is typically a deep neural network responsible for learning high-level representations from input data. It transforms input samples into a latent representation encoding valuable features for subsequent layers. The domain classifier G_d is another neural network component that predicts the domain of input samples based on extracted features, aiming to differentiate between the source and target domains. During training, the domain classifier seeks to maximize its accuracy, while the feature extractor aims to minimize this accuracy by gradient reversal. This adversarial training process results in the domain classifier being unable to distinguish features from different domains, indicating that the feature extractor can extract domain-invariant features. Additionally, the label predictor or regressor layer G_r utilizes these domain-invariant features to estimate the output, contributing to the overall goal of addressing the domain shift problem (Ganin et al., 2016). The objective function of the model is:

$$\mathcal{L}(\theta_f,\theta_r,\theta_d) = \frac{1}{n}\sum_{i=1}^{n}\mathcal{L}_r^i(\theta_f,\theta_r) - \lambda\left(\frac{1}{n}\sum_{i=1}^{n}\mathcal{L}_d^i(\theta_f,\theta_d) + \frac{1}{n'}\sum_{i=n+1}^{N}\mathcal{L}_d^i(\theta_f,\theta_d)\right) \quad (6)$$

where n and n' are the number of samples presented in the source domain and the target domain datasets respectively, and λ is a hyperparameter that controls the trade-off between the regression loss and the domain adversarial loss during training. $\mathcal{L}_r$ and $\mathcal{L}_d$ are defined as:

$$\mathcal{L}_r^i(\theta_f,\theta_r) = \mathcal{L}_r\big(G_r\big(G_f(x_i;\theta_f);\theta_r\big),y_i\big)$$
$$\mathcal{L}_d^i(\theta_f,\theta_d) = \mathcal{L}_d\big(G_d\big(G_f(x_i;\theta_f);\theta_d\big),d_i\big) \quad (7)$$

where θ_f, θ_r, and θ_d are the trainable parameters of the G_f, G_r, and G_d respectively.

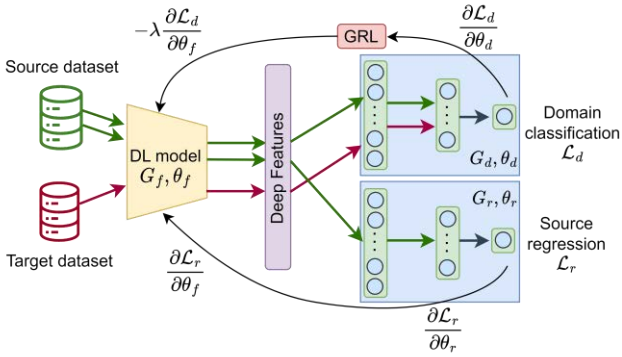

Figure 2. DANN architecture for regression task

3. Proposed Approach

To create a synthetic run-to-failure dataset by the digital twin, at first the dynamic characteristics of the phenomenological model should be tuned based on the real data. Then, the modifier functions $S(k)$ and $D(k)$, introduced in Section 2, are determined.

3.1. Dynamic characteristics

Given the fact that rolling element bearings vibrate even in healthy conditions due to the waviness of the surfaces and other sources of imperfections (Harsha et al., 2003; Jawad & Jaber, 2022), the resonance frequency of the structure can still be seen in the frequency content of the vibration signals (Ghafari et al., 2010). Therefore, by considering the Fast Fourier Transform (FFT) of the healthy signals, the dominant natural frequency of the structure, ω_n, can be found and then used in the phenomenological model as an equivalent SDOF system. Moreover, the logarithmic decrement can be used to see at which rate the amplitude of the impact responses, x, in real measurements is decreasing in order to determine ζ.

$$h(t) = e^{-\zeta\omega_n t}\sin\left(\sqrt{1-\zeta^2}\omega_n t\right)$$
$$\zeta = \frac{\delta}{\sqrt{4\pi^2+\delta^2}} \quad (8)$$
$$\delta = ln\left|\frac{x_1}{x_2}\right|$$

3.2. Influence of speed, $S(k)$

The real signals before the detection of the anomaly can be used to recognize the influence of speed on the amplitude of the vibration signals. Figure 3 (a) shows a speed profile and its effect on the peak-to-peak amplitude of the vibration. The important point here is to consider the possibility of the structure resonance when speed is varying. In other words, increasing speed does not necessarily result in an increasing amplitude. Figures 3 (b) and (c) show two possible behaviors that can be seen in speed-varying scenarios. Increasing amplitude with increasing speed can be a sign of crossing no resonance frequency in that specific speed range (Salunkhe & Desavale, 2021).

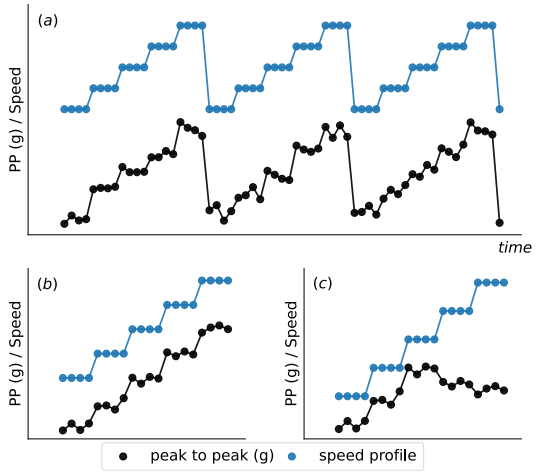

Figure 3. (a) Varying speed effect on the peak-to-peak amplitude of the signals, (b) in case of no resonance crossing, (c) in case of crossing a resonance frequency

Corresponding to each operating speed, a constant parameter c can be found to create a link between the rotating speed and the vibration amplitude or the peak-to-peak:

$$P_j = c_j \,.\, rpm_j \tag{9}$$

where P is the peak-to-peak of real signals, c is a constant parameter, rpm is the operating speed, and j is the index of measurements. In this way, any non-linearity between speed and vibration due to the frequency response of the structure can be captured (Figure 4).

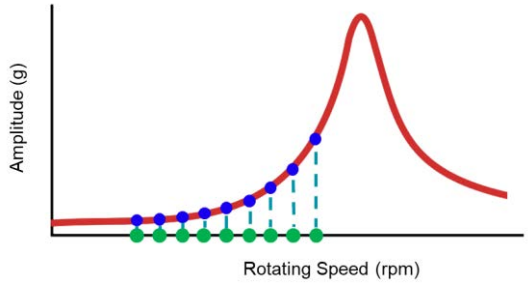

Figure 4. Capturing the complex relationship between speed and vibration amplitude in real measurements

It should be noted that these analyses must be done based on a few measurements at the beginning of the operation of the machine to be far from the influence of bearing faults. After the detection of the anomaly, when the synthetic run-to-failure dataset should be created, a speed profile should also be provided so that the digital twin can generate signals accordingly. Since a random speed profile might be desired at this stage, an interpolation would be needed to find the correct value of c while dealing with unseen speed values. Then, the modifier function $S(k)$ in equation 1 will be:

$$S(k) = c_k \,.\, rpm_k \tag{10}$$

3.3. Normalized health indicator

By knowing the relation between speed and vibration, the effect of speed can be removed from the peak-to-peak amplitude of the vibration signals by equation 11, meaning that any changes in the health indicator that are not associated with speed can manifest itself more clearly. This method will be used to find anomalies. The Normalized peak-to-peak amplitude, P_N, is constructed as follows:

$$P_{N,j} = \frac{P_j}{c_j \,.\, rpm_j} \tag{11}$$

Obviously, for the healthy samples before the detection of the anomaly, $P_N \sim 1$. Figure 5 (b) shows the normalized peak-to-peak amplitude whose mean and standard deviation in the time interval $[t_0, t_1]$, which is at the beginning of the measurements, can be used as the threshold for anomaly detection. $K_{anomaly}$ is used to refer to the k-th signal in the degradation process where the anomaly occurs. As shown in Figure 5 (b), the fluctuations caused by the varying speed profile no longer exist in the normalized peak-to-peak amplitude.

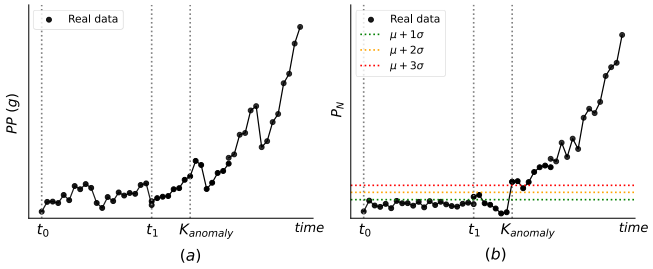

Figure 5. (a) Peak-to-peak amplitude of real data, (b) anomaly detection by the normalized peak-to-peak

3.4. Influence of damage, $D(k)$

After the anomaly, a limited number of signals will be used for curve fitting in order to estimate the degradation rate of the real bearing so that the digital twin will be able to generate a synthetic run-to-failure dataset with almost the same degradation rate as the real bearing. As shown in Figure 6 (a), curve fitting is done based on the normalized peak-to-peak

amplitude because the effect of speed has been removed, and it is only the degradation process that plays a role. The modifier function $D(k)$ in equation 1 can be modeled by an exponential function to approximate the degradation trajectory of the normalized peak-to-peak amplitude:

$$D(k) = e^{a(k-K_{anomaly})} \tag{12}$$

where a is a constant parameter that defines the degradation rate. By introducing slight variations in the parameter a in function $D(k)$, various degradation trajectories can be built in order to have a big synthetic run-to-failure dataset. The variations are such that the time difference between the synthetic EoLs is limited to the *Simulation range* as shown in Figure 6 (b). This figure shows the typical degradation trajectories of the peak-to-peak amplitude of the synthetic dataset generated by equation 1. Domain adaptation is also done using a few real unlabeled available measurements after the detection of the anomaly.

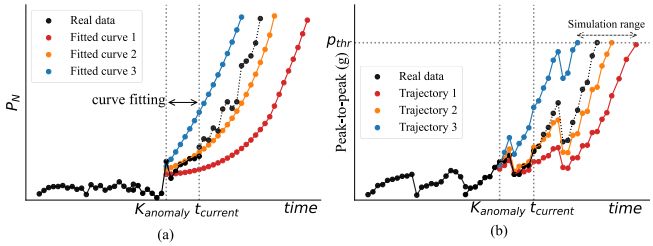

Figure 6. (a) Curve fitting according to the normalized peak-to-peak amplitude, (b) peak-to-peak amplitude of the synthetic dataset

3.5. Encoding

In order to encode the speed and sequence label of each measurement, which will be fed into the deep learning model, this paper adopted one of the well-known methods of information encoding from the natural language processing (NLP) research domain. Positional encodings are used to make the transformers aware of the relative or absolute order of the words inside a sentence (Vaswani et al., 2017). To encode the positional information, *sine* and *cosine* functions with different frequencies can be used:

$$PE_{(pos,2i)} = sin\left(\frac{pos}{10000^{2i/d_{model}}}\right)$$
$$PE_{(pos,2i+1)} = cos\left(\frac{pos}{10000^{2i/d_{model}}}\right) \tag{13}$$

where pos is the position of the word, d_{model} is the dimension of the word embeddings, and i represents the dimension of the positional encoding. Unique encoding for each position is achieved by using *sine* and *cosine* functions with varying frequencies, making the model able to distinguish the sequential order of measurements. It is important to highlight that each positional encoding with offset k, PE_{pos+k} can be described as a linear function of the positional encodings PE_{pos}, this characteristic enables the model to readily learn the relative dependencies between different positions, contributing to the model's ability to capture sequential information and relationships effectively (Vaswani et al., 2017).

The concept of positional encoding can be transferred to the prognosis research domain. The sequential order of vibration signals obtained from a bearing holds significant importance in prognosis, serving as an indicator of how the damage progresses over time. Moreover, equation 13 can be utilized for encoding speed information. While this encoding method might lack a direct physical interpretation, it serves the purpose of making the neural network aware of distinctions among vibration signals working in different conditions. Each operating condition should have a unique encoding by which the raw vibration signals are accompanied while feeding to the model. d_{model} is a hyperparameter that will be determined in section 4.1, and the value of pos is an integer number that starts from 1, representing the sequential order of each measurement. The same way is followed to encode the speed information. For example, $pos = 1$ is used for the lowest rotational speed. For each pos, the value of i starts from 0 and ends in $\frac{d_{model}}{2}$, forming a vector of length d_{model}. For each i there are two values, one from $sine$ function and the other from $cosine$ function. For example, the encoding for $pos = 1$ is $[PE_{(1,0)}, PE_{(1,1)}, \dots, PE_{(1,d_{model}-1)}]$ which is a one-dimensional vector.

3.6. RUL curve for varying speed scenario

One of the most important outcomes of the proposed methodology is to see how the speed is influencing the RUL. Obviously, for higher speeds, lower RUL is expected, and vice versa. To the best knowledge of the authors, no paper has taken into account the effect of speed on the RUL curve.

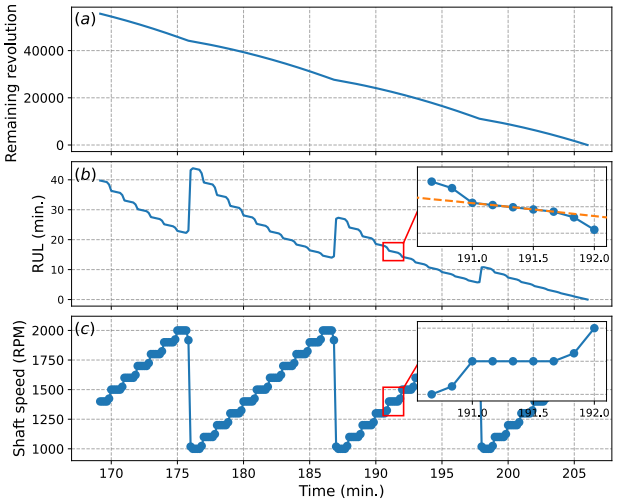

Figure 7. (a), (b) Remaining revolutions and remaining time after the detection of anomaly, (c) the corresponding speed profile

The proposed idea is to estimate the remaining revolutions until the end-of-life, and in the post-processing step, the number of revolutions can be transferred to the remaining time by simply dividing it by the operating speed. Figure 7 shows the remaining revolutions and the RUL for a measurement campaign which has been done under varying speed operating conditions. Equation 14 is used to calculate the total number of revolutions after the detection of anomaly which are then used as the labels in the model training.

$$Rev_{Total} = \sum_{i=K_{anomaly}}^{N} rpm_i . \Delta t$$

$$Rev_n = Rev_{Total} - \sum_{i=1}^{n} rpm_{i+K_{anomaly}} . \Delta t \qquad (14)$$

$$RUL_n = \frac{Rev_n}{rpm_{n+K_{anomaly}}}$$

where Rev_{Total} is the total number of revolutions after the detection of anomaly, N is the number of samples in the run-to-failure experiment, Δt is the length of each measurement. Rev_n and RUL_n are the remaining revolutions and the remaining time until the end-of-life for the n-th sample, respectively. Rev_n is used as the labels for model training.

The important point is that the slope of the RUL curve is -1 as long as the speed is constant, as shown in Figure 7 (b) by the orange line, preserving the most useful property of the RUL curve.

3.7. Deep-learning model

As mentioned in Section 2.2, a deep learning model based on the DANN model is used to estimate the RUL of the real bearings. Two supplementary information, speed and sequential ordering of the measurements, have been encoded and will be fed to the model as extra inputs in addition to the raw vibration signal. As shown in Figure 8, Convolutional Neural Network (CNN) is used to extract the local information and deep features automatically from the raw vibration signals. The extracted features are concatenated by two encoded inputs to form a bigger 1-D vector which is followed by two parallel Fully Connected (FC) layers, a domain discriminator, and a source regressor. The loss function of the regressor part is the mean squared error and the loss function of the discriminator part is the binary cross entropy which is expressed as follows:

$$\mathcal{L}_d = -y . log(\bar{y}) - (1 - y) . log(1 - \bar{y}) \qquad (15)$$

where $y \in \{0, 1\}$ is the domain label and $\bar{y}$ is the predicted value between 0 and 1. Table 1 and Table 2 show the network parameters in detail. As depicted in Figure 8, the gradient reversal layer (GRL) with the trade-off parameter $\lambda = 0.1$ is also added as the first layer of the discriminator part to reverse the gradient in the backpropagation process.

Table 1. Network parameters of the feature extractor

Layer	Type	Filter/ Kernel/Stride	Activation function
1	1D CNN	4/128/16	ReLU
2	Max Pooling	-/8/8	-
3	1D CNN	16/16/8	ReLU
4	Max Pooling	-/8/8	-

Table 2. FC parameters in the regressor and the discriminator

Regressor part		Discriminator part	
Layer	Units/Activation function	Layer	Units/Activation function
1	64/ ReLU	1	64/ ReLU
2	32/ ReLU	2	32/ ReLU
3	1/ ReLU	3	1/sigmoid

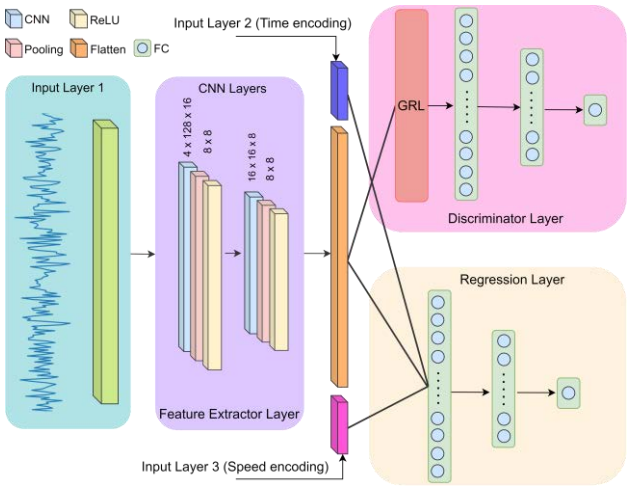

Figure 8. The architecture of the proposed model

It is important to emphasize that the length of the input signal must be sufficiently long to encompass an adequate number of impacts resulting from faults in the bearing. Notably, the number of impacts due to a ball defect in one revolution of the shaft is lower compared to other types of faults. Using equation 16, the number of data points needed to cover at least 1 impact due to the ball defect can be calculated. This number will cover more than one impact if a different type of defect is present at any speed (Hosseinli et al., 2023).

$$L_c = \frac{F_S}{BSF} \qquad (16)$$

where L_c is the critical length of the signal, BSF is the ball spin frequency at the lowest shaft speed, and F_S is the sampling frequency.

4. Application of the Methodology and Results

4.1. Case study

Smart Maintenance (SM) dataset provided by Flanders Make (Ooijevaar et al., 2019) consists of accelerated life tests where indentations were deliberately created on the inner races (IR) of bearings using a Rockwell-C indenter with a force of 100 kg before the tests started to run. The radial load is 9 kN and the rotational speed follows a periodic stepwise profile starting from 1000 rpm to 2000 rpm, each step is 100 rpm and is maintained for 60 seconds. The type of test bearings is 6205-C-TVH from FAG. The sampling rate frequency is 50 kHz, and a peak-to-peak amplitude of 15g is considered the end-of-life criterion in this study. Figure 9 shows the peak-to-peak amplitude and the speed profile of one of the measurement campaigns. Table 3 shows the specifications of all the bearings used in this study.

Table 3. Bearing information in the SM dataset

Bearing	Test duration	Anomaly detected at	Fault
A148	142.5 min.	112.6 min.	IR
A150	197.5 min.	169.1 min.	IR
A153	229.3 min.	207.8 min.	IR
A154	126.0 min.	98.8 min.	IR
A155	369.3 min.	348.6 min.	IR
A156	251.3 min.	224.0 min.	IR

Referring to equation 16, a signal of 25000 data points is set as the input to make sure that at least 20 impacts will be covered in the critical scenario for the Smart Maintenance dataset. The length of the encodings, d_{model} in equation 13, should be kept lower than the length of the deep features after the Flatten layer. This ensures that subsequent layers can effectively learn the deep features by maintaining a lower dimensionality for these encodings compared to the deep features, the model can efficiently process and integrate additional information without overwhelming the learning process or introducing unnecessary complexity. For the architecture described in Table 1, the length of the deep features for the input length of 25000 is 112.

Table 4. Length of the inputs of the proposed architecture

Input No.	Length
Input 1 (raw signal)	25000
Input 2 (time encoding)	24
Input 3 (speed encoding)	24

4.2. Results and discussions

Before the anomaly occurs, the relation between speed and vibration amplitude is analyzed. After the anomaly, curve fitting is done based on the available data, as shown in Figure 12. 10 minutes of measurements are used at this stage. This few unlabeled available real data is also used for domain adaptation while model training. It should be highlighted that the unlabeled past samples will be labeled in the inference stage. Despite the passage of time, labeling the past samples is still valuable, since it indicates what were the predictions from a few moments ago which can be used for decision-making. Figure 10 shows the result of anomaly detection and the corresponding speed profile for bearing A148.

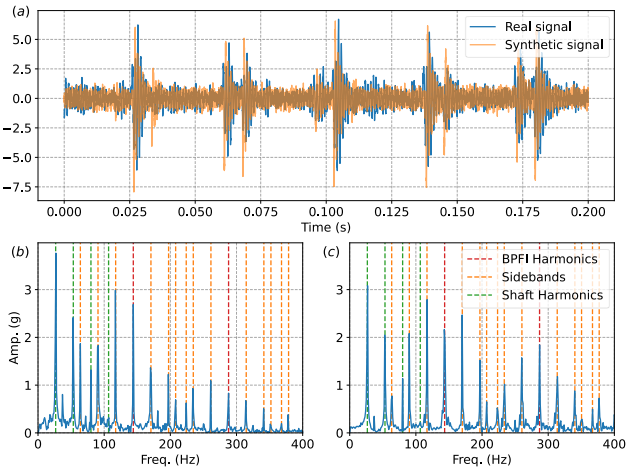

Figure 11. Bearing A148; (a) Comparison between the real and generated signals, (b) envelope spectrum of the real signal, (c) generated signal

Figure 11 shows one of the examples of the generated signals for bearing A148 after the anomaly. The results of the proposed method for anomaly detection are mentioned in Table 3.

After adapting the digital twin in terms of the speed influence and degradation rate, 6 trajectories are generated as shown in Figure 12. Their corresponding raw vibration signals will be the input of the deep learning model for training. The *Simulation range* is chosen to be 40 minutes. The synthetic run-to-failure dataset is used to train 5 models. A simple CNN model that neither includes the discriminator part of the architecture nor encodings, a DANN model without encodings, proposed model 1 with CNN and only speed encodings, proposed model 2 with CNN and only sequence encodings, and proposed model 3 with DANN and both speed and sequence encodings. Table 5 shows the superior performance of the proposed model 3 which in all cases can improve the root mean squared error, RMSE, of the RUL predictions compared to the DANN and CNN model. As discussed before, the important point of feeding the operating condition and the sequential information to the models is to make the model aware of the working environment and any other information that influences the physical behavior of the assets. This fact is perfectly shown in Figure 13 where by using the t-distributed stochastic neighbor embedding (t-SNE) technique the feature distribution of the second to the last fully connected layer in the regressor part of the proposed model is visualized. This layer outputs a 32-dimensional feature space that t-SNE can reduce the dimension to a lower one such as a 2-dimensional feature space which is easier to visualize. Figure 13 shows how the extra information fed to the model helps to distinguish between different speeds, resulting in better predictions. More importantly, supplementary information fed to the model makes the model more robust against the major changes in the speed profile. For example, bearing A156 underwent two major changes in operating speed after the detection of the anomaly. As depicted in Figure 14, abrupt speed changes from 2000 rpm to 1000 rpm in a short time interval led the CNN and DANN models to have a higher error in the predictions. Proving that these models have less control over the predictions when speed plays an impactful role. The proposed model makes satisfying predictions at the moment of abrupt speed changes and the predicted RUL is not too far from the ground truth, showing that the proposed model understands the relationship between rotating speed, vibration, and degradation severity thanks to the encodings. Most importantly, the estimated RUL is reactive to the operating speed. Higher speeds lead to lower RUL and vice versa. This property of the proposed method makes it applicable to real industrial cases where a varying speed profile is used.

5. Conclusion

The objective of this study is to create a digital twin based on the simple physical knowledge of the fault progression phenomena. Utilizing a phenomenological model to generate synthetic signals helps to have a big synthetic run-to-failure dataset under varying speed operating conditions for training the machine learning models. On the other hand, leveraging the phenomenological model and simulated signals enhances the cost-effectiveness of the proposed approach by minimizing the reliance on historical run-to-failure datasets. The proposed methodology shows how the synthetic dataset should be adapted while facing varying speed scenarios. Additionally, the proposed model facilitates the integration of supplementary information regarding the working conditions and sequential ordering of measurements in a deep-learning model for prognosis and demonstrates that using extra information in the architecture of the DANN model enables the model to gain knowledge about both the operating conditions and the dynamics of damage progression. Moreover, a few unlabeled measurements from the real dataset after anomaly are used for domain adaptation in an adversarial way to reduce the gap between the feature distribution of the real and simulated dataset. Encoding the extra information, despite the lack of physical meaning, can aid the network in distinguishing signals from different operating conditions and identifying their relative relationships. Experimental results on the SM dataset demonstrate that the proposed model achieves improved RUL estimation accuracy, particularly in scenarios involving abrupt speed changes, and delivers more reliable predictions. The estimated RUL can also react to the operating speed which is a must in prognosis and decision making. Thanks to the t-SNE technique, the model's ability to discriminate between different operating conditions has been validated. The flexibility of the proposed method in recognizing the speed influences on the amplitude of the signals makes it applicable to the various speed profiles including random profiles, and also different speed ranges, whether or not they cross the resonance frequency of the structure. Experimental results have shown the capability of the proposed method compared to the models that do not utilize encodings.

ABSTRACT

Wind energy plays a vital role in meeting the sustainable development goals set forth by the United Nations. Performance of wind energy farms degrades gradually with aging. For deriving maximum benefits from these capital-intensive projects, these degradation patten should be analyzed and understood. Variations in the capacity factor over the years could be an indication of the age-related degradation of the wind farms. In this study, we propose a novel data-driven model to estimate the capacity factor of wind farms, which could then be used to estimate its age-related performance decline. For this, a 1-dimensional convolutional neural network (1-D CNN) is developed with a soft ordering mechanism under this study. The model was optimized using Huber loss to counteract the effects of outliers in data. The developed model could perform very well in capturing the underlying dynamics in the data as evidenced by a normalized root mean squared error (NRMSE) of 0.102 and a mean absolute error (MAE) of 0.035 on the test dataset.

1. INTRODUCTION

The United Nations and its member states have set forth the sustainable development goals (SDGs), in which SDG 7 outlines a commitment towards "*ensuring access to affordable, reliable, sustainable, and modern energy for all*" (Sachs, Kroll, Lafortune, Fuller, & Woelm, 2022). Five key targets have been identified towards attaining this goal. Targets 7.1 and 7.2 are of particular interest (*Goal 7: Affordable and clean energy*, 2024):

- Universal access to affordable and clean energy sources prioritizing the transition to renewable energy and energy-efficient technologies by 2030 (Target 7.1).
- Increasing the share of renewable energy in the global energy mix, encouraging the adoption of cleaner and greener alternatives to fossil fuels by 2030 (Target 7.2).

Wind energy, with its meteoric growth in recent years, will play a significant role in contributing towards these targets. For example, the share of wind energy in the global energy mix has increased from 342 TWh in 2010 to 2, 125 TWh in 2022 (International Energy Agency, 2023). With many large-scale wind projects in various stages of development, this trend is expected to continue in the coming years as well.

Wind turbines in a farm are often exposed to complex and harsh operational environments which adversely affects its health conditions and thereby its life expectancy. The average lifetime of wind turbines varies from 20 to 25 years, depending on the design features and operational environment (Adedipe, & Shafiee, 2021; Ziegler, Gonzalez, Rubert, Smolka, & Melero, 2018). During this period, wind turbines undergo gradual degradation in performance owing to the mechanical wear and tear over the years (Hamilton, Millstein, Bolinger, Wiser, & Jeong, 2020; Pan, Hong, Chen, Feng, & Wu, 2021), or the reduction in aerodynamic efficiency due to material erosion over the blade tips (Mathew, Kandukuri, & Omlin, 2022; Ravishankara, Ozdemir, & Weide; Sareen, Sapre, & Selig, 2014). It is estimated that, in Europe, nearly half of the wind turbines in operation will reach their end of designed life by 2030 (Windeurope Asbl/Vzw, 2024). Thus, estimation of the long-term performance of wind turbines in a farm is essential for identifying the possible system degradations over the years and thereby to plan the maintenance strategies and end-of-life decision support.

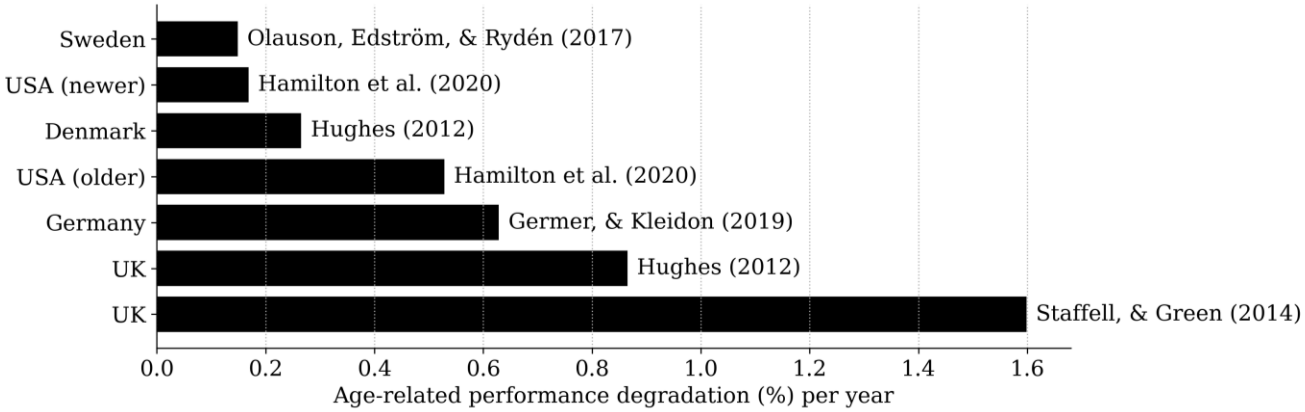

Figure 1. Age-related decline in capacity factor as reported by different studies.

Despite the significance of understanding the health status of wind turbines through its performance degradation during its lifetime, most of the earlier studies on condition monitoring focus solely on component level system reliability and availability (Staffell, & Green, 2014).

Wind turbines have several components integrated within the system and several of such turbines work together with mutual interactions in a wind farm. Hence, an analysis at turbine and farm level would help in giving a wholistic picture of the degradation issues. With the extensive deployment of supervisory control and data acquisition (SCADA) systems, time series performance of wind turbines and farms can be analyzed using data-driven models. Further, the degradation pattern in wind turbines over their life span is highly site-specific in nature (Mathew et al., 2022). Thus, data-driven models can help in estimating the performance degradation in wind turbines accurately and accounting for site-specific factors leading to their degradation. The authors have earlier developed a site-specific degradation estimation model for a wind turbine operating in Norway (Mathew et al., 2022). It was found that the reduction in performance of a wind turbine can be estimated using SCADA data and data-driven models. Further, it was estimated that on average, the performance of the wind turbine under study declined 0.64% every year of its operation. Similar studies have been carried out for turbine-level estimation of performance degradation at Irish, and Italian sites (Astolfi, Byrne, & Castellani, 2021; Byrne, Astolfi, Castellani, & Hewitt, 2020), showing degradation estimates of 8.8% and 1.5% over 12 years of operation. Such wide variation in the performance degradations of wind turbines further strengthens the argument for their site-specific analysis.

At a wind farm level, age-related decline in efficiency is quantified using the plant capacity factor (C_f), which is the ratio of the actual energy produced by the wind farm to the maximum possible energy it could have produced if it were operating at full capacity over the same period. In one of the earliest studies in estimating the wind farm level performance degradation, Hughes (2012) calculated the monthly capacity factor of wind farms operating in the UK and Denmark using 10 years of operational data, which was used to estimate the decline in performance of 13% in the UK and 4% in Denmark over the course of its operation, respectively. Similar results were reported by several studies (Germer, & Kleidon, 2019; Hamilton et al., 2020; Hughes, 2012; Olauson, Edström, & Rydén, 2017; Staffell, & Green, 2014) in the literature as illustrated in Figure 1. In the figure, the age-related decline in performance of wind farms estimated using capacity factor is normalized to per year values as reported in these studies.

These studies help in understanding the age-related performance decline in wind farm level and reiterate the regional and site-specific nature of the degradation phenomenon. However, most of these studies are based on cumulative data from different windfarms collected from public databases. Additionally, they depend on modelling the capacity factor based on meteorological reanalysis data and manufacturer's power curve (MPC) of the wind turbine. Hence, these studies are not based on the data measured from the specific wind farm site under study. The site-specific dynamics play a significant role in the age-related performance degradation of wind turbines, and the performance estimated using MPCs generally differ significantly from field performance of the turbines (Veena, Manuel, Mathew, & Petra, 2020). This could adversely affect the accuracy of these analyses. A more systematic and accurate analysis of the wind farm level performance degradation can be achieved through models based on the site-specific data, derived from the SCADA systems.

In this paper, we propose a deep neural network-based model to estimate the capacity factor of wind farms which can further be used for identifying the age-related performance degradation in wind farms. Apart from using the realistic data derived from SCADA for the site-specific analysis as discussed above, another novelty of the study is the use of convolutional neural network (CNN) model with the soft ordering mechanism. The remainder of the paper is organized

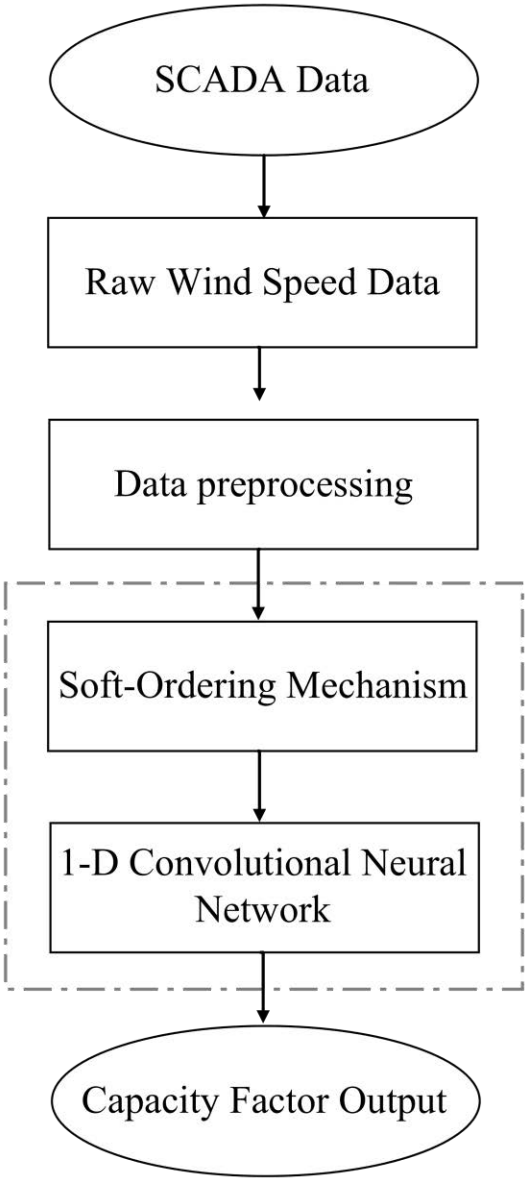

Figure 2. Schematic representation of modelling.

as follows: Section 2 starts by explaining the rationale behind using CNNs. In Section 2.1, the theoretical framework behind CNNs is briefly explained. The soft ordering mechanism employed in order to transform the input data into appropriate inputs to the CNNs is introduced in Section 2.2. Section 2.3 briefly discusses the 1-D CNN architecture and Section 2.4 describes the methodology followed in training, validating, and testing this model. The results from this study are detailed in Section 3 and finally Section 4 concludes this work and traces the next steps in this ongoing study.

2. METHODOLOGY

The performance of wind turbines in a wind farm is significantly influenced by the high spatial and local correlation of wind speed at each of the turbines through site-specific wake effects. But these correlations are further complicated due to the directional and stochastic nature of wind, making it harder for a straightforward analysis. Owing to their capability to extract salient feature representations from data with inherent spatial and local correlations, CNNs are a compelling approach to be explored. The overview of the methodology in estimating the capacity factor is shown in Figure 2.

2.1. Convolutional Neural Networks

The model for estimating the capacity factor in this study is based on CNN. CNNs are inspired by the natural vision in mammals and were popularized by Lecun et al. (1989) particularly for image recognition tasks. Even though the theoretical framework for CNNs predates this work, they used this architecture for automated extraction of features for vision related tasks.

Convolutional layers are the fundamental building blocks in CNN. They serve as the feature extractors exploiting local connectivity, and spatial locality (Kiranyaz et al., 2021; Rawat, & Wang, 2017). In convolutional layers, a learned kernel convolves with the input producing a feature map. The property of local connectivity arises from the fact that each element in the feature map is connected to a local subset of neurons in the previous layer or the input pixels. Spatial locality, on the other hand, is the result of the high correlation between the local subset of input to the convolutional layer. The feature map element at (i, j) in the kth feature map of the lth layer can be calculated as:

$$z_{i,j,k}^{l} = \boldsymbol{w}_k^l \boldsymbol{x}_{i,j}^l + b_k^l \quad (1)$$

where $\boldsymbol{w}_k^l$ and b_k^l are the weight vector and bias term of the k^{th} filter of the l^{th} layer, respectively. $\boldsymbol{x}_{i,j}^l$ is the local subset of input to the convolutional layer centered at (i, j). However, when used for tabular dataset, convolutional layers expect spatial and local correlation between the features. Non-linearity is generally introduced after convolution by using elementwise non-linear activation functions such as rectified linear unit (ReLU). ReLU outputs the input values as such if the input is positive and zero if the input value is negative.

$$a_{i,j,k}^{l} = max\left(0,\, z_{i,j,k}^{l}\right) \quad (2)$$

where $a_{i,j,k}^{l}$ is the activation at position (i, j, k) in layer l after applying ReLU function.

Pooling layers are an optional layer in CNNs which introduce shift-invariance to the feature maps produced by convolutional layers. Shift-invariance is achieved by reducing the resolution of the feature maps through average pooling or max-pooling depending on the task. The average pooling operation is given by:

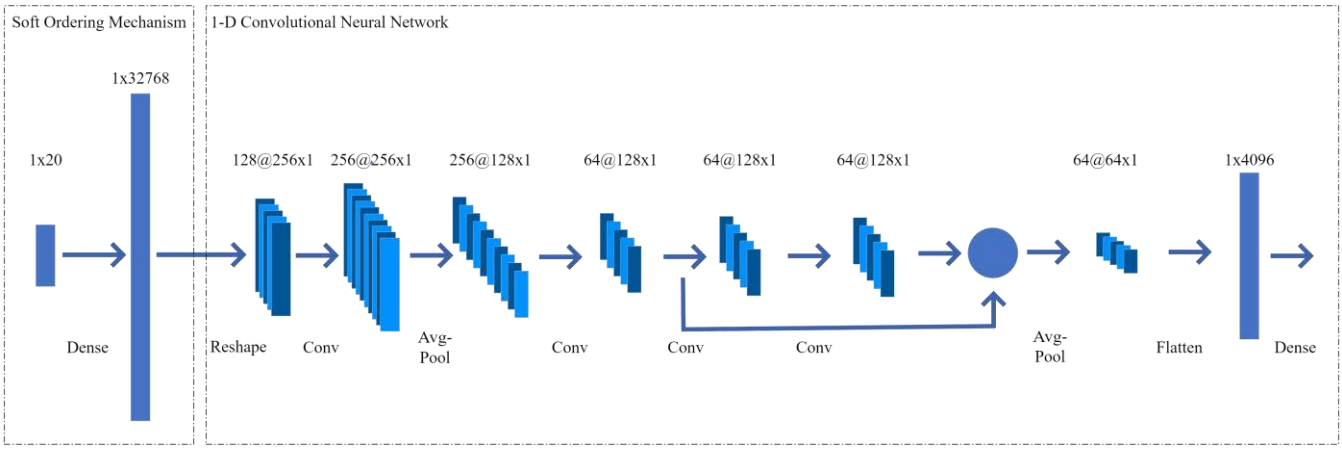

Figure 3. Architecture of the proposed 1-D CNN with soft ordering mechanism.

$$AvgPooling(\boldsymbol{A})_{i,j,k} = {}^{1}/_{N} \sum_{m,n \in R_{i,j}} a^{l-1}_{m,n,k} \qquad (3)$$

where $\boldsymbol{A}$ is the activation map from layer (l-1), N is the number of elements in the pooling window $R_{i,j}$ of dimension (m, n), and $a^{l-1}_{m,n,k}$ is the activations from the pooling layer within the pooling window.

Several convolutional and pooling layers are stacked in a CNN to extract higher level feature representations. Further one or more fully connected (FC) layers are used to achieve higher level reasoning in CNNs (Simonyan, & Zisserman, 2014). The output layer is the final layer that uses task appropriate activation functions (e.g., sigmoid for classification or ReLU for regression).

However, a key challenge is that CNNs are designed to work with data presented in a uniform grid-like structure akin to images. The wind speed input from the wind farm cannot be fed directly to the CNNs assuming each point as a "pixel" in the pseudo-image, as generated from the wind farm layout. This is because the layout of wind turbines in a wind farm is non-uniform, often dictated by the availability of wind and other external factors such as terrain, land use regulations etc.

One solution for the irregular layout of wind farms is to pad the layout with zeros to make it a uniform grid like structure, which results in sparseness in the data. Sparseness in data may result in slowing down of training, reduction in model performance, and loss of spatial resolution.

To overcome these limitations, in this study, we propose a novel application of soft ordering mechanism for CNNs in estimation of the capacity factor. Under this method, the wind data, which is in tabular form, is reshaped into a multi-channel image format. The advantage of this method is that the spatial or sequential relationships of the data are preserved without the need for following a rigid order. This makes the proposed method unique and more suitable for modelling wind farms, which normally have nonrigid geometries. The proposed soft ordering 1-D CNN consists of two parts: a soft-ordering mechanism, and a 1-D CNN.

2.2. Soft ordering mechanism

Soft ordering is a technique to rearrange the data to introduce or preserve spatial or sequential relationships without following a rigid order. In this work, soft ordering is achieved by using an FC layer. The FC layer maps the input features into another higher dimensional feature space. This transformation helps in providing enough pseudo-pixels for the convolutional layers as well as to reorganize the features such that it mimics the spatial or sequential relationships in the data. The FC layer is followed by a non-linear activation function, ReLU in this work, for ensuring that the transformation can effectively learn a non-linear mapping.

Finally, the newly rearranged features are reshaped into multi-channel pseudo-images. Thus, the convolutional layer extracts the features from a rearranged non-linear transformation of the original data, and the model learns to effectively rearrange the features adaptively. Thus, the entire model can be trained in an end-to-end manner without significant preprocessing steps.

The soft ordering mechanism is shown in Figure 3, which takes in the input features and transforms them into non-linear higher-dimensional representations of size 32768. These representations are then reshaped into 128 channels with a signal size of 256 to be fed into the 1-D CNN.

2.3. 1-D CNN Architecture

As opposed to CNNs used for image tasks, where the convolution is applied to a 2-D tensor, a 1-D convolutional layer takes in a single dimensional signal and applies a convolutional kernel of similar dimensionality, typically smaller than the signal. This makes it suitable for applications

like natural language processing, audio signal processing, and time series analysis.

In this work, the representations from the soft ordering mechanism are fed into the 1-D CNN. The 1-D CNN architecture is also shown in Figure 3. The first convolutional layer increases the number of feature channels to 256 while maintaining the size of each feature map at 256 by applying a convolution kernel of size 5. Subsequent adaptive average pooling layer reduces the feature map resolution to 128 x 1. The next three convolution layers apply a kernel of size 3 with a stride of length 1 and output 64 channels of feature maps of size 128. A skip connection is also added from the output of the second convolutional layer to the output of the fourth convolutional layer as shown in Figure 3 to solve the problem of vanishing gradients and hence network degradation (He, Zhang, Ren, & Sun, 2016). A second average pooling layer further reduces the size of the feature maps while ensuring enough receptive fields to facilitate learning. Finally, the output from the average pooling layer is flattened and fed into a fully connected layer which makes the capacity factor estimations. ReLU activation function is used throughout the network to introduce non-linearity except to the outputs of the FC layer in the soft ordering mechanism, where continuously differentiable exponential linear unit (CELU) activation (Barron, 2017) has been used. CELU ensures that non-linearity introduced is smooth and continuous for all values and helps in capturing the negative values effectively avoiding dying ReLU problem (Lu, Shin, Su, & Karniadakis, 2019).

Batch normalization has also been implemented to help the model learn faster and make training more stable by reducing internal covariate shift (Ioffe, & Szegedy, 2015). Further, weights normalization is also implemented to counteract vanishing or exploding gradients and improving generalization by preventing the weights from growing too large or too small (Salimans, & Kingma, 2016).

2.4. Network Training

The model was trained on a wind farm dataset operating at a Norwegian site, by collecting 13 years of operational data. Each of the twenty pitch-controlled wind turbines has a 2 MW rated capacity. The turbines have cut-in, rated, and cut-out velocities of 3 m/s, 18 m/s, and 25 m/s, respectively. The turbines had a rotor diameter of 82.4 m and were installed at a hub height of 70 m. The SCADA data from these turbines had a temporal resolution of 10 minutes (Under the non-disclosure agreement, the data cannot be shared with this paper). The wind speeds and power generated by these turbines were collected from the data and cleaned for missing data and outliers. The initial four years of data from 2007 to 2010 was used to train the model.

The capacity factor of the plant was calculated which served as the target variable and the individual wind speeds served as the features. The data was divided into training, validation, and testing sets in the ratio 3:1:1. Huber Loss was used to calculate the losses for back propagation. Huber Loss is given by:

$$l(y,x) = \begin{cases} \frac{1}{N}\sum_{n=1}^{N} 0.5\,(\epsilon)^2, & if\ |\epsilon| < \delta \\ \frac{1}{N}\sum_{n=1}^{N} \delta\,(|\epsilon| - 0.5\delta), & otherwise \end{cases} \quad (4)$$

where $\epsilon = y_n - x_n$, is the residual, δ is the threshold for switching between the δ-scaled L1 and L2 losses, and y_n is the model's estimation of x_n. The advantage of the Huber Loss is that it combines the benefits of both L1 loss (absolute error) and L2 loss (squared error) reducing the penalty for residuals less than the threshold and thereby making the model less sensitive to outliers than L2 loss. The Huber loss is sensitive to the threshold (δ) and was set as two times the standard deviation of the residuals from a basic regression model developed initially using inlier data. Additionally, L1 losses and L2 losses across the training epochs were monitored to ensure that the model's improvement on Huber loss is translated into real world improvement in the estimation of the model performance. Adam optimizer was used in this study for updating the parameters with $\beta_1 = 0.8$ and $\beta_2 = 0.999$. The learning rate (LR) for the optimizer was empirically set to 8×10^{-4}, with an exponential LR decay with $\gamma = 0.9$, meaning the LR would decay after each epoch gradually. This helps in having higher adjustments to the parameters in the beginning and relatively smaller ones towards the end of training. The model was trained over 200 epochs implementing an early stopping mechanism that monitors the validation losses with a patience of 25 to avoid overfitting. Further, L2 regularization was implemented to reduce the chances of overfitting. While dropout layers were investigated for better generalization, it was found that the performance of the model was worse, and convergence was very slow. In the next section, we discuss the results of this experiment in detail.

3. Results and Discussions

The various losses tracked during the training and validation phases are shown in Figure 4: (a) Huber loss, (b) L1 loss, and (c) L2 loss. As expected, the losses are high initially then quickly declining to a more gradual and stable loss condition.

The validation losses in all three of the metrics show high variability across the initial epochs as the model begins to learn from the training data quickly stabilizing showing improvements in generalizability of the model. The best performing model was detected at the 94th epoch with a training and validation loss (Huber loss) of $3.1 \times 10^{-3}$and 1.6×10^{-3}, respectively. The higher training loss observed

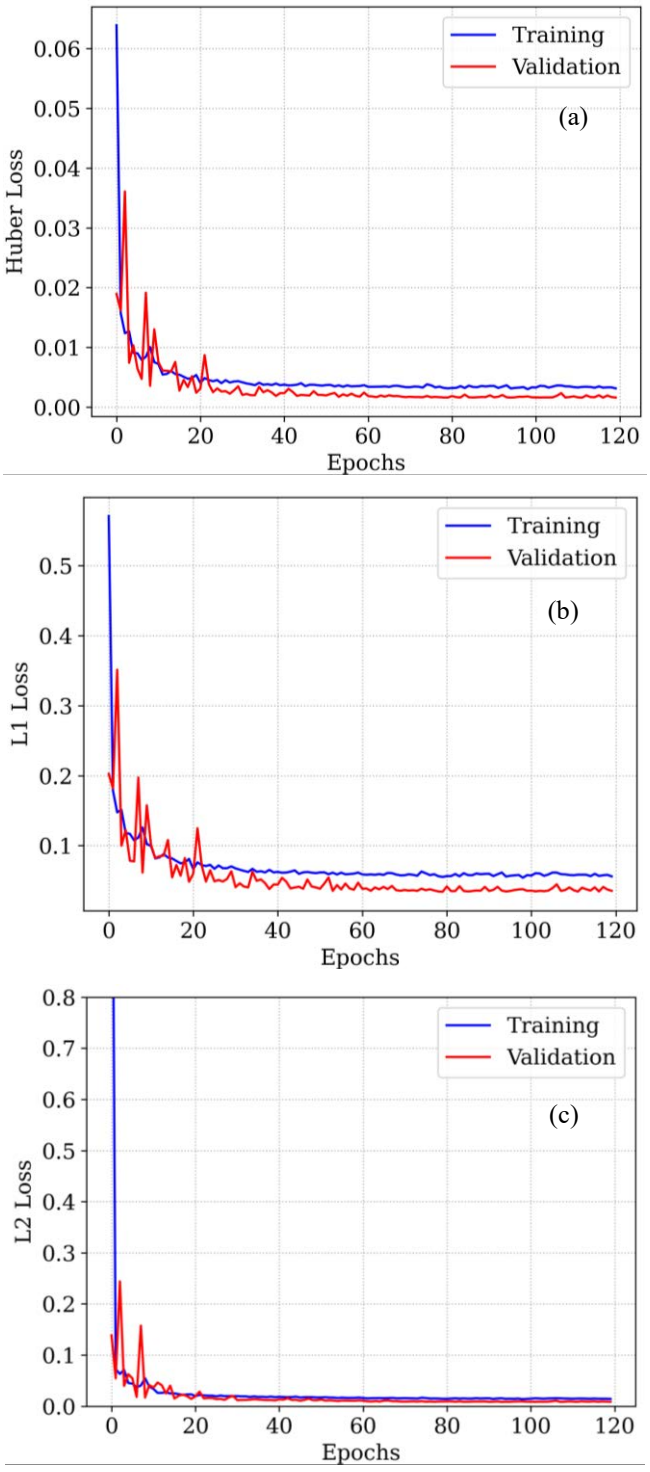

Figure 4. Various losses tracked during training: (a) Huber Loss, (b) L1 Loss, and (c) L2 Loss.

across the epochs are a result of the regularization methods applied during training. The corresponding MAE and mean squared error (MSE) for the training and validation phase can be seen in Table 1.

Table 1. Performance of the best model in training, validation, and test datasets.

Loss	Training	Validation	Test
Huber loss	3.1×10^{-2}	1.6×10^{-3}	1.7×10^{-3}
MAE	5.6×10^{-2}	3.5×10^{-2}	3.5×10^{-2}
MSE	1.4×10^{-2}	8.5×10^{-3}	1.0×10^{-2}

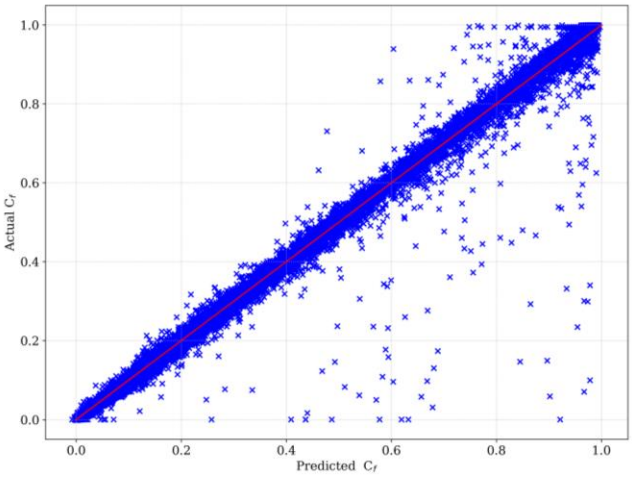

Figure 5. Comparison of the model predicted capacity factor to the measured capacity factor.

The model thus finalized, was tested with test data, which was not used in the training or validation phases to measure the generalizability of the model. Figure 5 shows the performance of the model on the test dataset. The blue scatter indicates the model prediction compared to the calculated values and the distance of these points from the red line indicates the residuals of the prediction model. The training curves (Figure 4) and the comparison in Figure 5, highlight the generalizability of the model to new data and performance of the model on new data, respectively.

The different error metrics in Table 1 quantifies this performance with a slightly higher Huber loss in predicting new datapoints. The normalized root mean squared error in predicting the capacity factor for the test dataset was 0.102. With only 0.363% of the test dataset having a residual value of more than 0.2, the model is found to be effective in capturing the plant capacity factor.

Figure 6 shows the actual and predicted power over different months in a year. It is evident that the predictions and the calculated values are in close agreement with each other. The yearly capacity factor of the farm was calculated as 0.298 against which the model prediction was 0.305. These results further support the argument that the model performs exceptionally well in predicting the wind farm capacity factor.

In previous studies on the age-related performance decline of windfarms, instead of the real data collected from the sites,

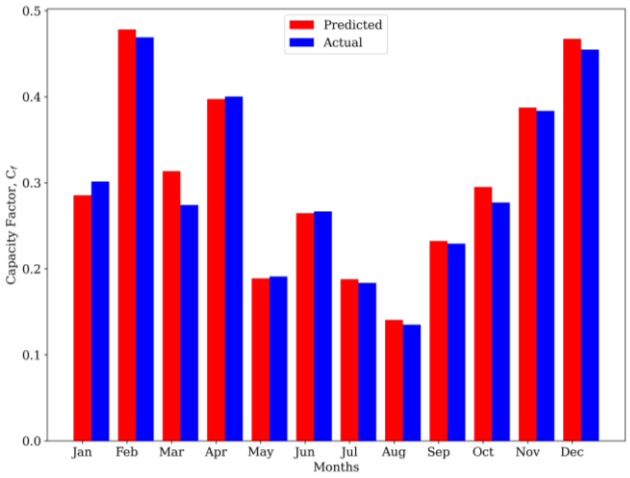

Figure 6. Comparison of actual and predicted power over different months in a year.

the wind estimates from the numerical weather prediction (NWP) models are used for estimating the capacity factors. Though the errors due this approximation are not specified in these studies, obvious differences between the NWP wind predictions and the real velocities available for the turbines could bias the model and thereby adversely affect the reliability of the results. In contrast, real wind measurements are used in the present work which resulted in accurate capacity factor predictions as evident from the low errors values. Similarly, while comparing with some CNN based studies for wind farm performance predictions (Chen et al., 2021; Kazmi, Gorgulu, Cevik, & Baydogan, 2023; Liu et al., 2021), the proposed soft ordering approach could improve the performance of the capacity factor estimations.

4. Conclusion

Wind turbines operating in a farm are exposed to complex operational conditions, causing degradation in their performance over the years of their operation. This age-related performance decline, if quantified at a wind-farm level, could contribute towards making efficient decisions at their end-of-life. As a first step towards this objective, we developed an intelligent algorithm for the estimation of wind farm capacity factor in this paper.

To predict the capacity factor of a wind farm, a 1-dimensional convolutional neural network has been trained exploiting the local connectivity inherent in wind farms. However, to sidestep the irregularity in wind farm layouts, while still using CNNs to model their performance, a soft ordering mechanism is used. The soft ordering mechanism in addition to the 1-D CNN, was able to effectively capture the inherent spatial dynamics in the wind farm as evidenced by the results discussed in the previous section. The model developed in this paper has a normalized root mean squared error of 0.102. This indicates that the errors in the model predictions are approximately 10.2 % of the range of the target values. This indicates that the proposed method could predict the capacity factor of the wind farm with high accuracy. Further, the performance of the model on previously unseen dataset (MAE: 0.035, MSE: 0.010), shows that the model can generalize well to newer data coming from the wind farm even though it was trained on data from earlier.

For developing the proposed model, high quality SCADA data are required, which may limit its applications in farms which do not have such systems in place. Nevertheless, most of the contemporary wind farms have implemented the SCADA systems and with the availability of the required data, the soft ordering 1-D CNN model developed under the study could further be used to estimate the age-related performance degradation in wind farms. This will be demonstrated by the authors through their ongoing research where logs on the turbine maintenance will also be considered.

BIOGRAPHIES

Manuel S. Mathew is a PhD Research Fellow at the Information and Communication Technology department at the University of Agder, Norway. His interest is in the application of artificial intelligence in renewable energy systems particularly focusing on prognostics for wind farms. He completed his master's degree in Renewable Energy in 2021 from the University of Agder. In addition, he also holds a master's degree in systems engineering by research from the University of Brunei Darussalam. He did his bachelor's degree in electrical and electronics engineering from the Mahatma Gandhi University, India.

Surya Teja Kandukuri is a Senior Scientist at NORCE. He holds a part-time position as a Researcher at University of Agder, Grimstad, Norway. He obtained his PhD in condition monitoring from the University of Agder in 2018. He has over 12 years of experience in industrial research within aerospace, energy, marine and oil & gas sectors, developing condition monitoring solutions for high-value assets. He received his master's degree in systems and control engineering from TU Delft, The Netherlands, in 2006 and bachelor's in electrical engineering from Nagarjuna University in India in 2003.

Christian W. Omlin has been a professor of Artificial Intelligence at the University of Agder since 2018. He has previously taught at the University of South Africa, University of the Witwatersrand, Middle East Technical University, University of the South Pacific, University of the Western Cape, and Stellenbosch University. His expertise is in deep learning with a focus on applications ranging from safety to security, industrial monitoring, renewable energy, banking, sign language translation, healthcare, bio conservation, and astronomy. He is particularly interested in the balance between the desire for autonomy using AI technologies and the necessity for accountability through AI imperatives such as explainability, privacy, security, ethics, and artificial morality for society's ultimate trust in and acceptance of AI. He received his Ph.D. from Rensselaer Polytechnic Institute and his MEng from the Swiss Federal Institute of Technology, Zurich, in 1995 and 1987, respectively.

State-of-Charge and State-of-Health Estimation for Li-Ion Batteries of Hybrid Electric Vehicles under Deep Degradation

ABSTRACT

In recent industry, hybrid vehicles are gaining more recognition as a practical means for future transportation due to the longer distance, reduced charging time, and less charging stations dependency. The batteries in the hybrid vehicles, however, undergo more complex operation of charge depleting and sustaining modes alternately, which may need more accurate battery state estimation. In this study, a model based method is explored for the Li-ion batteries in the hybrid electric vehicles to estimate State-of Charge (SOC) and State-of-Health (SOH) accurately. While there have been widespread studies for this topic in the batteries research, not many are found that have investigated hybrid operation modes. Also the estimations are mostly limited to normal batteries or shallow degradation with the SOH higher than 90%. In this study, an algorithm based on the dual extended Kalman filter (DEKF) and enhanced self-correcting (ESC) model is developed for the simultaneous estimation of the SOC and SOH. Degradation data for plug-in hybrid vehicle (PHEV) are taken for the study, which undergo the deep degradation of 30%. In order to maintain the accuracy such that the root mean square error (RMSE) of the SOC is within 5% over the entire degradation cycles, two practical methods are proposed: First, the SOH is estimated separately during the battery charging, and is used as a constant in the SOC estimation in the discharging cycles. Second, battery modeling is conducted and the parameters are reset in every intermittent cycles at which the SOH is reduced by 10% initially and by 5% thereafter.

1. INTRODUCTION

Lithium-ion batteries have been applied extensively in various fields, including portable electronic devices, road transportation, and power supply systems, expecting their future role in energy sustainability (Zubi et al., 2018). As battery-powered vehicles such as pure electric and hybrid electric vehicles gain popularity, the development of battery management systems (BMS) estimating the state-of-charge (SOC) and state-of-health (SOH) of the batteries becomes crucial to ensure reliable and efficient battery operation (Mishra et al., 2021). In the BMS research, most SOC and SOH estimators have been developed for pure electric vehicles that primarily operate in charge-depleting (CD) mode. However, there is an increasing demand for hybrid vehicles that can handle higher loads and longer distances, which involves switching between CD and charge-sustaining (CS) mode during the operation. This can make the SOC estimation more difficult than those in the CD mode alone. Therefore, SOC and SOH estimation under combined mode is necessary for improved accuracy (Yoo et al., 2023).

Fundamentally, it is impossible to measure the SOC and SOH of batteries directly, thus methods are designed for estimating them based on measurable data such as current, voltage and temperature. Among the many achievements, Kalman Filter-based algorithms, which belong to the model-based approach, have proven their effectiveness and account for more than half of the SOC estimation methods (Shrivastava et al., 2019). Nevertheless, it is a challenge to estimate SOC for degraded batteries, which requires the SOH estimation as well (Hannan et al., 2017). Investigations into the simultaneous estimation of SOC and SOH, in view of both the effectiveness and efficiency, have remained relatively

Table. 1. Literature using model-based SOC and SOH estimation with aged battery data.

Author	Year	Battery Model	Methods (SOC-SOH)	Estimation Factor	Results of Estimation	Level of Degradation
R. Xiong	2014	1 RC model	EKF-EKF (multi-scale)	SOC, All Parameters	SOC, Capacity	100%, 82.6%, 82.1% and 72.1%
N. Wassiliadis	2018	2 RC model	EKF-EKF	SOC, Capacity, Resistance	SOC, Capacity, Resistance	100%, 97%, 85%, 78% and 49%

X Hu	2018	fractional second-order model	EKF-EKF	SOC, Capacity, Resistance	SOC, Capacity, Resistance	86.1%, 81.7% and 74.5%
L. Ma.	2022	fractional second-order model	MIUKF-UKF (multi-scale)	SOC, Capacity, Resistance	SOC, Capacity	98.1%, 94.7%, and 91.5%

insufficient (Wang et al., 2021). Even in the simultaneous estimation of SOC and SOH, substantial portion have targeted normal batteries (Campestrini et al., 2016; H. Guo et al., 2017; R. Guo & Shen, 2022; Hossain et al., 2022; C. Hu et al., 2012; Lee et al., 2008; Plett, 2004, 2006; Shrivastava et al., 2022; Ye et al., 2023; Zhang et al., 2016)

Model-based SOC and SOH estimation for aged battery can be categorized into two groups. The first involves updating the model's parameters to account for battery aging (Li et al., 2019; Sepasi et al., 2014; Shrivastava et al., 2019; Xu et al., 2022). While it is possible to update the model through optimization, using which the SOC is estimated, it comes at the cost of high computational burden. Additionally, there is a challenge in determining an appropriate updating period. The second approach involves co-estimation of the states and parameters of a battery model (X. Hu et al., 2018; Ma et al., 2022; Wassiliadis et al., 2018; Wu et al., 2019; Xiong et al., 2014). While this can be achieved using the dual filter algorithms (Yoo et al., 2023), it presents a significant challenge due to the substantial number of parameters in the model. This is further compounded by the fact that the only directly measurable output is the voltage under the given currents. Consequently, only a few parameters such as the capacity, i.e., the SOH, and internal resistance are estimated, while the others are held at fixed values. However, this approach may result in a less accurate model of aged battery.

Upon the survey of relevant literature, it follows that the approaches on the co-estimation of SOC and SOH by the dual filters need a comprehensive discussion in various aspects: battery model, type of filters, specific settings of these filters, initial values of state and parameters, and the level of degradation. Regarding the battery model, used models are Thevenin model with first-order (1RC) (Xiong et al., 2014) or second-order (2 RC) (Wassiliadis et al., 2018; Wu et al., 2019), or fractional second-order model (X. Hu et al., 2018; Ma et al., 2022). While the extended Kalman filter (EKF) is usually used, other filters such as adaptive extended Kalman filter (AEKF) or unscented Kalman filter (UKF) have sometimes been used, and there is a case where a dual filter has different time intervals considering the characteristics of state and parameter. Regarding the settings of filter (such as error, noise and measurement covariance), many did not specify values and conditions, except (X. Hu et al., 2018; Wassiliadis et al., 2018).This may make the results less trusted in terms of practical application. In view of the degradation levels, only one paper (Wassiliadis et al., 2018) has explored capacity fade over 50%, but the results are given without confidence intervals. As a result, despite the abundance of literature, these limitations pose challenges in adopting a practical approach to BMS development. Table 1 summarizes the representative papers in terms of model, methods, results of estimation, and level of degradation.

This study presents a more practical methodology to co-estimate the SOC and SOH by the dual Kalman filter for the batteries undergoing hybrid operations. Two key insights are applied for this research. First, it is observed that the co-estimation of SOC and SOH may yield inaccurate results due to the poor observability of the capacity. To mitigate this, a

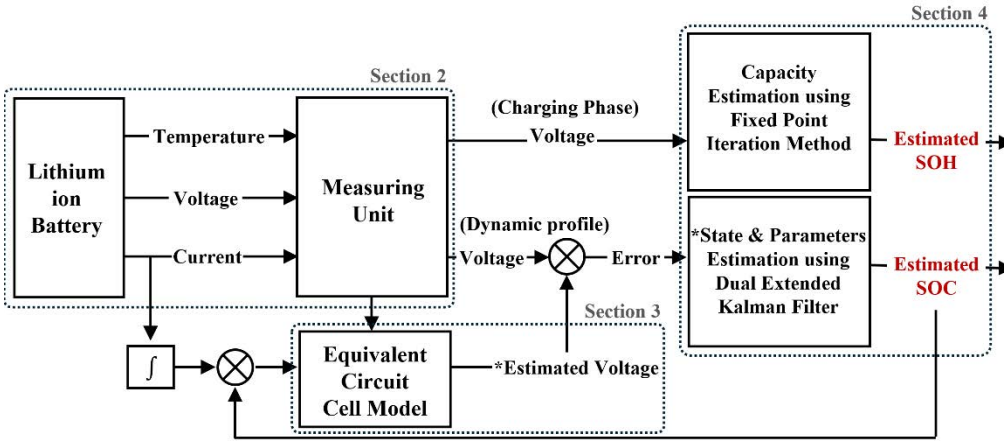

Figure 1. An overview of the core methodology

practical solution is developed by separating the SOC and SOH estimation, namely, estimating the SOC using the Dual Extended Kalman Filter (DEKF) in the discharging phase while estimating the SOH using the Fixed-Point Iteration Method (FPIM) in the charging phase. The reason is that the capacity estimation during the charging process is generally standardized and exhibit less dynamics as opposed to the discharging process. Second, when the batteries degrade by more than 10% in capacity, even the performance of this approach falls below acceptable level. Therefore, remedial action is applied by updating the parameters of battery model periodically.

The approach is validated by utilizing thirty battery cell datasets. These datasets are obtained through tests conducted under three distinct dynamic profiles representing plug-in hybrid electric vehicles (PHEVs), captured at ten points throughout the cycles ranging from 0% to 30% of capacity fade. Section 2 outlines the experimental method to measure temperature, voltage and current, and three types of dynamic profiles in charging phase. In Section 3, two battery models: Thevenin and Enhanced Self-Correcting (ESC) are addressed, which is to estimate voltage from the measured data. Section 4 explains the procedure of SOC and SOH estimation by the DEKF and FPIM respectively. An overview of the key methodology proposed in this paper can be found in Figure 1. Finally, key findings are summarized in Section 5, providing comprehensive insights and limitations.

2. BATTERY CELL TEST

In this study, the same battery cell and equipment described in the literature (Yoo et al., 2023) are used for the test, which is a Samsung SDI, 18650-35E lithium-ion battery cell with nominal capacity of 3.5 Ah and a nominal voltage of 3.7 V. The battery is operated by a DC electronic load (Kikusui, PLZ1004W), a DC power supply (Kikusui, PWR800L) and a charge-discharge system controller (Kikusui, PFX2512) as shown in Figure 2. The test profiles are divided into dynamic test and aging test. The dynamic profiles comprise of three scenarios of Plug-in Hybrid Electric Vehicles (PHEV) as shown in Figure 3: City, Highway, and High-speed. City and Highway profiles consist of charge-depletion (CD) mode and charge-sustaining (CS) mode, while High-speed has CD mode only.

Figure 2. Experimental setup

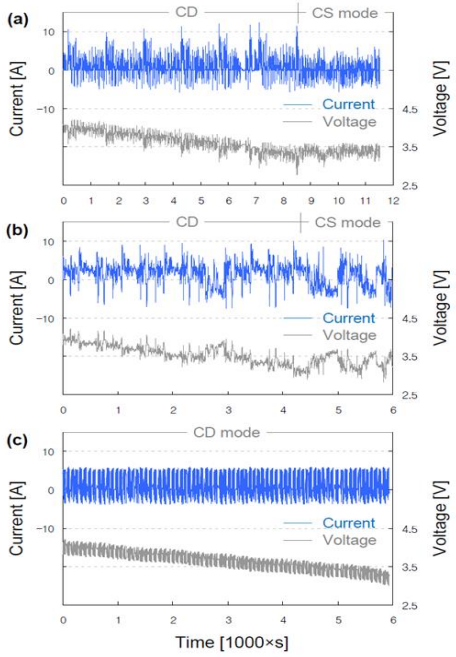

Figure 3. Voltage response to the current profiles adopted: (a) City, (b) Highway, and (c) High-speed

Aging test is performed to acquire aged battery data, by repeating charging and discharging cycles up to the capacity degradation of 30% as shown in Figure 4. Once the battery cell exhibits a noteworthy degree of capacity fade, three different dynamic profiles are applied. Before proceeding the aging test, static test is conducted to obtain the relation between the open circuit voltage (OCV) and SOC as shown in Figure 5. In the aging test, 2100 cycles are used to make capacity fade of 30%. Dynamic tests are conducted at 10 time points with the intervals of every 100 cycles during the period from the initial to the 300th cycles, and with the intervals of every 300 cycles from the 300th to the end of the cycles, which is depicted in Figure 6. The failure threshold for SOH is given at the 80% of initial capacity as shown in the dotted horizontal line in the figure. The capacity decreases mostly in linear fashion, except from 1200 to 1500 cycles where it is constant. The dynamic test data at each cycle, which are 0, 300, 1200 and 2100 cycles, are presented in Figure 7. For each cycle, three dynamic profiles are applied with the initial SOC set at approximately 0.9 (90%). As the degradation proceeds, each profile exhibits an abrupt termination because the cutoff voltage is reached earlier, indicating that the capacity has faded.

3. BATTERY MODEL

In this study, Thevenin and Enhanced Self-Correcting (ESC) models are reviewed to select a suitable battery model based on the gathered test data. The Thevenin model, one of the most widely utilized equivalent circuit models (ECMs) for model-based estimation of batteries, describes battery behavior by accounting for voltage drop through a resistor element and time-varying polarization voltages through one or more parallel resistor-capacitor (RC) elements.

The ESC model, proposed by Plett (2015), extends the Thevenin model by incorporating a hysteresis term to describe the hysteresis voltage of batteries with empirical modeling. Its configuration is shown in Figure 8, where v_T is terminal voltage, v_{oc} is open-circuit voltage, z is SOC, i is current (current bias ib is ignored in this study) flowing through R_0 (ohmic resistance), i_R is the current flowing through R_j and C_j (polarization resistance and capacitance), h is hysteresis, M is maximum hysteresis voltage, M_0 is instantaneous hysteresis voltage, and s is sign function of i.

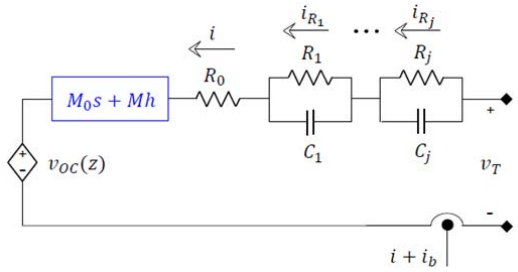

Figure 8. Circuit schematic for the ESC model which is the same as the Thevenin model except the addition of hysteresis voltages (in blue)

This study considers cases with 1 or 2 RC pairs for both the Thevenin and ESC models, denoted as Thevenin 1RC/2RC, and ESC 1RC/2RC. In order to estimate the model parameters, method by Plett, (2015) and Yoo et al., (2023) is employed, using the dynamic data for each cycle. Consequently, the models enable calculation of terminal voltage under the given current. The performance of each model is summarized in Figure 9 by the root mean square error (RMSE) between measured and estimated voltage. It is noteworthy that the ESC model outperforms the Thevenin model consistently for all the collected data. This superiority becomes more remarkable as the battery is aged. It is found that the hysteresis term in the model is useful to describe aging of the battery. Another observation is that the incorporation of additional RC pairs primarily yields a positive effect in the case of the Thevenin models, whereas it does not in the ESC model. This is from the fact that the hysteresis term diminishes the relative influence of additional RC pairs in the ESC model. This observation supports that adding the hysteresis term is better than adding the number of RC pairs. Therefore, the ESC 1RC model is chosen in this study. However, it is important to note that even the performance of the ESC model experiences accuracy loss in the aged batteries, which means that the model error increase is inevitable as the battery ages.

4. SOC AND SOH ESTIMATION

In this section, the procedure of SOC and SOH estimation by the DEKF and FPIM are outlined along with the corresponding result. The initial step involves the application of a general DEKF as reviewed in Section 1, based on the

ESC 1 RC model as determined in Section 3. Subsequently, the inherent weak observability of capacity in the DEKF algorithm is identified. To address this, the FPIM, a capacity estimation technique, is integrated into the DEKF framework. However, despite this integration, there exsists a decline in estimation performance for deep degraded battery cells. Therefore, remedial solution is proposed: an initial parameter estimation update is recommended after a 10% capacity loss to enhance estimation performance. Estimation results are summarized in each step of this process. In summary, the contribution of this study is to improve and validate methodologies to estimate SOC and SOH for test datasets with various dynamic profiles, including hybrid operation modes, and various degradation levels, up to 30% of capacity loss of battery cells.

The dual extended Kalman filter (DEKF), one of the approaches to generalize the extended Kalman filter (EKF) for simultaneous estimation of state and parameters, comprises of two filters: one for estimating the state and the other for estimating the parameters (Plett, 2005, 2015). Each filter executes the steps, and they are linked by exchanging information during the time update sequence. In this research, we propose a hybrid approach incorporating the DEKF and the capacity estimation technique to overcome the inherent weak observability of the capacity in the DEKF algorithm (Wassiliadis et al., 2018). The capacity estimation is implemented by the fixed-point iteration method (FPIM) during battery charging, and the estimated capacity value is used as a known value in the DEKF during the battery discharging (Sung & Lee, 2018).

At first, the DEKF is applied for the co-estimation of SOC and SOH, and the results are evaluated by the RMSE in the case of SOC and the last estimated value in the case of SOH in each dynamic profile, whose true values were obtained through coulomb counting of current during the conducted profiles and capacity testing after the profiles, respectively. Then, our proposed approach is applied, where the SOH estimation is separated from the DEKF and is made by the FPIM during the charging cycle.

Estimation Results of SOC and SOH using DEKF

By applying the DEKF based on the ESC 1RC Model to all 30 datasets, estimation results are obtained for SOC and SOH. Regarding the SOC, the RMSE for each profile and cycle is illustrated in Figure 10. It was observed that prior to 600 cycles, the estimation performance exhibits RMSE of less than 3% for all datasets. However, beyond 600 cycles, a significant degradation in estimation performance become evident. As the degradation progresses, it can be observed that the error in the initial SOC gradually increases.

Involving OCV-SOC tests at specific time intervals and subsequently updating the battery model can mitigate inaccuracies in estimation. Nevertheless, static tests for acquiring OCV-SOC lookup tables are time-consuming, and selecting suitable test time points poses a challenge.

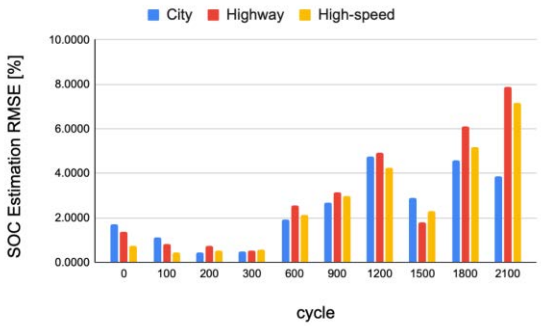

Figure 10. Estimation results of SOC using DEKF

Table. 2. Initial SOC estimation of each dataset

Cycle	City	Highway	High Speed
0	0.88	0.88	0.88
100	0.88	0.88	0.88
200	0.87	0.88	0.88
300	0.87	0.87	0.87
600	0.85	0.85	0.85
900	0.84	0.83	0.83
1200	0.81	0.82	0.82
1500	0.81	0.82	0.83
1800	0.79	0.80	0.80
2100	0.79	0.78	0.78

In this paper, a methodology is explored to mitigate inaccuracies in estimation without additional static tests. Hence, the inaccurate initial SOC estimation due to the battery aging remains as an inherent error in estimation without updating the battery model.

In the SOH estimation, it was observed that, except for the early degradation stage, the capacity generally does not satisfy the acceptable level of performance. Figure 11 depict the results of SOH estimation as the battery ages for each profile. It is observed that the capacity has low observability, and its estimation depends on the specific profile. This may be due to the fundamental issues in estimating various states and parameters based on limited measurement data. Meanwhile, for internal resistance, overall estimation performance was found to be superior when compared to the reference values. It is noted that the internal resistance has high observability compared to the capacity. Thresholds for failure based on each SOH were established at 80% of the initial capacity and twice the initial value for the internal resistance. Reference values of internal resistance were derived from battery modeling results rather than obtained through power tests. In this investigation, capacity was regarded as the indicator of SOH since the true capacity was measured at each time point. Consequently, the failure point of the battery is estimated to occur around 1,000 cycles, coinciding with the battery's capacity dropping below 80% of

its initial capacity, as shown Figure 12. This failure point couldn't be accurately predicted due to the low observability of capacity in this estimation algorithm.

Estimation Results of SOC and SOH using DEKF and FPIM

SOH Estimation

To overcome the low performance in capacity estimation, we have applied capacity estimation techniques separately using the charging profile data. Among various techniques, fixed-point iteration method (FPIM) was selected to estimate capacity during charging. Since there is only one type of profile in the charging, we can obtain a single capacity estimation result, as shown in Figure 13.

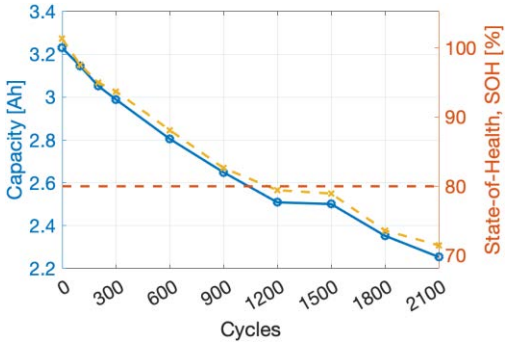

Figure 13. Results of the SOH estimation.

The estimation error was confirmed to be within 3%, indicating a significant improvement in estimation performance compared to the DEKF methodology, which estimates simultaneously from each profile.

SOC Estimation

Utilizing the estimated capacity during charging as a fixed value for SOC estimation using DEKF, the performance of SOC estimation is depicted in Figure 14. Unfortunately, despite improvements in capacity estimation performance, there is no corresponding enhancement observed in SOC estimation. It is observed that the performance significantly deteriorates with RMSE exceeding 5% after 600 cycles.

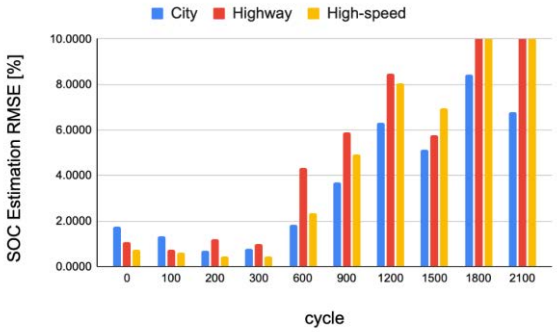

Figure 14. Estimation results of SOC using DEKF and FPIM

The everlasting decrease in the performance of SOC estimation as battery ages, despite the capacity being so close to the true value, can be attributed to several factors. These encompass the initial SOC estimation error and inaccuracies in model assumptions, as previously mentioned. Additionally, nonlinearities in the battery behavior and limitations in the estimation algorithms employed contribute to this phenomenon. Moreover, the interaction among these factors can exacerbate the complexity of the estimation process, further impeding the accurate SOC estimation. In the battery modeling of Figure 9, it has been observed that the ESC 1RC demonstrates sufficient capability to simulate the behavior of aged batteries. Consequently, there is an expectation that the SOC estimation would perform well if the parameters were estimated to optimal values. However, the challenge arises when attempting to simultaneously estimate the states and parameters to their optimal values within the filter algorithm, especially based on the limited measurement data. To address them, the initial parameter estimation values were set as the last parameter estimation values from the former dataset for each profile. This approach aimed to leverage the previous dataset's knowledge and fine-tune the initial parameter values for improved estimation accuracy in subsequent cycles. By initializing the parameters with values derived from the previous dataset, it was expected that the model could benefit from the accumulated insights and trends observed in earlier profiles, thereby enhancing the robustness and reliability of the estimation process. However, while it has been noted that internal resistance exhibits high observability in the estimation algorithm, the majority of parameters display low observability. Furthermore, unlike capacity or internal resistance, there is no discernible trend for each parameter during degradation. This lack of observable trends makes the efforts useless in the estimation process.

Estimation Results of SOC using DEKF, FPIM and initial parameter estimation update

SOC Estimation

To address the issue of deteriorating SOC estimation performance despite the improvement in SOH estimation through separate estimation, a method was applied to conduct the battery model at specific time points and reset the initial parameter estimation values.

Based on the degradation threshold of 20% capacity loss as the failure point for SOH, the battery modeling was conducted using dynamic profiles at intervals of 10% capacity loss initially, and 5% capacity loss subsequently. This method involved conducting the battery model at 600, 1200, and 1800 cycles to reset the initial parameter values. As a result, the SOC estimation performance was improved to within RMSE 5% after 600 cycles. The SOC estimation performance and the SOC estimation errors at 0, 600, 1200, and 2100 cycles are illustrated in Figure 15. Internal resistance estimation showed no significant impact compared to the previous method, as confirmed in Figure 16.

5. CONCLUSION

In this study, a methodology is investigated to estimate SOC and SOH of the battery whose capacity degraded from 0 to 30%. A hybrid approach is proposed that the DEKF and the capacity estimation technique are incorporated to overcome the inherent weak observability of the capacity in the DEKF algorithm. The capacity estimation is implemented by the fixed-point iteration method (FPIM) during the battery charging, and the resulting estimated capacity value is held constant in the process of DEKF during battery discharging. However, we observed a decline in estimation performance beyond a 10% capacity loss, prompting us to propose an initial parameter estimation update to address this issue. As a result, the proposed methodology achieves an accurate and reliable co-estimation of SOC and SOH, even in the battery aging with SOC estimation error lower than 5% and SOH estimation error lower than 3%, even for a battery cell with a capacity fade of 30% for three profiles including hybrid operation modes.

ABSTRACT

Prognostics and Health Management (PHM) is a framework that assesses the health condition of complex engineering assets to ensure proper reliability, availability, and maintenance. PHM can be used to determine how long a machine can function before failure by predicting the Remaining Useful Life (RUL). Neural networks have been used for RUL prediction, but these data-driven models rely solely on data to explicitly integrate knowledge. Recently, authors have proposed physics-informed neural networks (PINNs) to address this limitation. PINNs are neural networks that incorporate expert knowledge and physics in different ways (observational, inductive, and learning bias). Despite their significance, these models tend to be case-dependent and challenging to configure. In this work, we propose statistical neuron units that can be integrated into any neural network. The proposed neuron units extract features from raw data using various statistical functions. Importantly, these modules can be located in different parts of the neural network, and they can be optimized automatically by backpropagating the modules' weights during training. In a study involving bearing degradation behavior, we compare a classical neural network with our modular version. Our proposed RUL estimation model outperformed the baseline, with a reduction of 13% in the root mean square error and a reduction of 7% in the mean absolute error. We also observe an increase of 40% and 21% for the $\alpha - \lambda$ accuracy metric for an α equal to 0.1 and 0.2 respectively. Our code is available publicly on **Github**.

Keywords: Feature extraction, knowledge integration, optimization of parameters, interpretability, accuracy, modularity, neural network

1. INTRODUCTION

Prognostics and Health Management (PHM) is a critical aspect of modern industrial systems, enabling the early detection of faults and the implementation of timely maintenance and repair strategies. One of the key components of PHM is the prediction of the Remaining Useful Life (RUL), which estimates the time until a system or component fails. Accurate RUL prediction is essential for optimizing maintenance schedules, reducing downtime and costs (Ramezani et al., 2019). To predict the RUL, multiple approaches have been developed, which can be classified as physical models, data-driven methods, and hybrid methods (Hasib et al., 2021; Ferreira & Gonçalves, 2022).

Recently, models infused with domain expertise have received much attention, such as physics-informed neural networks (PINNs), a subfield of neural learning that incorporates explicit prior knowledge (Nguyen et al., 2019). This knowledge can come from two sources: scientific knowledge and expert knowledge (Willard et al., 2022; Kang et al., 2021). Scientific knowledge spans a broad spectrum of domains and engineering disciplines, such as empirical equations (J. Wang et al., 2020) or high-resolution bearing dynamic simulations serving as a method for training the model (Sobie et al., 2018). Expert knowledge refers to knowledge obtained through experience that can be used for various purposes during the process of selecting and developing features.

Despite some successful cases of knowledge integration in data-driven models, some limitations persist (Dourado & Viana, 2020; Nascimento & Viana, 2019). Typically, knowledge inclusion is predetermined and fixed, so it cannot be optimized during training. Another challenge is the interpretability of the model, which remains an issue. The lack of explainability power of neural networks makes it difficult to understand how certain models use knowledge in their predictions (Faroughi et al., 2022).

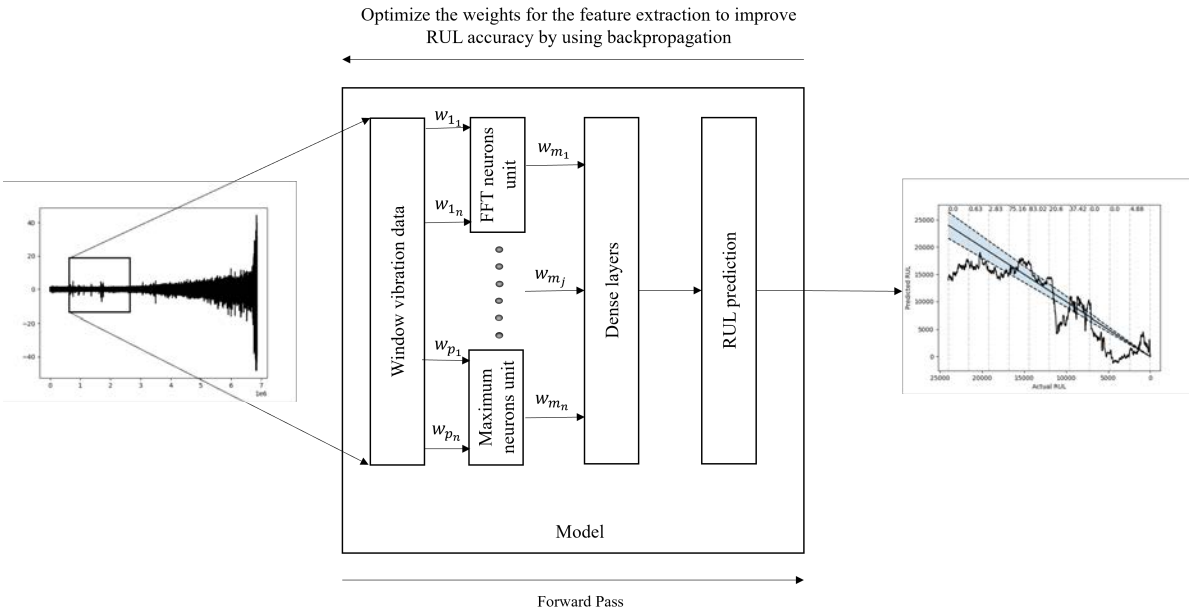

Figure 1. A generic diagram of how one neural network model incorporating the neuron units works. At first, a portion of the vibration signal is fed to the neural network model. This vibration signal is then passed to the different neuron units, which first weight the data received by their own weight and then extract the features needed. The different features extracted are then fed to the dense layers, which are then used to predict the RUL. During training, the neural network model optimizes the weights through backpropagation.

This paper proposes the concept of "knowledge-infused statistics" neuron units for neural networks. These modular units aim to make the structure of neural networks more accurate. Our proposed approach allows the model to train and optimize statistical knowledge during the training stage. Importantly, our proposed neuron units incorporate knowledge that can be fine-tuned and optimized. Since they are modular, these neuron units can be located/ positioned at various locations within the neural network, providing flexibility and adaptability. This novel approach improves neural network performance by optimizing knowledge-infused statistics neuron units.

We investigate the impact of 21 novel neuron units in a bearing case study. Bearings play a crucial role in machinery and mechanical systems, enabling smooth rotation, friction reduction, and support for heavy loads, ensuring operational efficiency and reliability. Our proposed neuron units aim to optimize (improve/enhance) feature extraction during training. The bearing case study is sourced from FEMTO[1] University (Nectoux et al., 2012).

In the implementation of 21 neuron units, we explore the impact of three **novel** neuron configurations: Single Feature Extraction (SFE), Multiple Feature Extraction (MFE), and Weighted Multiple Feature Extraction (WMFE). The SFE type extracts only one feature, while the MFE type extracts multiple features simultaneously. The WMFE layer extracts multiple features and computes/weights the importance of the extracted output features.

The contribution of this paper can be summarized as follows:

- **Modular knowledge-infused statistics Integration:** Introduction of 21 modular and statistical neuron units within a neural network for predicting bearing residual life.
- **Accuracy:** By incorporating these neuron units, we improve the network's ability to extract the features in an optimized way, which, in this case study, led to an improvement in RUL predictions.

In Fig.1, we present a diagram of how our proposed approach works. First, a window of vibration values is given as input to the neural network model. These data are used by the different neuron units to extract features. Each neuron unit has input and output weights (as well as bias) that are used to capture and measure the importance of the features (Fast Fourier transform, skewness factor, maximum amplitude, etc.). The neuron output is given to the dense layers, which then proceed to predict the RUL. The model updates all the weights automatically (by backpropagation) to obtain a better RUL prediction.

The remainder of this paper is organized as follows: Section 2 provides a review of the literature in PHM and the different modeling approaches. Section 3 describes the methodology

[1]FEMTO = Franche-Comté Électronique Mécanique Thermique et Optique

employed in this study and the evaluation metrics. Section 4 presents the case study used in this paper in more detail. Section 5 presents the results obtained and their interpretation. Finally, Section 6 concludes the paper and outlines directions for future research.

2. Related Work

Prognostics and Health Management (PHM) is a significant area of research that has gained attention in recent years. One of the primary goals of PHM is to predict the Remaining Useful Life (RUL) of engineering systems and components. This is important because it helps to ensure the safety and reliability of these systems, reduce maintenance costs, and optimize maintenance schedules (Guo et al., 2019). To predict the RUL, multiple approaches have been proposed: physics of failure (PoF), data-driven (DD) and hybrid approaches (L. Liao & Köttig, 2014).

The PoF approach in PHM employs mathematical representations that describe the underlying physics of the system under study (Cubillo et al., 2016). To improve the precision of the remaining useful life (RUL) estimate, Q. Wang et al. (2021) proposed a linear mapping technique that directly relates the degradation characteristics of the bearing with its remaining useful life. However, when a linear algorithm is not feasible due to nonlinearities, an alternative approach is needed.

For example, the Extended Kalman Filter (EKF) can be employed to transform the nonlinear problem into a linear one. Singleton et al. (2014) applied an EKF to predict the RUL. However, linearization can lead to unstable filters if the assumption of local linearity is violated, affecting the accuracy and reliability of the estimation process. The unscented Kalman filter (UKF) is also used for RUL prediction (Cui et al., 2019). While prognostics methods based on Kalman filtering approaches can provide precise predictions of the RUL, they typically assume perfect knowledge of the failure system, which is not feasible in most cases.

Another type of algorithm used for physics of failure are particle filters (PF). PF are a type of sequential Monte Carlo method that can effectively handle nonlinear and non-Gaussian degradation processes (Y. Wang et al., 2021). They represent the state of a system using a set of weighted particles, which are updated with new measurements (Elfring et al., 2021). Cai et al. (2020) proposes a similarity-based particle filter method for remaining useful life prediction with improved performance by incorporating historical knowledge and providing probabilistic RUL estimates.

The DD approach relies on the historical data of a system to predict its future state. According to Kefalas et al. (2019), data-driven approaches rely mainly on statistics or machine learning. Statistical models rely on statistical parameters to make predictions (Si et al., 2011). Xiao et al. (2018) proposes a modified duration-dependent hidden semi-Markov model for online machine health prognostics. Jia & Zhang (2019) presented a Bayesian model to reduce model uncertainty for the prediction of RUL.

Artificial Neural Networks (ANN) have been used to estimate RUL (See a review in Ge et al., 2021). Kang et al. (2021) used the Principal Component Analysis (PCA) for data preprocessing and a Multi-Layer Perceptron (MLP) for the prediction of RUL in production lines. Zhao et al. (2019) utilized a recurrent neural network (RNN) to capture temporal dependencies in the degradation process. They first evaluated the trend features to feed their model with the best trends. Zhang et al. (2018) introduced a method to predict RUL of lithium ion batteries using an LSTM.

The dependency on historical run-to-failure (RTF) data is a common issue when implementing DD approaches for RUL prediction. The availability of RTF data is limited, especially for critical components (Hakami, 2024). This limitation poses a significant challenge, as the effectiveness of predictive maintenance, condition-based monitoring, and other DD methods is highly dependent on this historical information. Without comprehensive data on past failures, models may struggle to accurately predict and prevent future breakdowns in crucial equipment.

To overcome the limitations of physical and DD approaches, (hybrid) machine learning models integrating knowledge have been developed (Karniadakis et al., 2021; Dash et al., 2022). This knowledge can be incorporated by transforming the input data, the loss function, or the model. We designate this observational bias, learning bias and inductive bias respectively (Karniadakis et al., 2021). Chao et al. (2022) presents a novel hybrid framework that combines information from physics-based performance models with deep learning algorithms for prognostics. Chen et al. (2022) proposes a model that integrates the knowledge of natural degradation of mechanical components, which is monotonic throughout the life of the bearings and is characterized by temperature signals. Y. Yu et al. (2020) introduced a physics-guided Recurrent Neural Network (RNN) for structural dynamics simulation, where they integrate the underlying physics of structural dynamics into data-enabled machine learning models for the training and prediction of ML models. Xiong et al. (2023) proposed a hybrid framework that combined the controlled physics-informed data generation approach with a deep learning-based prediction model for prognostics.

Physics-Informed Neural Network (PINN), have also been proposed as a way to implement knowledge inside a neural network. X. Liao et al. (2023) introduces a self-attention mechanism into the architecture of the neural network, allowing the mapping of raw data to a hidden state space. Dourado & Viana (2020) presented a PINN modeling approach for the estimation of bias in the prognosis of corrosion fatigue.

The physics-informed layers embed well-understood physical phenomena, and the data-driven layers are used to implement the physical processes that are difficult to model.

Despite the introduction of knowledge within the model, limitations persist (Huang & Agarwal, 2023). Although hybrid models offer the advantage of incorporating knowledge into the learning process, the interpretability of the learned representations and the basis for predictions can still be limited. This lack of transparency can cause problems, especially in critical domains. Neural network interpretability is crucial, as it allows one to explain how and why a neural network produces specific outputs, enhancing trust and understanding. Various methods aim to provide interpretability by visualizing activations, weights, or features and generating textual explanations (Linardatos et al., 2020; Fan et al., 2021).

In the context of Artificial Neural Networks (ANNs), a Modular Neural Network (MNN) can be decomposed into subnetworks based on its connectivity pattern, allowing for a more granular understanding of the network's behavior (Kirsch et al., 2018). Amer & Maul (2019) classified modularization techniques into four main classes (domain, topology, learning, and output), where each class represents the attribute of the neural network manipulated by the technique to achieve modularity. Understanding the modular structure of neural networks can provide insight into their inner workings, making them more interpretable.

This study introduces novel (modular) neuron units that integrate statistical knowledge for neural network training. The concept behind these "neuron units" is their ability to extract essential characteristics (features) from the model during training. Importantly, this feature extraction is automatically optimized by the network. Using these modular layers, we can also visualize the significance of different parts of the input signal (in this case a vibration signal) to predict the RUL.

3. METHODOLOGY

The subsection 3.1 presents our hypothesis for our research framework. Subsection 3.2 describes our approach that we used to test our hypothesis. Subsection 3.3 presents the features that we used to train the models and subsection 3.4 presents how we evaluated the different models.

3.1. Research Hypothesis

We investigated the following research question:

How can we develop (modular) knowledge-infused statistics neuron units for the prediction of RUL?

And with this question, we have the following hypothesis:

A neural network incorporating knowledge-infused statistics neuron units will present an improvement in RUL prediction accuracy.

The use of these "knowledge-infused statistics" neuron units is intended to improve the model at the level of accuracy (and interpretability). By incorporating these novel neurons into the neural network architecture, we aim to facilitate the integration of feature extraction within the model, allowing it to optimize feature selection.

In this paper, we infuse statistical knowledge into the neuron units. We develop 21 neuron units, each incorporating a different and specific statistical feature. With these neuron units we can better understand the contributions of each neuron to the overall prediction performance, enabling more informed decision-making and model refinement. In addition, we can reuse these neuron units in different tasks (Castillo-Bolado et al., 2021). The statistical knowledge that is implemented is generic (max, min, Fourier transform, etc.). We can position the neuron units in different locations within the neural network which can result in multiple model configurations.

We evaluate our hypothesis on the PRONOSTIA bearing data provided by FEMTO (Nectoux et al., 2012). This dataset constitutes a prognostics case study for bearings based on laboratory RTF vibration signals. The PRONOSTIA dataset is explained in more detail in Section 4.

3.2. Modular Approach

In this study, we use a Multi-Layer Perceptron (MLP), a type of neural network widely used in artificial intelligence (Park & Lek, 2016). The connections between neurons are defined by weights, and the output signals are determined by the sum of the inputs to the node, adjusted by a nonlinear transfer function known as the activation function.

To train an MLP, features are extracted from the data and then fed to the model. In this paper, we do feature extraction inside the network, by designing modular neurons units. By organizing the feature extraction process into modular units, we aimed to enhance the MLP's capacity to learn and extract relevant features effectively for RUL prediction. Each modular unit acts as a neuron within the MLP, focusing on capturing specific characteristics present in the input data.

For example, we have developed modular neuron units to extract fundamental features such as peak-to-peak amplitudes, frequency domain features, and vibration characteristics. In addition, we incorporated modular neuron units to extract multiple features simultaneously, allowing a more comprehensive representation of the features.

This modular design facilitates the integration of statistical knowledge into the model architecture. The neuron units are called modular because their architecture allows them to be placed in different parts of the model. As these modules are responsible for feature extraction, they are placed after the input layer, and their output is then fed into the hidden layers for further processing. Fig.2 illustrates how these modular

neuron units are implemented within the MLP.

Each neuron unit has input- and output trainable weights that are optimized during the training process. The input weights equal the input size. In this case, we fed an input with 500 vibration values. We have chosen 500 for computational effectiveness. The neuron unit have 500 trainable weights. We initialize the weights with ones as values.

The neurons multiply the inputs by the weights and extract the features from these weighted inputs. We have three types of neuron unit: single feature extraction (SFE), multiple feature extraction (MFE) and weighted multiple feature extraction (WMFE).

The SFE neuron unit extracts one feature and performs a single extraction operation. For example, to extract features from the frequency domain, the vibration raw dataset is fed to the Fast Fourier transform neuron units and then given to the other neuron units to extract features. As this type of neuron unit performs a single extraction or operation, we call it Single Feature Extraction (SFE).

The MFE neuron unit integrates multiple features inside of it and extracts an array of features. In this case, there are two variants: one in which the features are then fed to the dense layers and one in which the feature arrays are multiplied by a weighted array. This array modifies the values of the features in a way that allows the model the possibility to choose which one was more impactful for RUL prediction. We designate the first version Multiple Feature Extraction (MFE), and the second one is presented as Weighted Multiple Feature Extraction (WMFE).

The first type of module (SFE) is the most simple, as the weights are updated only to extract one feature or perform one operation. In contrast, in the second one (MFE), the weights are updated to extract multiple features efficiently. The third option (WMFE) is the most complex. We created these three modules to extract multiple features classified into fundamental, frequency, and vibration features.

In this work, we focused on the integration of features inside the model; thus, we did not do feature selection. We used the model to optimize feature extraction by itself, where the implementation of trainable weights could help the model do feature selection. However, as they are modular, adding or removing features in the model can be done in a flexible way. These neuron units were not built with the integration of an activation function, as we did not want to force non-linearity on the features extracted. Instead, the dense neurons use the ReLu activation function.

In this paper, we did not study the impact of modular neuron units as the output layer. However, the output layer can be changed to adapt to any necessary prediction. For example, it is possible to implement a modular neuron unit that extracts the minimum as the last layer if the desired prediction is the minimum RUL remaining. The topic of which activation function to use remains a research question for our group.

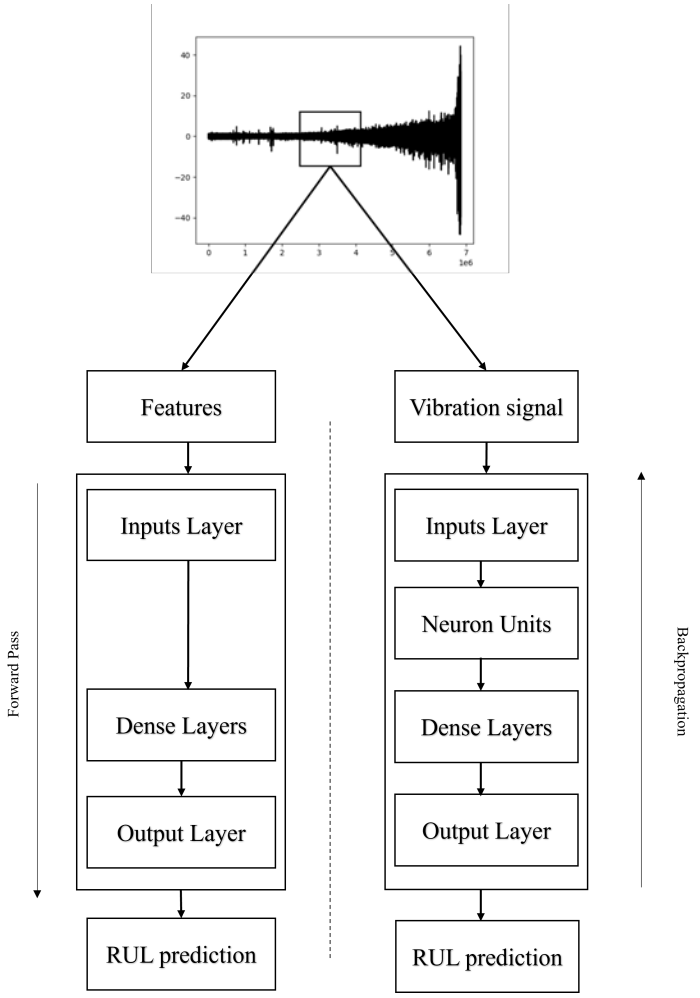

Figure 2. An MLP model without our proposed neuron units on the left and an MLP model with them on the right. The two models have the same number of dense layers with the same number of neurons. The inputs given to the model are different. In the left side model, we feed the model with the features extracted from the vibration signal, while on the right side, we give the model a raw vibration signal.

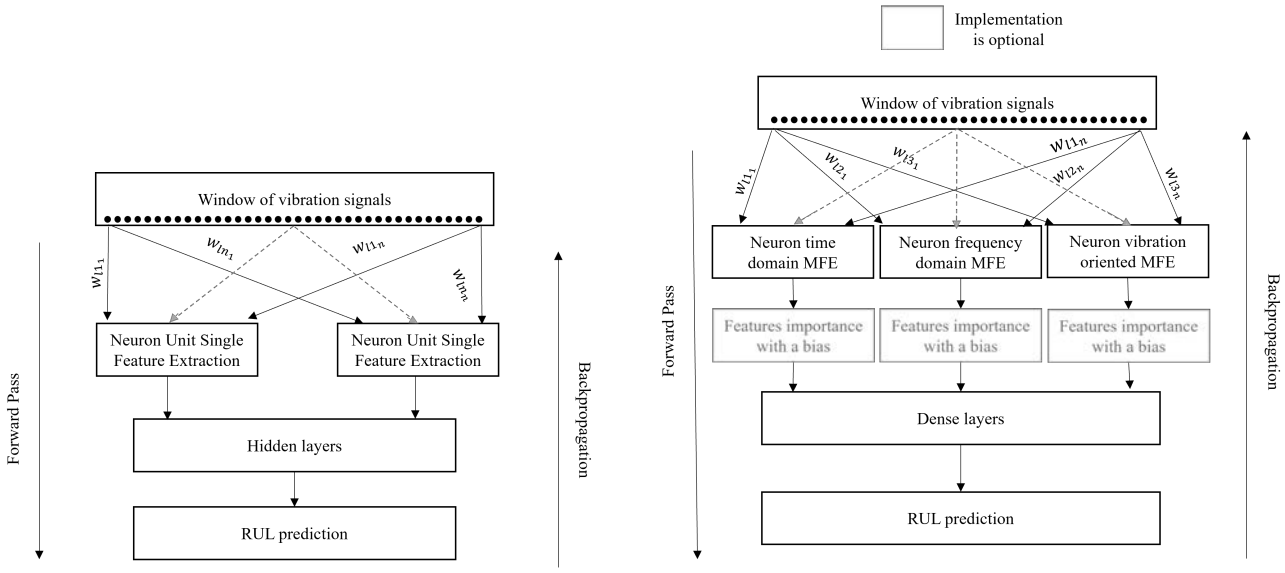
Table.1 shows the different groups and features used. Fig.3 shows the architecture of the model incorporating SFE, MFE and WMFE neuron units.

3.3. Feature Selection

We utilize multiple features to predict the Remaining Useful Life (RUL). Initially, we implemented classical statistical features, which were extracted from the raw time series data of the vibration signal. These features were termed fundamental because of their general nature. Subsequently, we implemented features in the frequency domain. Initially, we uti-



(a) SFE model

(b) MFE and WMFE model

Figure 3. Figure (a) details how a Single Feature Extraction (SFE) neuron units work inside a MLP. Each SFE has its own weights that they multiply by the inputs received. Figure (b) shows how a Weighted Multiple Feature Extraction (WMFE) and Multiple Feature Extraction (MFE) work. As in the SFE, each neuron unit has its own weights that they multiply on the inputs. However, they extract multiple features in one neuron unit, features that are weighted in a WMFE.

lized the Fast Fourier Transform (FFT) to extract frequency features. Then, we computed the magnitude by taking the absolute value of the FFT. Following the magnitude calculation, we were able to compute the Power Spectral Density (PSD) and the Power ratio of Maximum defective frequency to Mean (PMM) (J. Yu, 2011). From the PSD, we extracted the maximum, sum, mean, and the variance. The final feature type was signal features, encompassing general signal-based statistical metrics applicable to any type of signal, including vibration signals (Khlaief et al., 2019). Table 1 displays all the features used. These features were selected because they are usually used for vibration case studies (Riaz et al., 2017).

3.4. Evaluation Methodology

Since we are dealing with a small dataset, we applied a leave-one-out (LOO) strategy to evaluate the models. In the LOO strategy, we remove one of the bearings from the training set and use it as a test set, leaving us with the remaining bearing vibration signals for the training and validation sets. We employed three widely used metrics in the evaluation: the root mean square error (RMSE), the mean absolute error (MAE) and the $\alpha - \lambda$ metric. These metrics provide valuable insights into the accuracy and precision of the models' predictions. The equations for RMSE and MAE are described in Eqs.1 and 2.

$$\sqrt{\sum_{i=1}^{n}(x_i - y_i)^2} \tag{1}$$

$$\sum_{i=1}^{n}|x_i - y_i| \tag{2}$$

The third assessment method was the α-λ metric, which is a binary measure determining if a prediction at a given time t_λ falls within the α bounds. This metric measures how well predictions remain within an accuracy cone that narrows over time. We split the total time interval into 10 equal time intervals and calculated the percentage of predictions that fell between the $\alpha = 0.1$ and $\alpha = 0.2$ bounds. We have chosen two strict α to evaluate which models predictions were the most accurate, as a higher percentage of predictions inside the cone indicates a more accurate and reliable RUL prediction model.

4. Case Study

To verify the effectiveness of the proposed methodology, we use the PRONOSTIA bearing dataset. PRONOSTIA is an experimentation platform dedicated to testing and validating bearing fault detection. Fig.4 presents an overview of PRONOSTIA.

The PRONOSTIA dataset was part of the IEEE PHM 2012 Prognostic Challenge. PRONOSTIA comprises three main

Table 1. Features used and their formula

Fundamental		**Frequency**		**Vibration**	
Name	Formula	Name	Formula	Name	Formula
Maximum	$\max(x)$	Maximum	$\max(x)$	Peak to Peak	$\lvert \max(x) - \min(x) \rvert$

Root mean square	$\sqrt{\frac{1}{n}\sum_{i=1}^{n} x_i^2}$			Skewness	$\frac{\sum_{i=1}^{n}(x_i-\bar{x})^3/n}{s^3}$
				Kurtosis	$\frac{\sum_{i=1}^{N}(x_i-\bar{x})^4/n}{s^4}$

parts: a rotating part, a degradation part, and a measurement part:

- The rotating part. The asynchronous motor is the actuator that allows the bearing to rotate through gearing and different couplings. The rotation motion of the motor is transmitted through a gearbox, allowing the motor to reach a speed of 2830 rpm. The human-machine interface of PRONOSTIA allows the operator to change the operating condition.
- The degradation part. A radial force is applied to the test ball bearing, thus reducing the bearing's life duration. This radial load is generated by a force actuator in a pneumatic jack.
- The measurement part. The measurement part acquires the bearing's operation condition and the bearing's degradation. The bearing's degradation is based on two types of sensors: vibration and temperature. The acceleration measures are sampled at 25.6 kHz, and the temperature measures are sampled at 10 Hz.

The dataset consists of three different operating conditions, with a total of seventeen run-to-failure vibration signals given, including six training datasets and eleven testing datasets. The dataset is small, and the life duration of a bearing is relatively large (from 1h to 7h) for the sampling rate. In Fig.5, we present two vibration signals. We did not include all six vibration signals to improve clarity.

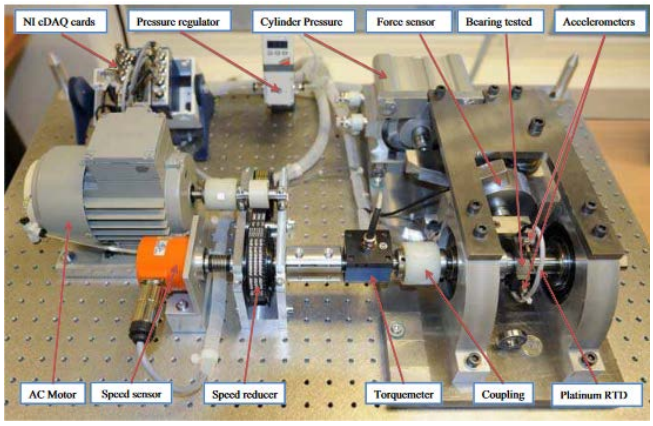

Figure 4. Overview of PRONOSTIA.

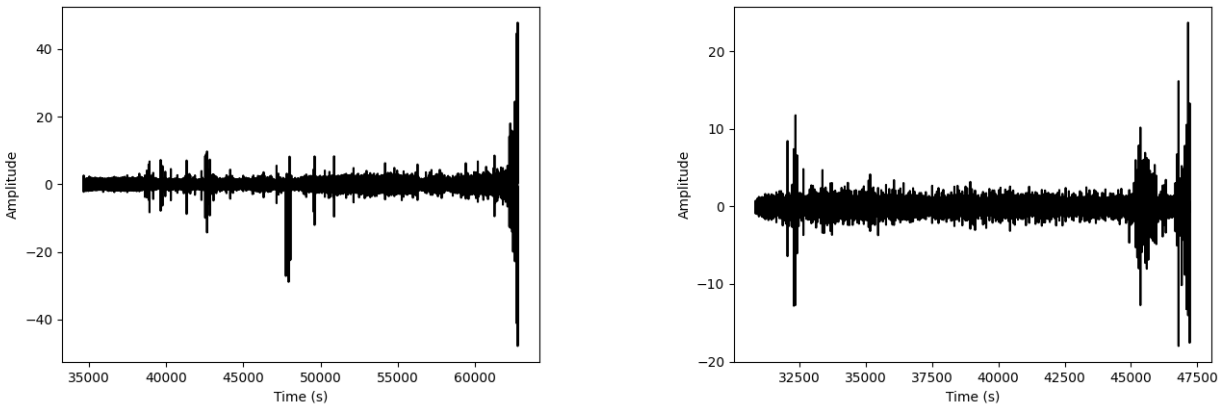
5. Results and Discussion

We can confirm our hypothesis: **A neural network incorporating knowledge-infused statistics neuron units will present an improvement in RUL prediction accuracy**. We see in Table.4 and Table.5 on the first bearing that the implementation of MFE neuron units, helped achieve the best $\alpha - \lambda$ score. The MFE model achieved the best RMSE and MAE for the first bearing, according to Table.2. We can see the predictions made by the different models for the first bearing in Fig.6. We can see clearly that the MFE model prediction is the closest one to the true RUL, followed by the baseline model, and then by the SFE and WMFE models.

For the third bearing, despite the baseline model performing better than the other model on the end-of-life, the SFE model



(a) Bearing 1

(b) Bearing 6

Figure 5. Vibration raw signals of the different bearings.

still performs better on the $\alpha - \lambda$ score. With an $\alpha = 0.2$ the SFE model scores a total $\alpha - \lambda$ score of 29 ± 42 while the baseline model scores a total $\alpha - \lambda$ score of 22 ± 21. However, the baseline, has the lowest RMSE and MAE.

If we compare the mean RMSE and MAE values obtained by the different models, we see that the SFE model obtains the lowest values, as seen in Table.3, whereas the baseline is the second best, the WMFE the third one, and the MFE the last one. For the $\alpha - \lambda$ we achieves the best score with the model incorporating the SFE neuron units, while the MFE model is the second best for a small α while the baseline performs better than the MFE model on a higher α.

The results demonstrate that the implementation of knowledge-informed statistics neuron units present an improvement in RUL prediction accuracy, as we have the MFE outperforming the different models in the first bearings and the SFE performing well on the other bearings. These neuron units leverage statistical properties in the model to enhance the RUL prediction.

By adding these knowledge-infused statistical neuron units, we expect to improve interpretability, as we can study the weight evolution during training. The weight evolution can guide us regarding how the model optimizes the feature extraction to predict the RUL. As we know, the model gives a weight to each vibration value given as input. We could then evaluate which part of the signal is more essential for extracting the features needed for an accurate RUL prediction.

6. Conclusion

The objective of this study was to develop a set of novel neuron units for the classical multi-layer perception (MLP). We have evaluated the importance of having these knowledge-informed neuron units inside a neural network aimed at Remaining Useful Life (RUL) prediction. The neurons were infused with statistical knowledge. Concretely, we have implemented 21 neuron units that capture time domain, frequency domain, and time-frequency domain statistical knowledge. Examples of this type of knowledge are the Fourier transform and kurtosis/skeweness.

By using the proposed neuron units, one can create a neural network that incorporates knowledge in an easy and modular way. To test our methodology, we used our network on a bearing case, PRONOSTIA, to predict the RUL. We have demonstrated that these statistical neuron units improve the model prediction compared to a baseline model with classical feature extraction.

Our results showed that the best overall model was the one that incorporated the single feature extraction (SFE) neuron units. This model was able to outperform the baseline on the overall RMSE, MAE and on $\alpha - \lambda$ accuracy. Regarding the $\alpha - \lambda$ accuracy metrics, the SFE model obtained the best overall accuracy. In contrast, the multiple feature extraction (MFE) obtained the second-best score for a strict α (0.2) and the best $\alpha - \lambda$ accuracy metric for the first bearing.

Despite the good performance of MFE on the first bearing, this approach failed to replicate this performance on the remaining bearings. Importantly, the WMFE obtained the best score at the End-of-Life. However, this model did not achieve good accuracy in the previous time intervals.

One potential reason for the underperformance of the models incorporating MFE and WMFE neuron units could be attributed to their architectural design. As they include more features inside of them, their optimization is more challenging. Another reason is that the selection of the features in-

Table 2. RMSE and MAE results for the predictions made on the different bearings by the different models. WMFE stands for Weighted Multiple Feature Extraction, MFE for Multiple Features Extraction, and SFE for Single Features Extraction.

cluded in them was made arbitrarily. A way to improve this type of neuron unit is to have a neuron unit composed of all the features instead of splitting them into three different neuron units. This will be researched in future work. The difference between the performance of the MFE and WMFE can be explained by the weights implemented on the feature output array. As the dense layers already have their own weights that are multiplied by the inputs they receive, in this case the feature array, having a weight that does the same operation in the WMFE can be counterproductive.

The proposed models (SFE, MFE and WMFE) were constructed using a typical neuron unit (dense) from TensorFlow, which limits their ability to retain information from prior raw vibration signals and updates the weights solely for a particular time during the bearing's lifespan. As a result, these neuron units might struggle to capture complex patterns in the vibration data. Another limitation of these neuron units is that they need to adhere to the forward and backward propagation mechanisms, which can restrict the complexity of the extracted features.

Another area of optimization can be the placement of neuron units in different locations of the model. In this study, the neuron units were only added at the beginning of the model, after the input layers but before the hidden layers. We can also study the impact of our neuron units at the output layer. For example, because we are predicting the RUL, the minimum neuron unit can be used as the output layer, as the model is attempting to predict the minimum value of the RUL from the values provided as input.

More research is needed to determine whether the implementation of memory-based modular neuron units can achieve better results. Moreover, given that we are dealing with time series data, changing the model architecture could be beneficial for both the baseline and the proposed models. For instance, incorporating long-short term memory (LSTM) layers could improve the model's ability to capture temporal dependencies and patterns in the data. Additional research may impose constraints on the neuron units trainable parameters, forcing the model to extract features in a manner that differs from the existing neuron units. Given their modular nature, we might consider incorporating them not only after the input layer but also in other parts of the model architecture.

Lately, this model was trained offline, and future research can also focus on how to train these neuron units in an online case study where the data will be fed continuously to the model.

Although the primary focus of this study has been on improving prediction accuracy, we recognize the importance of interpretability and aim to leverage knowledge-infused neuron units as a stepping stone towards more transparent and explainable RUL prediction models. Future research efforts will explore techniques to further enhance the interpretability of these models, for example, by the implementation of dif-

ferent neuron units, tracking the weights value during training, or by creating different neurons units that can replace the usual dense layers.

The contribution of this research is the proposal of knowledge-informed neuron units infused with statistical knowledge. These neuron units implement a novel method of extracting statistical features and feeding them to a model, in which the network optimization by backpropagation has a greater impact on the statistical features extracted than if they were directly fed to the model.

ACKNOWLEDGMENT

We would like to thank Dr. Manuel Arias Chao and Kristupas Bajarunas for their help and feedback on this work.

BIOGRAPHIES

Thomas Pioger (MSc. in Aerospace and Computer Engineering, Institut Polytechnique des Sciences Avancées, September 2021) is currently a Ph.D. student at the Aerospace Faculty of TU Delft since 2022. His main research interests are in the area of Modular Neural Networks for Prognostics and Health Management with a particular focus on the Remaining Useful Life prediction.

Marcia L. Baptista (BS and MSc. in Informatics and Computer Engineering. Instituto Superior Tecnico, Lisbon, Portugal September 2008) is an Assistant Professor at the Aerospace Faculty of TU Delft since 2020. She holds a PhD from the Engineering Design and Advanced Manufacturing (EDAM) program under the umbrella of MIT Portugal. Her research focuses on the development of prognostics techniques for aeronautics equipment. Her research interests include eXplainable Artificial Intelligence (xAI), machine learning, hybrid modeling, maintenance and prognostics.

SurvLoss: A New Survival Loss Function for Neural Networks to Process Censored Data

ABSTRACT

This paper presents SurvLoss, a novel asymmetric partial loss and error calculation function for survival analysis and regression, enabling the inclusion of censored samples. An observation in a dataset for which the complete information regarding an event of interest is not available is called censored. Censored samples are ubiquitous in the industry and play a crucial role in Prognostics and Health Management (PHM) by providing a realistic representation of data, improving the accuracy of analyses, and supporting better decision-making in various industries and the healthcare sector. The proposed approach can effectively equip the conventional regression loss functions such as Mean Absolute Error (MAE), Mean Squared Error (MSE), or Root Mean Squared Error (RMSE) with the ability to process censored samples. This can impact the field hugely by providing a more accessible usage of neural network models in survival analysis. The proposed survival loss incorporates censored samples by penalizing predictions outside the censoring region and skipping them otherwise. Then, it uses weighted averaging to aggregate the loss from censored samples with the loss from event samples. Unlike many other methods in the field, the proposed model distinguishes itself by avoiding superficial assumptions and exclusively relies on the available information, considering the entirety of the data.

We compared the proposed loss function with its baseline on two publicly available datasets. The first dataset, called C-MAPSS, is from NASA Turbofan Jet Engines simulation, and the second is a recently published real-world dataset from SCANIA trucks. The goal of both datasets is to predict the remaining useful life (RUL) of the machines. The experimental results show that optimization algorithms for training deep neural networks like Adam can effectively utilize the proposed loss function to calculate gradients, update the model's weights, and reduce training and test errors. Moreover, the proposed model outperformed the baseline by taking advantage of the censored samples. The proposed loss function paves the way for the employment of advanced architectures of neural networks with bigger training sizes in survival analysis.

1. INTRODUCTION

This paper deals with the problem of time-to-event prediction. Specifically, the prediction of time until a component fails or, in other words, the component can no longer perform its intended functionality. The literature has three main directions for tackling this problem. The remaining useful life prediction (Revanur, 2020; Altarabichi, 2020; Karlsson, 2023), risk classification (Rahat, Pashami, Nowaczyk, & Kharazian, 2020), and survival analysis (Wang, Li, & Reddy, 2019). While each of these directions has benefits and drawbacks, a shared challenge among all three approaches is dealing with the censored samples. While some methods, like Cox proportional hazards (Cox, 1972), consider them using the partial likelihood function, most methods simply ignore censored samples. Nonetheless, censoring is an inherent aspect of time-to-event prediction, especially in long-term studies. Censored samples refer to data points for which the event of interest (such as death or failure) has not been observed by the end of the study or at the time of analysis. Censoring can happen, for instance, when the exact time of the event is unknown; typically, since the event has not occurred yet, the subject has been lost to follow-up, or the study finishes before we observe the event. With the censored samples, we have incomplete information about the individual, i.e., we don't know when the event happened. Still, we know the event has not occurred during a specific period.

Generally, three types of censoring are recognized in survival analysis (Kleinbaum & Klein, 1996). The right censoring

where the event of interest has not happened for some individuals by the end of the study, but it may occur at an unknown time in the future. In other words, the event time for these individuals is known to be longer than the observed follow-up time. The left censoring happens when we know that the event of interest happened before a specific time, but we don't know precisely when, i.e., the survival time is shorter than the study's start time. Finally, we have interval censoring, where we only observe the event that has happened within a specific time window, but again, we don't know precisely when. Right censoring is considered the most common type; hence, it is regarded as the primary focus of this paper. It is worth mentioning that although we only looked at the right censoring, the proposed loss function can be generalized similarly to all three types.

Censoring is prevalent in the industry for many reasons, such as the long life of components or changes in the conditions of the equipment, like the expiry of a warranty period. In real-world industrial applications, it is common to access much more censored samples than those that fail. Depending on the cases, the ratio of censored to death varies, but this ratio can reach, for instance, 30 censored samples per 1 death or more. Most available methods in the field struggle with consuming censored samples and end up ignoring these samples. This means that they essentially ignore a significant portion of their available data.

An exception to this general rule is methods based on survival analysis designed to take advantage of the censored information. However, survival analysis is much more common in clinical studies than in industry due to its practical limitations, such as the inability to process big data sizes or their shortage in handling temporal information, like sequences of observations from the same individual over time. Additionally, they mostly rely on the Cox proportional assumption, which is known to be naive and not genuine in many real-world cases. On the other hand, there is no way to validate the survival functions produced by these models as we only have access to the time of the event, and the actual degradation curves are unknown. That is why, in many industrial applications, we rely on the median or the mean point of the survival functions. Concordance index (C-index) (Harrell, Califf, Pryor, Lee, & Rosati, 1982) is the typical survival analysis evaluation metric which only considers the order of the events and is known to be biased (Hartman, Kim, He, & Kalbfleisch, 2023; Alabdallah, Ohlsson, Pashami, & Rögnvaldsson, 2024). Most survival datasets are clinical records of patients with a very small number of data points (around 1000) and features (around 10), and there are limitations regarding the proportion of censored data compared to event instances. In most studies, clinical researchers maintain this percentage below 50%.

Additionally, specific constraints are related to applying neural networks within the survival analysis domain. While a handful of methods have been proposed to merge the capabilities of neural networks with survival analysis (Katzman et al., 2018; Kvamme, Borgan, & Scheel, 2019), the prediction accuracy for deep learning methods remains comparable to the classical methods such as Cox and Random Survival Forest (Ishwaran, Kogalur, Blackstone, & Lauer, 2008) in many datasets. It is shown that the performance gain using deep learning or neural network-based approaches is often around 0.02 to 0.03 in concordance index (Chen, 2020). This is primarily due to various underlying assumptions made by methods, such as the constant ratio of risk over time or the small sizes of the standard survival analysis datasets. On the other hand, the neural network field is growing rapidly, and it is crucial to search for new ways to employ their incredible computational power in fields such as time-to-event prediction.

This paper contributes to the mentioned challenge by introducing a new loss function called survival loss, which essentially enables conventional neural networks to process censored samples along with the standard event samples. The idea is to penalize the model in accordance with the information available. For the event samples, the survival loss performs similarly to an ordinary loss by considering the distance between the model predictions and actual values. For the censored samples, the survival loss only penalizes the model if the predicted value falls outside the censoring time interval. As an example for the right censored samples, the model gets penalized only if its prediction is below censoring time (which we already know the event has not happened in that period). On the other hand, if the model's prediction is larger than the censoring time, the proposed survival loss effectively ignores that sample in the loss calculation as there is no evidence of the precise event time. Ultimately, the final loss value will be reported as a weighted average of the error values from censored and event samples. The weighting of the two error values takes place in accordance with the number of considered samples in each part. The following section defines the proposed loss function in more detail.

2. METHODOLOGY

We first visually explain the intuition behind the proposed survival loss and later define it mathematically. Figure 1 describes how the proposed survival loss function calculates the amount of error for an event sample, right-censored sample, left-censored sample, and interval-censored sample. The follow-up region (represented in red) indicates the period where we monitored the individual, and we know that the event of interest has not occurred inside it. The censoring region (represented in green) displays the period where the event has happened or will happen inside it, but we don't know precisely when. Finally, the red-dotted region represents the time in the future after the event has occurred.

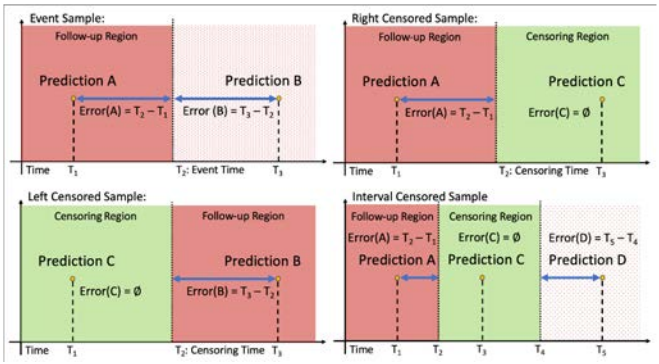

Figure 1. Visual explanation of the proposed loss function.

The loss calculation for an event sample is straightforward. The distance between prediction and actual event time indicates the amount of error. Here, we can use any loss calculation formula like mean absolute error (MAE), mean squared error (MSE), root mean squared error (RMSE), etc. For the sake of simplicity, this paper primarily focuses on the MAE, but any other mentioned error measurement functions can interchangeably be employed.

Unlike the event samples, the proposed loss uses an asymmetric error calculation algorithm for the right censored sample. If the prediction falls within the follow-up region (i.e., the outside of the censoring region), we penalize the prediction according to its distance from the censoring time. Note that this error partially captures the whole error of the prediction as the event happens sometime after censoring time, and the actual error is greater than the proposed partial one. Since calculating the exact error for these samples is impossible, we resort to partial penalization. This partial error from the censored samples can help the optimization algorithm calculate gradients more accurately. Conversely, if the prediction falls within the censoring time, the amount of error is set to null. Note that a null error differs from a zero error since, in the former, we remove the sample from the total number of samples in the batch and, therefore, from the denominator of the averaging function. Finally, a similar logic can also handle the left-censored and interval-censored samples. Again, for the sake of simplicity, we primarily focus on the right censored samples and mean absolute error. Still, the method can be generalized to all censoring types and error calculation functions.

Figure 1 also provides some example prediction points and their associated error values for varying conditions. The errors for prediction A, B, C, and D are respectively $T_2 - T_1$, $T_3 - T_2$, $\emptyset$, and $T_5 - T_4$, where $\emptyset$ means we ignore the sample in the loss calculation.

Assume (X, t, δ) represents a random survival data point where $X \in \mathcal{R}^d$ is a d-dimensional covariate vector and $\delta \in \{0, 1\}$ is an event indicator such that $\delta = 1$, if we observed the event and $\delta = 0$ in case of censoring. Moreover, $t = \min(y, c)$ is the observed time, where $y \in \mathcal{R}^+$ is the actual event time and $c \in \mathcal{R}^+$ is the censoring time.

In the context of PHM and without loss of generality, we define the set of failed samples where the event of failing happened for them (i.e., $\delta_i = 1$) as:

$$(X_i, y_i)_{i=1}^{N_{Failed}} \tag{1}$$

and similarly the set of censored samples (i.e., $\delta_i = 0$) as:

$$\left(\widetilde{X}_j, c_j\right)_{j=1}^{N_{Censored}} \tag{2}$$

which means we divide the samples into two groups of failed (aka event) and censored samples where the total number of samples is $N = N_{Failed} + N_{Censored}$. Then, for a given predictive model f, we define $\hat{y}_i = f(X_i)$ and similarly, $\hat{c}_j = f(\widetilde{X}_j)$ as the output of the predictive model for the failed and censored samples. Note that we have access to the ground truth values for $f(X_i)$, but ground truth values for $f(\widetilde{X}_j)$ are unknown, and the only information we have regarding them is that the actual event time is greater than c_j. This means that we can only penalize the model if the prediction of the model $\hat{c}_j$ is less than c_j; otherwise, we ignore the sample in our loss calculation. Note that ignoring a sample in the loss calculation is different from having an error equal to zero for that sample since by ignoring the sample, we do not consider it in the total number of samples in the denominator of the loss function.

The new survival loss function is defined as a weighted sum of the error for the censored and failed samples:

$$E = \frac{N_{Failed} \times E_{Failed} + N_{Censored'} \times E_{Censored'}}{N_{Failed} + N_{Censored'}} \tag{3}$$

where $Censored'$ represents the set of samples for which the model predicts a survival time less than the censoring time, i.e., $\hat{c}_j < c_j$ and is defined as follows:

$$N_{Censored'} = \left\| \left(\tilde{X}_j, c_j\right) \quad given \quad \hat{c}_j < c_j \right\| \tag{4}$$

this means that $N_{Censored'} \leq N_{Censored}$ since:

$$\{\left(\widetilde{X}_j, c_j\right) \quad given \quad \hat{c}_j < c_j\} \subseteq \{\left(\widetilde{X}_j, c_j\right)\} \tag{5}$$

Then, equations 6 and 7 represent the standard calculation of the mean absolute error for the two groups of $Failed$ and $Censored'$.

$$E_{Failed} = \frac{1}{N_{Failed}} \times \sum_{i=1}^{N_{Failed}} |y_i - \hat{y}_i| \tag{6}$$

$$E_{Censored'} = \frac{1}{N_{Censored'}} \times \sum_{j=1}^{N_{Censored'}} |c_j - \hat{c}_j| \; given \, \hat{c}_j < c_j \tag{7}$$

and if we plug in equations 6 and 7 into equation 3, we get Equation 8 that defines Survival Mean Absolute Error (S-MAE). Equation 8 can easily be modified for Mean Squared Error (MSE) and Root Means Squared Error (RMSE). Note that in the extreme cases of very high censoring ratio, the denominator of the Equation 8 can become zero. To avoid such cases, we recommend reducing the censoring ratio by randomly skipping some of the censored samples or increasing the batch size of the gradient descent algorithm.

3. Experimental Results

We first provide some general information about the experiments and the two datasets used in section 3.1. This is followed by the experimental results and discussion for the first dataset in section 3.2, and that of the second dataset in section 3.3.

3.1. Experimental Setup

For the experiments, we used two public run-to-failure datasets, one on lab-simulated data and the other on real-world data from the field. The first dataset is the well-known NASA Commercial Modular Aero-Propulsion System Simulation, also known as C-MAPSS (Saxena, Goebel, Simon, & Eklund, 2008). It is a widely used benchmark dataset in prognostics and health management (PHM) developed by NASA to support research in aircraft engine health monitoring and prognostics and to estimate the remaining useful life. The dataset consists of simulation measurements from turbofan jet engines with multiple subsets, each corresponding to different operating conditions and engine fault modes. It includes sensor measurements collected from various sensors installed on the engine, along with information about the engine's health and remaining useful life. The C-MAPSS dataset contains temporal information in the form of multiple observations during time from each engine.

The C-MAPSS dataset originally did not contain censored samples as it is a simulated dataset, and the actual failing time for all the engine cases is provided. Since the goal of this paper is to study the effect of having censored samples in the dataset, we used the algorithm introduced in (Rahat, Kharazian, Mashhadi, Rögnvaldsson, & Choudhury, 2023) to transform the dataset into survival settings by defining a specific study period and labeling all the failed samples after the end of the study as censored.

The second dataset is the recently published SCANIA Component X Dataset (Kharazian, Lindgren, Magnússon, Steinert, & Reyna, 2024; Lindgren, Steinert, Andersson Reyna, Kharazian, & Magnússon, 2024). This dataset is collected from an unknown engine component (called component X) of a fleet of trucks. We refer to the second dataset as the Scania dataset. This dataset contains sensor measurements from 21278 censored trucks and 2272 instances of trucks where their component X failed. We define the censoring ratio for a dataset as the percentage of censored samples to the total samples, i.e., the number of censored samples divided by the total number of samples. Therefore, in this dataset, the censoring ratio is 90%, which is way beyond the common censoring ratios in the survival analysis domain. Looking at the literature, it is very rare to see a dataset that contains more than 50% censored samples. Similar to C-MAPSS, this dataset includes temporal measurements from trucks. The only difference compared to C-MAPSS is that in C-MAPSS, the intervals between the observations are the same, but here they vary.

The predictive model used for the experiments is a multilayer Perceptron neural network that contains an input layer followed by five dense layers, each containing 14 neurons, followed by a single neuron as the output, where all layers use the ReLU activation function. The purpose of the network is to predict the remaining useful life of a piece of equipment according to the covariate features received as input. All the networks are trained using the Adam optimization algorithm, and the batch size for all experiments is 32.

There is no need to spend too much time optimizing the neural network's architecture, as both the baseline and the proposed model use the same architecture in terms of fairness of the comparisons. We also tweaked the network's architecture and confirmed that the proposed loss function is not sensitive to the architecture and can perform robustly regardless of its structure. Two models are compared in the following sections. The first model uses the mentioned neural network architecture with S-MAE as the loss function and is referred to as the proposed model. Due to the use of S-MAE, the proposed model can consume censored samples. The second model also uses the mentioned neural network architecture. The only difference is using the standard MAE loss function, which makes the second model unable to render censored samples as there are no ground truth target values associated with them in the dataset. We refer to the second model as the baseline model. The code is implemented in Python using Keras running on a TensorFlow backend. A code implementation of the S-MAE function in TensorFlow is also provided in the appendix section.

$$E_{S-MAE} = \frac{\left(\sum_{i=1}^{N_{Failed}} |y_i - \hat{y}_i|\right) + \left(\sum_{j=1}^{N_{Censored'}} |c_j - \hat{c}_j| \; given \; \hat{c}_j < \; c_j\right)}{N_{Failed} + N_{Censored'}} \tag{8}$$

3.2. SCANIA Dataset

We used the SCANIA dataset for the first experiment. Here, the number of censored to failed samples is enormous, which means most of the components did not fail during the study period. As mentioned before, the ratio of censored vehicles is 90%. In other words, we have around 9 censored vehicles per failed one. Including all censored samples in the experiments is technically impossible, as this will cause the loss to become zero for almost all batches, and consequently, the gradients will become NaN. We randomly down sample censored instances to 500 vehicles. We also include all 2272 instances of failed trucks. The resulting dataset has a censoring ratio of 18%. Additionally, we ignored the temporal information and randomly picked one observation per truck for this experiment. The number of independent features in this dataset is 105, and the goal is to predict the remaining useful life of component X.

The objective of the experiment is to investigate how the inclusion of censored samples impacts a model employing the proposed survival loss function compared to a standard loss function. We conducted two experiments with the model outlined in the experimental setup. In the first experiment, the model is equipped with the ability to incorporate censored samples through the proposed S-MAE loss function. Conversely, the second iteration excludes censored samples from the training data, as the model employs a conventional loss function, making it unable to process partially observed instances. Both models are trained for 10 epochs. The test data used for evaluating both models contains both censored and failed cases, and the S-MAE loss function is used to report the models' performance.

Figure 2 represents the five-fold cross-validation results for the Scania dataset. The two models' average training and test curves across five folds are presented using lines. The shaded confidence bands visualize the respective standard deviations of the test data across five folds. The green curves represent the model's performance using S-MAE, and the red curves represent the conventional MAE loss function. The y-axis shows the value of error using S-MAE. Similar to the standard MAE, the lower values of S-MAE indicate better performances. As you can see in the figure, the model that used the proposed S-MAE consistently outperforms the conventional MAE. Furthermore, the standard deviation of both models decreased during the training epochs.

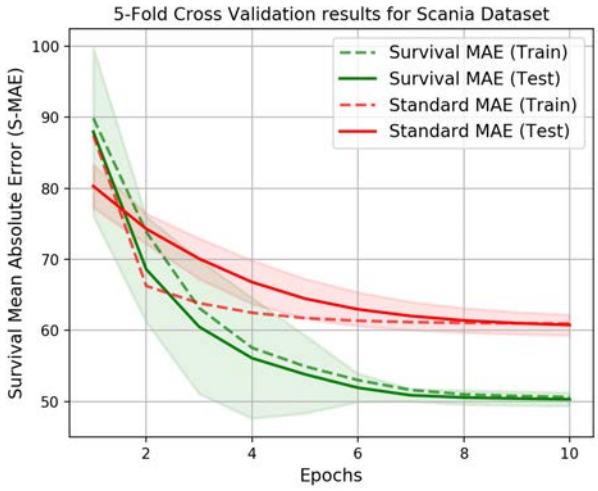

Figure 2. Five-fold cross-validation results for Scania dataset.

3.3. C-MAPSS Dataset

In the second experiment, we performed an assessment similar to the first experiment but with the C-MAPSS dataset. We used the dataset related to the first operational setting (FD001) representing condition one (Sea Level) with 14 covariate features and the remaining useful life of the equipment as the target. The train and test trajectories each contain 100 units, and a varying number of readouts is available in the dataset for each unit. We merged the train and test units from the original dataset to get a dataset with 200 units and reduced the samples by randomly picking 20 readouts from each engine unit. Again, we employed a 5-fold cross-validation approach to evaluate the performance of the proposed method and compare it to our baseline model. Both models are trained for 15 epochs. To simulate censoring, we used the technique described in (Rahat et al., 2023) and set the end-study parameter to 200 in this experiment. The simulation resulted in 1140 event (failed) samples and 646 censored samples with a censoring ratio of 36%.

Figure 3 displays the train (shown with a dashed line) and test (shown with a solid line) learning curves for the baseline and the proposed models. The green curves show the proposed model learning curves, while red is used for the baseline. The shaded area around the test curves represents the standard deviations between the results from the five folds. The standard deviations of the training curves are not visualized to avoid overcrowding and maintain readability. The models are trained until the learning curves flatten after about 15 epochs. As can be seen, the proposed model outperforms the baseline

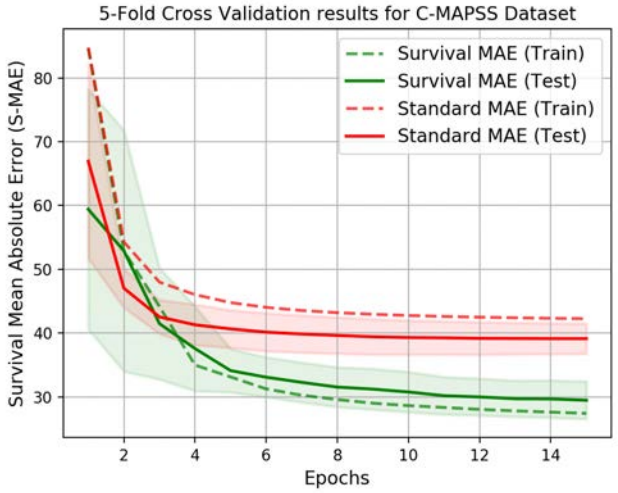

Figure 3. Five-fold cross-validation results for C-MAPSS dataset.

Table 1. The final performance of two models on the test data averaged over 5 folds.

	Scania Dataset	C-MAPSS Dataset
S-MAE	50.32 ± 0.85	29.49 ± 2.64
MAE	60.77 ± 1.31	39.14 ± 2.13

by a significant margin.

Table 1 compared the final performance of two models on the test data averaged over five folds. The proposed loss function significantly outperforms the standard mean absolute error with a margin of 10.45 units in the Scania dataset and with a margin of 9.65 units for the C-MAPSS dataset. There is no need to run statistically significant tests as the standard deviation of the models compared to the net improvement level is little.

4. Conclusion

We presented a novel loss and error calculation method that partially considers censored samples in the context of survival analysis and remaining useful life prediction. The proposed loss function can be used with any standard regression error function and can handle right, left, or interval-censored samples. To assess the algorithm, we tested it using a flat regressor on two public industrial datasets to predict the remaining useful life of engine equipment. The results indicated that the proposed loss function can significantly reduce the model loss on the test data compared to the baseline. The experiments only looked at the mean absolute error function and right censored samples. The application of other regression loss functions with varying censored settings is left for future work. Another suggested future work is to use the proposed loss function on advanced types of neural networks, such as long short-term memory networks (LSTM) or Gated recurrent units (GRU), to incorporate temporal information in survival analysis.

ABSTRACT

Wind energy plays a crucial role in the energy transition. However, it is often seen as an unreliable source of energy, with many production peaks and lows. Some of the drivers of uncertainty in energy production are the unexpected wind turbine (WT) failures and associated unscheduled maintenance. To support an effective health management and maintenance planning of WTs, we propose an integrated data-driven framework for Remaining Useful Life (RUL) prognostics and inspection planning of WTs. We propose a Long-short term memory (LSTM) neural network with Monte Carlo dropout to estimate the distribution of the RUL of WTs, i.e. we develop probabilistic prognostics. Different from existing studies focused on prognostics for single components, we consider the simultaneous health-monitoring of multiple components of the WTs, thus seeing the turbine as an integrated system. The obtained prognostics are further included into a stochastic planning model which determines optimal moments for inspections. For this, we pose the problem of WT inspections as a renewal reward process. We illustrate our framework for four offshore WTs which are continuously monitored by Supervisory Control and Data Acquisition (SCADA) systems. The results show that LSTMs are able to estimate well the RUL of the WTs, even in the early phase of their usage. We also show that the prognostics are informative for maintenance planning and are conducive to conservative inspections.

1. INTRODUCTION

The current global environmental crisis has prompted the active shift towards renewable energy solutions. For this, as outlined in the European Green Deal, the primary objective set forth by the Global Wind Energy Council is to actively contribute to meeting, by 2030, no less than 20% of the worldwide demand for electricity through the utilization of wind energy. Furthermore, the overarching ambition extends to realizing a fully decarbonized electricity supply by 2050, positioning wind energy at the forefront of renewable sources (Apunda & Nyangoye, 2017).

The focus on wind energy is motivated by the fact that wind is a clean, sustainable and inexhaustible source of energy, it has low operational costs, and that WTs can be installed in various locations, including remote areas where higher wind speeds can result in a higher energy production. Wind energy is, however, perceived as an unreliable source of energy, with many production peaks and lows. Some of the main drivers of uncertainty in energy production are the amount of unexpected failures and associated unscheduled maintenance (Letcher, 2023).

Horizontal Axis Wind Turbines (HAWTs), currently the most promising global wind energy technology (Rezamand et al., 2020), often face accelerated degradation due to their placement in regions with harsh and variable meteorological conditions (Astolfi, Pandit, Terzi, & Lombardi, 2022). Exposed to variable aerodynamic loads and mechanical stress (Tchakoua et al., 2014), WTs necessitate continuous health monitoring and dynamic maintenance planning to achieve reliable operations (Yang, Tavner, Crabtree, Feng, & Qiu, 2014; Tautz-Weinert & Watson, 2017).

In general, a HAWT integrates several essential subsystems, including aerodynamic rotor blades, a central hub for energy transfer, a gear reducer (Tong, 2010) (typically spur, helical (Errichello & Muller, 1994), or planetary (Ragheb & Ragheb, 2010)), an electrical generator for power conversion (Wagner, 2020), a nacelle housing all critical machinery, a yaw system enabling optimal wind alignment and a towering structure (Griffith et al., 2016). The subsystems with the highest fault rates for onshore wind farms are towers, gearboxes, and rotor blades, while for offshore wind farms, the most affected

components are gearboxes, rotor blades, generators, and towers (Rezamand et al., 2020). Generally, the most critical components of WTs are the gearbox, the main bearing, and the blades (Yang, Court, & Jiang, 2013).

To boost the reliability of WTs, recent studies have developed diagnostics and prognostics for components of WTs, focusing particularly on critical components such as gearboxes, main bearings, and blades. Given the increasing availability of condition monitoring measurements, a large fraction of these studies develops data-driven approaches for diagnostics and prognostics using machine learning. For data-driven diagnostics of WTs, frequent approaches are clustering algorithms, Principle Component Analysis (PCA), and Neural Networks. For example, in (Kim et al., 2011), a data-driven, unsupervised clustering algorithm, together with PCA is developed for diagnostics of gearboxes of WTs. Anomalies due to gearbox failures are identified based on measurements related to rotor speed and power production. In (Zaher, McArthur, Infield, & Patel, 2009), a multilayer neural networks is proposed to detect anomalies of the WT gearbox. The main input of the neural network is the temperature of the gearbox. In (Garan, Tidriri, & Kovalenko, 2022), the authors estimate whether the WT will fail or not within the next 60 days using a decision tree. Here, the focus is on optimizing the data preprocessing and feature selected steps of the methodology. A regression mode is proposed in (Orozco, Sheng, & Phillips, 2018) to detect anomalies of gearboxes.

For data-driven Remaining Useful Life prognostics using machine learning, which is also the case of our analysis, existing studies have focused on supervised neural networks. Frequently, vibration and/or Supervisory Control and Data Acquisition measurements are considered as input for these neural networks. Table 1 gives an overview of the main data-driven machine learning approaches, as well as the performance achieved. We note that all these studies focus on specific WT components when developing prognostics. The main components considered for prognostics development are the gearbox and the bearings. Neural networks are a frequently employed approach, which achieves accurate prognostics at various prognostics horizons (e.g., months/days before the actual failure). A recent study (Rajaoarisoa, Randrianandraina, & Sayed-Mouchaweh, 2024) develops a recurrent neural network to estimate the RUL of WTs, following the identification of faults using autoencoders. Completementary to this work, in this paper we propose a Long-short term memory (LSTM) neural network that directly estimates the RUL of the WTs. Here, the health monitoring and generation of RUL prognostics is performed at system level, i.e., the wind turbine is seen as an integrated system. Moreover, existing studies do not consider the development of maintenance planning models for WTs based on prognostics, e.g., predictive inspection planning for wind turbines. To the best of our knowledge, we propose for the first time a maintenance planning model for WTs based on RUL prognostics that are developed using actual measurements and machine learning models.

In this paper, we propose a LSTM neural network for RUL prognostics of WT. As datasets, we consider the recordings of the SCADA systems of the EDP Wind Farm open-source dataset (EDP, 2023). Different from existing studies, our approach involves the simultaneous health monitoring of multiple WT components such as the transformer, the gearbox, the generator, the hydraulic system. Consequently, we define the end-of-life of the WT as the occurrence of the first failure among its components. We use a LSTM neural network to estimate RUL prognostics for the WT seen as an integrated system, i.e., we determine system-level prognostics. By applying Monte Carlo dropout in the testing phase of the LSTM, we quantify the uncertainty associated with these prognostics, i.e., we determine probabilistic RUL prognostics. These prognostics are updated over time, as more measurements become available. The results show that the LSTM network is effective in accurately predicting the RUL of the WTs, even in the early stages of usage. Last, taking into account the obtained probabilistic RUL prognostics, we pose the problem of WT inspections as a renewal reward process and develop a planning model for inspections. The results show that the RUL prognostics support a conservative planning of inspections. This inspection planning is adjusted over time, as prognostics are themselves updated with newly acquired measurements.

The remainder of the paper is as follows. Section 2 introduces the open-source dataset considered for prognostics development. Subsequently, in Section 3.1, the importance of these features is quantified based on their SHAP values, and the most important features are selected for prognostics development. Section 3 proposes a LSTM neural network with Monte Carlo dropout for system-level probabilistic RUL prognostics for WT. Section 4 proposes a stochastic planning model for WT inspections, which integrates the probabilistic RUL prognostics obtained. Numerical results for WT system-level RUL prognostics and WT inspection planning are presented in Section 5. Last, conclusions are provided in Section 6.

2. DATA DESCRIPTION

We consider the Energias de Portugal (EDP) open-source dataset consisting of time-series of sensor measurements recorded for five offshore WT located in the West African Gulf of Guinea in the period 1st January 2017 - 31st December 2017. The information available in the EDP dataset consists of SCADA measurements, meteorological recordings, and the logs of the WT component failures, see also the complete list of measurements (EDP, 2023). The capacity of the each WT is 10MW. The measurements are recorded every 10min. For WT09, the logs recorded concern the Gearbox noise and Pitch position error, which does not indicate a proper fault/damage.

Table 1. Overview of data-driven prognostics for WT components, where ANFIS = Adaptive Neuro-Fuzzy Inference System, (K)ELM = (Kernel) Extreme Learning Machine, NN = Neural Network, SVM= Support Vector Machine; ACC = Accuracy, MA(P)E = Mean Absolute (Percentage) Error, NE = Normalized Error, PRC= Precision, (R)MSE = (Root) Mean Squared Error, SSE= Sum Squared Error.

As such, for our analysis, we consider the remaining four WTs (WT01, WT06, WT07, WT11).

Preliminary feature selection

Feature engineering from existing studies on prognostics and diagnostics for WTs (see also Table 1), indicate temperature-related features, production power, the generator and rotor speed rotation as parameters with a high explainability power for failures. In this line, we make a preliminary selection from the available parameters, leading to the following 31 features to be analysed for RUL prognostics: Average Temperature Hydraulic Oil (°C), Max/Min/ Average/STD Generator RPM (rpm), Average Temperature Bearing/ Bearing2 (°C), Average Temperature Generator Phase 1/2/3 (°C), Average Temperature Gearbox Oil (°C), Average Temperature Gearbox Bearing (°C), Average Temperature Nacelle (°C), Max/Min/Average Rotor RPM (RPM), Average Temperature High Volt Transformer Phase1/2/3 (°C), Average Temperature Grid Inverter Phase1 (°C), Average Temperature Controller Top (°C), Average Temperature Controller Hub (°C), Average Temperature Controller VCP (°C), Average Temperature Controller VCP Chokcoil (°C), Average Temperature VCP Cooling Water (°C), Average Temperature VCP Cooling Water (°C), Average Temperature Spinner (°C), Latest Production Total Active Power (Wh), Average Temperature Generator Slip Ring (°C), Average Temperature Grid Rotor Inverter Phase1/2/3 (°C).

3. System-level RUL prognostics for wind turbines

We consider a WT consisting of multiple components. The health of each component is monitored continuously by multiple sensors. We say that the system-level RUL of the WT is the remaining time until the first failure of any one of these components. We are interested in estimating the system-level RUL of the WT based on the sensor measurements recorded. At time step d (dth day), we have available the following measurements for WT $i, i \in \{1, 2, \ldots, n\}$,

$$x_d^i = \{x_{1,d}^i, x_{2,d}^i, \ldots, x_{m,d}^i\}, \quad (1)$$

where m is the total number of considered features and $x_{j,d}^i$ is the measurement corresponding to feature $j, 1 \leq j \leq m$ recorded on day d for WT i.

Then, the actual system-level RUL of WT i at time d is:

$$RUL^a(WT_i) = \min\{\tau(c_1^i) - d, \tau(c_2^i) - d, \ldots, \tau(c_n^i) - d\}, \quad (2)$$

where $\tau(c_j^i), 1 \leq j \leq n$ is the time of failure of component c_j^i of WT i, and n the total number of components of WT i.

We are interested in estimating the system-level RUL of the four WTs in the EDP dataset at various moments (k) in time. Table 2 shows four Cases when each of the WT is the testing set, while the datasets of the remaining three WTs constitute the training and validation sets. The failure of three out of the four WTs is due to a failure of the Hydraulic group. The remaining WT fails due to a failure of the Transformer.

3.1. Feature importance using SHAP values

In Section 2, a total of 31 features has been considered. In this section we quantify the importance of these features for WT system-level RUL estimation using the Shapley additive explanations (SHAP) values (Lundberg & Lee, 2017). SHAP values quantify the impact of a feature on the RUL prognostic. SHAP values are determined as follows:

$$\phi_i = \sum_{S \subseteq Fi} \frac{|S|!(|F| - |S| - 1)!}{|F|!} |f(S \cup \{i\} - f(S))|, \quad (3)$$

Table 2. Overview of data used for testing, training and validation - EDP dataset for WT health monitoring.

	Case 1	**Case 2**	**Case 3**	**Case 4**
Testing	**WT06**	**WT07**	**WT11**	**WT01**
Training	WT01, WT07	WT01, WT06	WT06, WT07	WT06, WT07
Validation	WT11	WT11	WT01	WT11
First fault	Hydraulic Group	Hydraulic Group	Hydraulic Group	Transformer
Actual Lifetime	8 months	6 months	4 months	8 months

with F the set of all features considered for RUL prognostics, $S \subseteq F$ a subset of features obtained from the set F except feature i, and $f(S)$ the expected algorithm output given by the set S of considered features. The SHAP value quantifies the magnitude of the impact, i.e., how much a specific feature value contributes to the accurate estimation of the RUL. A large SHAP value for a given feature indicates a large importance of this feature for the RUL estimation.

For each of the four Cases, we select the 60% most important features of the the total of 31 features, i.e., we select 20 features with the highest SHAP value, see Figures 1-4. The results show that, although the WTs have various components that trigger the failure of the entire system, i.e., either the hydraulic group or the transformer, the average RPM of the generator is the feature with the highest importance for all four WTs. These confirms the findings of existing literature (see also Table 1), that the health condition of the generator is crucial for the overall operation of WTs. Most importantly, these results show that regardless of the failure mode, the WT can be seen as a system and the available measurements can support the development of system-level prognostics.

3.2. Long-short term memory (LSTM) for probabilistic RUL prognostics

Given the long-term dependencies in the measurements, as well as the high nonlinearity of the features, we propose a Long-short term memory (LSTM) with Monte Carlo dropout (Hochreiter & Schmidhuber, 1997) to estimate the distribution of the RUL (probabilistic RUL prognostics) of the WTs in each of the four Cases.

We consider a LSTM consisting of L layers, each consisting of N neurons, and LeakyReLu activation layers (Graves & Graves, 2012). The last layer of the LSTM is a Dense layer, for which a ReLu activation function is assumed. The input gate i_t, the output gate o_t, and the forget gate f_t of the LSTM are defined as follows. The forget gate f_t determines whether to consider or not the previous state c_{t-1}, i.e,

$$f_t = \sigma(W_f \cdot [h_{t-1}, x_t] + b_f) \tag{4}$$

where x_t is the current input, h_{t-1} is the previous hidden state, W_f is a trainable weight, b_f is bias. The input gate determines whether to update the state of the LSTM using the current observation, using a sigmoid layer:

$$i_t = \sigma(W_i \cdot [h_{t-1}, x_t] + b_i). \tag{5}$$

where x_t is the current input, h_{t-1} is the previous hidden state, W_i is a trainable weight, b_i is the bias. The output gate o_t determines whether the hidden state h_t is passed to the next iteration, i.e.,

$$o_t = \sigma(W_o \cdot [h_{t-1}, x_t] + b_o). \tag{6}$$

where x_t is the current input, h_{t-1} is the previous hidden state, W_o is a trainable weight, b_o is the bias. Table 3 shows the hyperparameters of the considered LSTM.

Monte Carlo dropout for probabilistic RUL prognostics

Commonly, Monte Carlo dropout is applied in the training phase of the neural networks to avoid overfitting. To obtain the distribution of the RUL, i.e., to obtain probabilistic RUL prognostics, we also apply Monte Carlo dropout in the testing phase of the LSTM. In this line, (Gal & Ghahramani, 2016) shows that such a neural network with Monte Carlo dropout approximates a Bayesian neural network representing a deep Gaussian process.

Let X be the samples in the training set of the LSTM, and let Y be the corresponding RUL values. In a Bayesian neural network, we aim to estimate the posterior distribution $p(y|x, X, Y)$:

$$p(y|x, X, Y) = \int p(y|x, \omega)p(\omega|X, Y)d\omega \tag{7}$$

with ω the weights of the neural network, $p(y|x, \omega)$ the probability that the RUL is y, given the test sample x and the weights ω, and $p(\omega|X, Y)$ the posterior distribution of the weights, given the training samples X and Y.

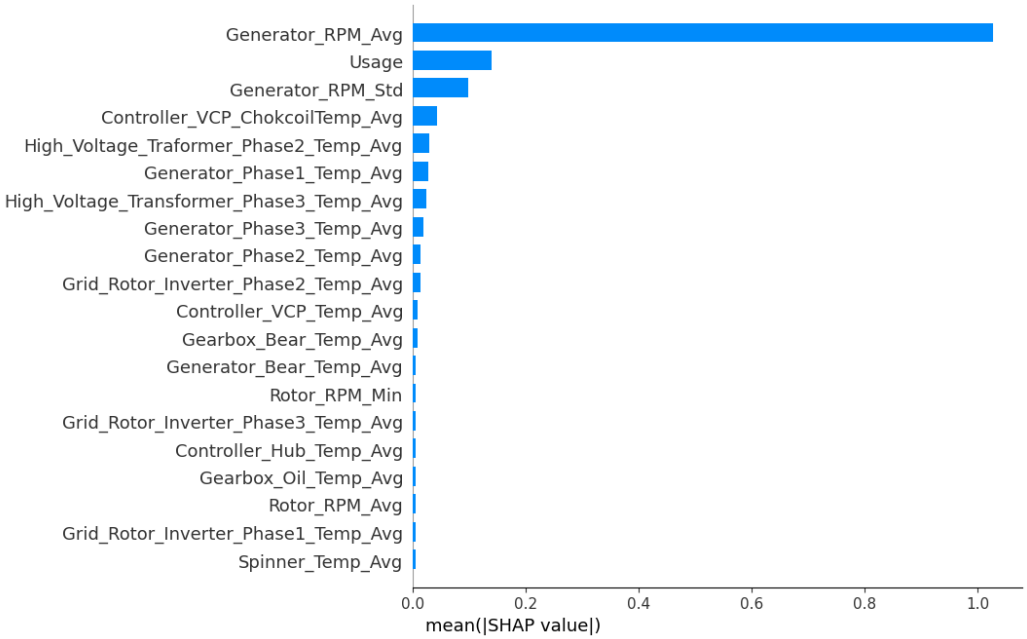

Figure 3. Case 3: WT11 - SHAP values of features.

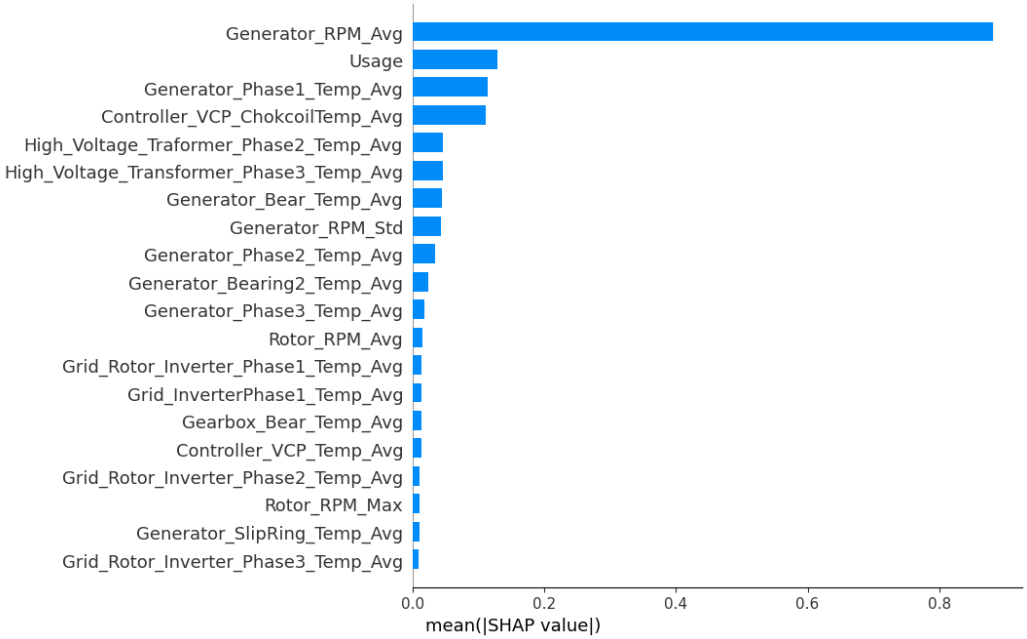

Figure 4. Case 4: WT01 - SHAP values of features.

It is computationally expensive to analyze the posterior distribution $p(\omega|X,Y)$ exactly (Gal & Ghahramani, 2016). As such, we approximate $p(\omega|X,Y)$ with a distribution $q(\omega)^*$ that minimizes Kullback–Leibler divergence KL with the true posterior distribution $p(\omega|X,Y)$, i.e. (Blei, Kucukelbir, & McAuliffe, 2017):

$$q^*(\omega) = argmin_{q(\omega)}\{KL(q(\omega|p(\omega|X,Y)))\}. \quad (8)$$

Using $q(\omega)^*$, we approximate the posterior distribution of the RUL of a test sample by:

$$q(y|x) = \int p(y|x,\omega)q^*(\omega)d\omega \quad (9)$$

where $q(y|x)$ is the approximation of $p(y|x,X,Y)$.

Lastly, we approximate the expected value $\hat{y}$ of the RUL of a test sample by:

$$\hat{y} = E_{q(y|x)}(y) = \frac{1}{M}\sum_{1}^{M}\hat{y_j}(x,\omega^j) \quad (10)$$

where M is the number of forward passes through the neural network, ω^j are the weights of the neural network belonging to the j-th forward pass (i.e., where some neurons are dropped out), and $\hat{y_j}(x,\omega^j)$ is the resulting RUL prediction from the j-th forward pass through the neural network. For the distribution of the RUL, we give each individual RUL prediction $\hat{y_j}(x,\omega^j)$ a probability $\frac{1}{M}$.

Performance metrics for RUL prognostics

To evaluate the ability of the LSTM model to predict the RUL, we consider the Mean Absolute Error (MAE), the Root Mean Square Error (RMSE), and the Continuous Ranked Probability Score (CRPS), which are defined as follows.

$$MAE = \sum_{i=1}^{n}\frac{|RUL_i^a - R\bar{U}L_i^p|}{n}, \quad (11)$$

$$RMSE = \sqrt{\sum_{i=1}^{n}\frac{(RUL_i^a - R\bar{U}L_i^p)^2}{n}}, \quad (12)$$

with n the number of days over which predictions are made, and $R\bar{U}L_i^p$ the mean predicted RUL at day $i, 1 \leq i \leq n$.

Since we estimate the distribution of the RUL, to be able to quantify the fitness of these distributions relative to the actual RUL (a point value), we consider the Continuous Ranked Probability Score (CRPS) and the Weighted CRPS ($CRPS^W$). Here, CRPS evaluates whether the estimated RUL distribution is centered around the actual RUL of the WT and whether the variance of this distribution is low (a high sharpness of the RUL prognostic) (Mitici, de Pater, Barros, & Zeng, 2023). The Weighted CRPS applies a (larger) penalty β when overestimating the RUL then when underestimating the RUL. This is of particular importance when planning the inspections of the WTs - planning too late inspections (after the actual failure of the wind turbine) does not make effective use of the prognostics to timely identify and act upon anticipated failures of the WTs.

CRPS is defined as follows (Gneiting & Katzfuss, 2014),

$$CRPS = \frac{1}{n}\sum_{i=1}^{n}CRPS_i, \quad (13)$$

$$CRPS_i = \int_{-\infty}^{\infty}(F_{\hat{y}_i}(x) - I\{y_i \leq x\})^2 dx \quad (14)$$

with $I\{y_i \leq x\} = \begin{cases} 1 & \text{if } y_i \leq x \\ 0 & \text{if } y_i > x. \end{cases}$

The weighted CRPS ($CRPS^W$) is defined as follows (Gneiting & Katzfuss, 2014):

$$CRPS^W = \frac{1}{N}\sum_{i=1}^{N}CRPS_i^W, \quad (15)$$

$$CRPS_i^W = (2-\beta)\int_{-\infty}^{y_i}(F_{\widehat{y_i}}(x))^2 dx + \beta\int_{y_i}^{\infty}(F_{\widehat{y_i}}(x) - 1)^2 dx, 0 \leq \beta \leq 2. \quad (16)$$

4. Inspection planning of wind turbines using probabilistic RUL prognostics

In this Section we pose the problem of WT inspections as a renewal reward process (Tijms, 2003), which integrates the probabilistic RUL prognostics developed in Section 3.2. We aim to determine optimal times for WT inspections.

We consider a renewal reward process $\{N_t\}$ where the process regenerates when a wind turbine is inspected, i.e., our knowledge about the actual health condition of the wind turbine is reset upon an inspection. At day k during the life of the WT, we are interested in determining an optimal time $k + t_k^*$ to inspect the WT. At day k, using the measurements recorded up to day k and a LSTM with Monte Carlo dropout (see Section 3.2), we estimate the probability that the RUL of the WT is i days, $i \geq 0$. Let $\phi_k(i)$ denote the probability that the WT, after being used for k days, has a RUL of exactly i days. To determine an optimal time to inspect the WT, we consider the expected cost per unit of time:

$$\frac{\text{[Expected cost over the current inspection cycle]}}{\text{[Expected current inspection cycle]}}. \quad (17)$$

At day k, we are interested in finding an optimal time for

inspection t_k^* such that:

$$t_k^* := argmin_{t_k>0} \frac{\mathbb{E}[C(k,t_k)]}{\mathbb{E}[L(k,t_k)]}, \quad (18)$$

with $C(k,t_k)$ the cost of inspecting the WT at day $k+t_k$, given that this WT has already been used for k days, and $L(k,t_k)$ is the length of the inspection cycle of the WT.

If the WT is scheduled for inspection at day $k+t_k$, then a cost c_r is incurred. If, however, the WT fails at some day $j, k < j < k+t_k$ before an inspection is planned, then a failure cost c_f is incurred (corrective maintenance).

With this, the expected cost over the current inspection cycle of the WT is:

$$E[C(k,t_k)] = c_f \sum_{i=0}^{t_k-1} \phi_k(i) + c_r(1 - \sum_{i=0}^{t_k-1} \phi_k(i)). \quad (19)$$

Also, the expected current inspection cycle is:

$$E[L(k,t_k)] = k + \sum_{i=0}^{t_k-1} i\phi_k(i) + t_k(1 - \sum_{i=0}^{t_k-1} \phi_k(i)). \quad (20)$$

Eq. (18) is solved using a numerical grid search. The estimate $\phi_k(i)$ after every day k is obtained using a LSTM and the methodology in Section 3.2.

5. Numerical results

In this Section we illustrate the results obtained for the probabilistic RUL prognostics and inspection planning for the four WTs for which measurements are available at (EDP, 2023).

5.1. Probabilistic RUL prognostics for wind turbines

Table 4 shows the performance of the system-level RUL prognostics for the WTs in the four Cases considered.

Table 4. Performance - RUL prognostics using LSTM.

	MAE	$RMSE$	$CRPS$	$CRPS^W$ $\beta = 1.9$
Case 1: WT06	12.72	15.52	9.98	2.51
Case 2: WT07	11.30	13.65	7.86	9.16
Case 3: WT11	9.40	11.80	6.93	6.88
Case 4: WT01	19.35	22.42	14.68	3.11

The results show that the lowest MAE and $RMSE$ are obtained for WT11, while the highest MAE and $RMSE$ are obtained for WT01. However, when considering the prognostics as input for inspection planning, we are interested in not missing the failures. This may, however, occur when we overestimate the RUL and, based on these overestimates, we plan late inspections. The Weighted CRPS captures the tendency of the prognostics to overestimate the RUL. We consider a large penalty for RUL overestimation ($\beta = 1.9$), given our ultimate goal of planning inspections for WTs based on prognostics. In this line, we are interested in planning inspection timely, to anticipate the actual failures of the turbines rather than missing these failures.

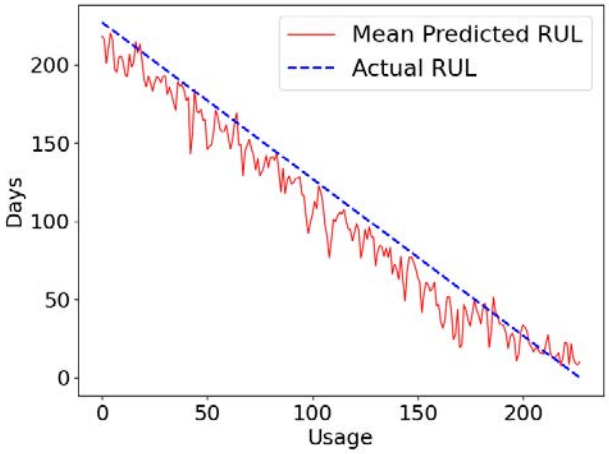

Figure 5. Case 1 - RUL estimation, WT06.

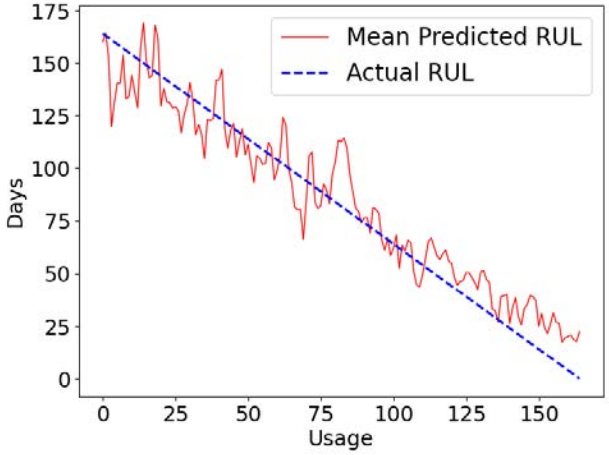

Figure 6. Case 2 - RUL estimation, WT07.

The results show that WT07 has the highest $CRPS^W = 9.16$, despite having a relatively low MAE and $RMSE$. This indicates that the RUL is predominantly overestimated and a conservative inspection planning should be considered, despite the low MAE and $RMSE$. The results also show that WT06 has the lowest $CRPS^W = 2.51$, despite having a relatively high MAE and $RMSE$ among all four turbines. This indicates that the prognostics have the least tendency to overestimate the RUL. These make the prognostics suitable for inspection planning, despite their high MAE and $RMSE$. Overall, the results show that considering MAE and $RMSE$ alone when aiming to use prognostics for maintenance planning is not sufficient. Additional metrics such as $CRPS^W$, through their ability to evaluate whether the

RUL is over/under-estimated, are particularly informative of the suitability of the prognostics for maintenance planning.

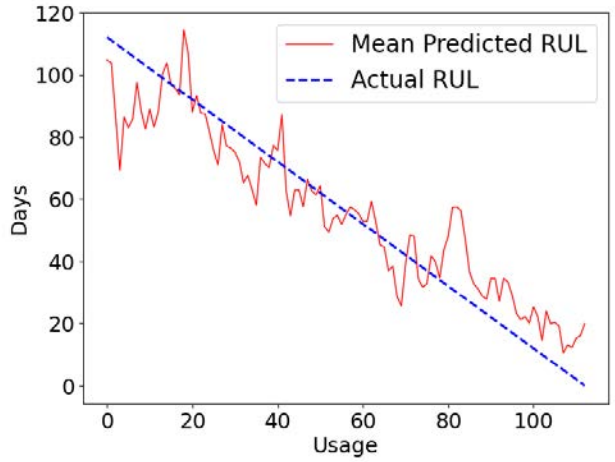

Figure 7. Case 3 - RUL estimation, WT11.

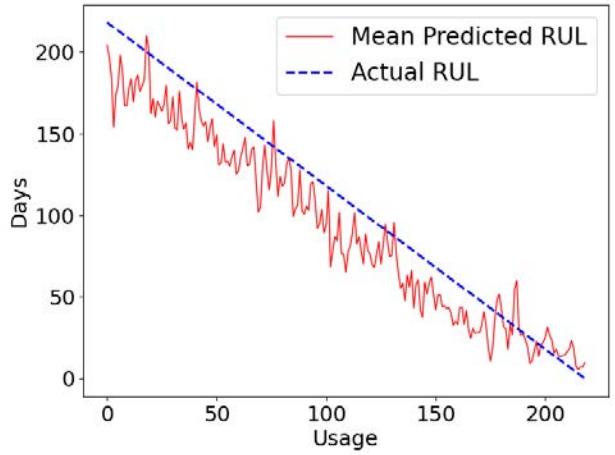

Figure 8. Case 4 - RUL estimation, WT01.

The RUL prognostics obtained over time are shown in Figures 5 - 8. The RUL of WT06 and WT01 are predominantly underestimated. The RUL of WT07 and WT11 are predominantly overestimated.

Figures 9 - 11 show the distribution of the RUL for WT06 (Case 1) at $\{202, 102, 2\}$ days before the actual failure of the WT. The results show that the sharpness of the estimated distribution increases closer to the time of failure of the WT.

5.2. Inspection planning for wind turbines using probabilistic RUL prognostics

For inspection planning, we consider $c_f = 100.000$ and $c_r = 100$. Every day k (or equivalently after k days of usage), based on the measurements collected up to this day, we develop RUL prognostics, i.e., the prognostics are updated ev-

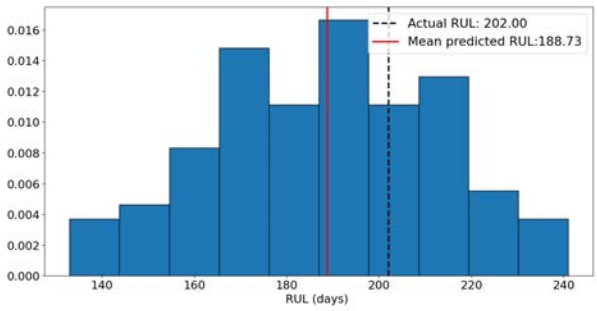

Figure 9. Estimated distribution of RUL, 202 days before the actual failure of WT06.

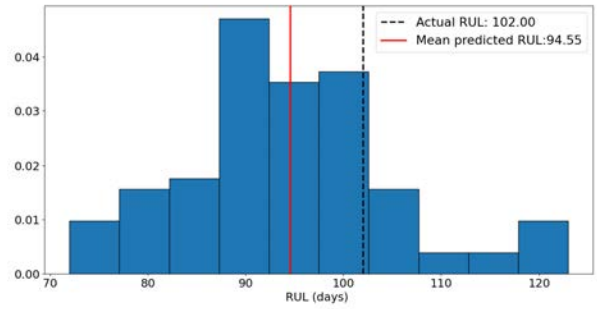

Figure 10. Estimated distribution of RUL, 102 days before the actual failure of WT06.

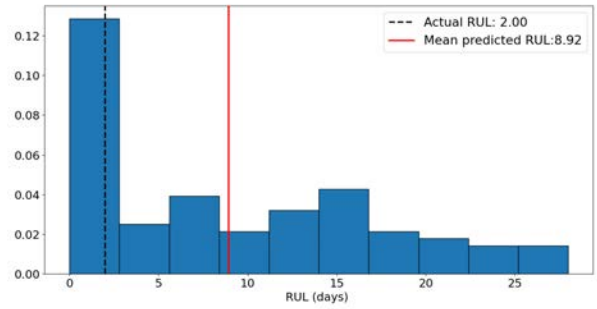

Figure 11. Estimated distribution of RUL, 2 days before the actual failure of WT06.

ery day. Based on these prognostics, every day k we determine an optimal time t_k^* to plan a WT inspection.

Figures 12 -15 show the results for the optimal inspection times of the four WTs relative to the actual RUL and the mean estimated RUL. For Case 1 - WT06, although the MAE and $RMSE$ are relatively high, the fact that $CRPS^W$ is low, i.e., the overestimation of the RUL is low, is reflected in the inspection planning - timely planning that does not miss the failure of the WT. In fact, in the last phase of the monitoring of this WT, it is consistently indicated that an optimal action

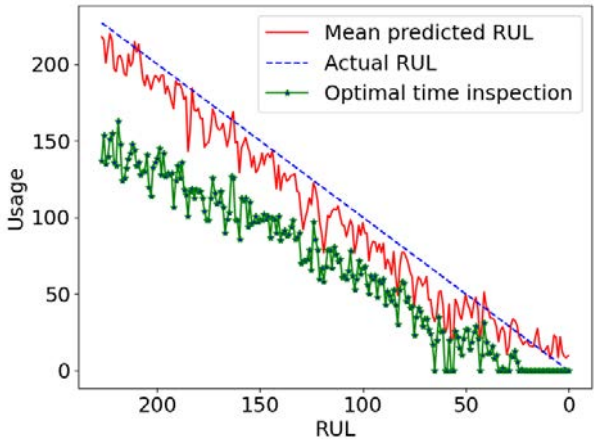

Figure 12. Case 1: WT06, Optimal time inspection.

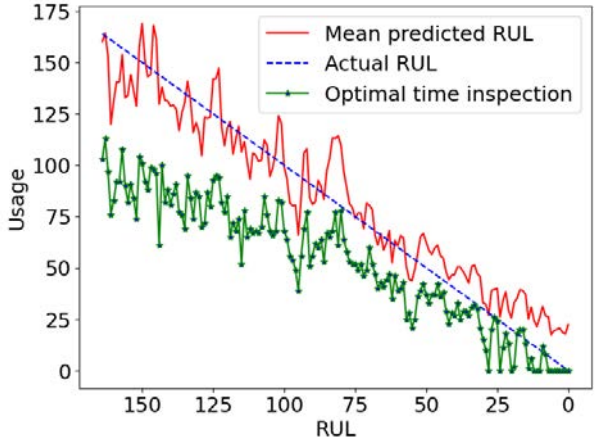

Figure 13. Case 2: WT07, Optimal time inspection.

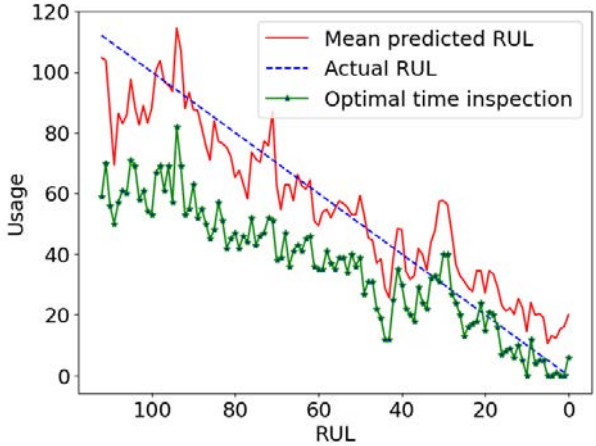

Figure 14. Case 3: WT11, Optimal time inspection.

is to plan an inspection immediately.

For Case 2 - WT07, the $CRPS^W$ is the highest, i.e., the prognostics have the tendency to overestimate the RUL, which is expected to delay the planning of the inspections leading to a potential miss of the failure. This is reflected in the inspection planning, particularly in the last phase of the monitoring of the WT, see also Figure 13. For Case 3 - WT11, the $CRPS^W$ is high, i.e. the prognostics have a tendency to overestimate the RUL. As a result, delayed inspections are planned in the last phase of the monitoring of the WT. For Case 4 - WT01, despite the lowest achieved MAE and $RMSE$, a moderate $CRPS^W$ is reflected in the inspection planning - timely inspection planning, particularly in the last phase of the WT monitoring, when an immediate inspection is consistently indicated as an optimal action (see also Figure 15). Overall, for all four cases, the planning of the inspections is conservative, where timely inspections are indicated as being optimal actions.

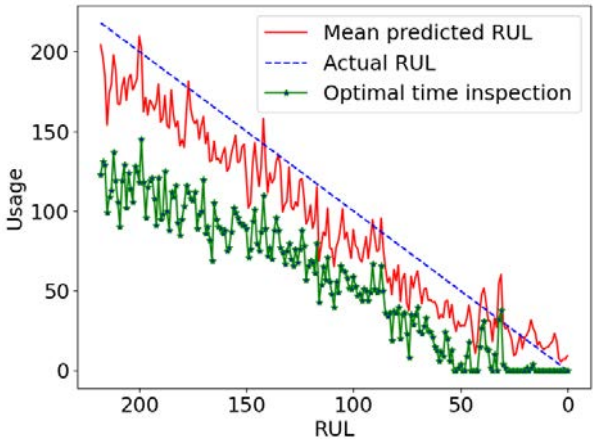

Figure 15. Case 4: WT01, Optimal time inspection.

Table 5. Optimal time for WT inspection.

	RUL^a	k	RUL^p	t_k^*
Case 1: WT06				
	200	27	193.82	139
	100	127	96.62	67
	50	177	49.96	27
	25	202	33.18	6
Case 2: WT07				
	150	14	135.44	101
	100	64	94.11	68
	50	114	38.61	37
	25	139	26.5	24
Case 3: WT11				
	100	12	86.72	53
	75	37	70.28	43
	50	62	61.64	39
	25	87	29.64	13
Case 4: WT01				
	200	18	192.69	118
	100	118	74.69	59
	50	168	28	4
	25	193	8.46	0

Table 5 shows in detail several moments throughout the monitoring of the WTs when inspections are planned (t_k^*), relative to the actual RUL (RUL^a), the usage of the WT (k), and the mean estimated RUL ($R\bar{U}L^p$).

6. Conclusions

This paper proposes a machine learning approach for system-level probabilistic RUL prognostics for WTs. In contrast with existing studies, which develop component-based prognostics, we see the WT as an integrated system and develop system-level RUL prognostics. These prognostics are further employed to determine optimal moments for inspections of the WTs, in anticipation of failures. To the best of our knowledge, this is the first study that proposes a maintenance planning model for WT based on data-driven prognostics. A LSTM with Monte Carlo dropout is developed to estimate the distribution of the RUL of the WTs, i.e., we develop probabilistic RUL prognostics. By using dropout in the test phase of the LSTM, the uncertainty associated with the RUL prognostics is quantified. To plan inspections for the WTs, a renewal reward process is proposed, which integrates these probabilistic RUL prognostics.

We illustrate our approach for four offshore wind turbines located in the West African Gulf of Guinea, and which have been monitored in the period 1st January - 31st December 2017. The results show that the proposed LSTM estimates well the RUL of the WTs, with a Mean Absolute Error ranging between 9.40 days to 19.35 days when considering all four wind turbines. Based on these RUL prognostics, inspections are planned conservatively, well ahead of the actual day of failure. The results show that, although imperfect, prognostics are informative for maintenance and support an efficient planning of inspection tasks.

As future work we aim to improve our RUL prognostics by considering additional features such as attention mechanisms integrated into the neural networks.

ABSTRACT

We present an investigation of how topological data analysis (TDA) can be applied to condition-based monitoring (CBM) of wind turbines for energy generation.
TDA is a branch of data analysis focusing on extracting meaningful information from complex datasets by analyzing their structure in state space and computing their underlying topological features. By representing data in a high-dimensional state space, TDA enables the identification of patterns, anomalies, and trends in the data that may not be apparent through traditional signal processing methods.
For this study, wind turbine data was acquired from a wind park in Norway via standard vibration sensors at different locations of the turbine's gearbox. Both the vibration acceleration data and its frequency spectra were recorded at infrequent intervals for a few seconds at high frequency and failure events were labelled as either gear-tooth or ball-bearing failures. The data processing and analysis are based on a pipeline where the time series data is first split into intervals and then transformed into multi-dimensional point clouds via a time-delay embedding. The shape of the point cloud is analyzed with topological methods such as persistent homology to generate topology-based key health indicators based on Betti numbers, information entropy and signal persistence. Such indicators are tested for CBM and diagnosis (fault detection) to identify faults in wind turbines and classify them accordingly. Topological indicators are shown to be an interesting alternative for failure identification and diagnosis of operational failures in wind turbines.

1. INTRODUCTION

The global demand for renewable energy sources has seen a significant rise in recent decades, with wind energy emerging as a prominent contributor to sustainable power generation (Q. Wang, Dong, Li, & Wang, 2022). Wind turbines, pivotal in harnessing wind energy, operate under diverse environmental conditions and mechanical stresses, making their maintenance and monitoring crucial for optimal performance and longevity. Condition-based monitoring (CBM) has emerged as a proactive approach to monitor the health of wind turbines, aiming to detect faults and predict potential failures before they escalate, thus minimizing downtime and maintenance costs (Stetco et al., 2019).
Traditional CBM methods often rely on spectral signal processing techniques to analyze sensor data for anomaly detection and fault diagnosis. Signal analysis techniques are commonly used for fault diagnosis and typically apply tools such as Fourier or wavelet analysis of frequency signatures from accumulated time series generated from sensors installed on wind turbines. Where possible, machine learning techniques are then used to identify early signatures of failure in the data and alert engineers as soon as the equipment's health starts deteriorating. However, frequency-based methods often require accumulating signals for a significant time before processing them successfully, making it an ideal method for analyzing failures after they occur. Online fault detection is much more challenging, and together with inherent complexity and non-linearity in wind turbine data, pose challenges for conventional analytical approaches.
To address these challenges, alternative data analysis techniques have gained attention for their ability to extract meaningful insights from complex datasets. Among those, topological data analysis (TDA) has recently risen as a possible

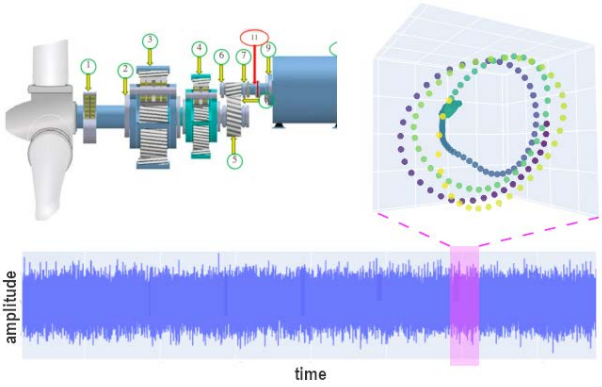

Figure 1. Overview of how the gearbox vibration data are processed by means of topological data analysis.

alternative. TDA is a branch of data analysis that focuses on revealing the the underlying structure of datasets by analyzing their shape: particularly their topology in high-dimensional state spaces. By representing data as multidimensional point clouds and leveraging mathematical tools from algebraic topology, TDA enables the identification of intricate patterns, anomalies, and trends that may not be discernible through traditional signal processing methods alone (see Fig.1).

In this study, we explore how TDA techniques can be employed to analyze vibration data collected from wind turbines at a wind park. Vibration sensors placed strategically in different locations of the turbine's gearbox provide high-frequency data capturing both vibration acceleration and frequency spectra.By employing a systematic data pipeline, including time-series segmentation and time-delay embedding, we transform the raw sensor data into a multidimensional point cloud and then, process it via topological analysis.

The primary objective of this research is to evaluate how topological indicators derived from TDA, such as Betti numbers, information entropy, and signal persistence can be used or complement more traditional spectral analysis as key health indicators for CBM and fault diagnosis in wind turbines.

2. Data description

For this analysis, we use vibration data collected from two wind turbine gearboxes from a wind park located in Norway. The data sets are proprietary, owned by the wind park operator ANEO (www.aneo.no) and this work is the first publicly available analysis of the data. The data was collected using accelerometers, located at various positions in the gearbox. For the analysis, we focused on sensors that were physically closest to the known failure positions and most correlated with the time of failure of the gearbox. The considered sensors are located at the gearbox high-speed stage front (GbxHssFr), at the gearbox intermediate stage (GbxIss), at the gearbox planetary stage (Gbx1Ps), and at the non-drive end of the generator (GnNDe). The left panel in Figure 2 show a 0.05 s example of vibrations recorded from GbxHssFr. The vibration / acceleration data were sampled at 25.6 kHz for 10 seconds at infrequent intervals. The two cases have respectively 23 and 21 samples of 10 s length with a sampling rate of 25.6 kHz. The data is collected at infrequent intervals over approximately a year until the time when failures happened, and the equipment was stopped for maintenance. In the first case, data were acquired from 2022-10-28 to 2023-10-11 and data ended with a ball bearing failure (BBF) at the non-drive end of the generator. In the second case, data was recorded from 2022-05-24 to 2023-06-21 ended with a gear tooth failure (GTF) at the planetary stage section of the gearbox.

3. Methods

In this section, we delineate the methodologies employed for analyzing complex data structures, focusing particularly on spectral analysis and topological data analysis (TDA). Spectral analysis, rooted in the principles of linear algebra and signal processing, extracts valuable insights from data by decomposing it into its constituent frequencies. Conversely, topological data analysis, drawing from the field of algebraic topology, examines the shape and connectivity of data through the lens of persistent homology, providing a holistic understanding of its underlying structure.

Both spectral analysis and TDA offer distinct yet complementary approaches to understanding complex datasets. While spectral analysis emphasizes frequency-based decomposition, TDA highlights the intrinsic topological features of the data. By comparing and contrasting these methodologies, we aim to elucidate their respective strengths, limitations, and applicability in various analytical contexts. This comparative analysis serves as a foundation for our subsequent exploration and interpretation of results, contributing to a comprehensive understanding of the dataset under investigation.

3.1. Spectral analysis

Spectral analysis, a fundamental technique in signal processing and data analysis, provides a powerful framework for decomposing complex data. Rooted in the principles of Fourier series, spectral analysis offers invaluable insights into the underlying structure and dynamics of various data types across diverse domains, including engineering, physics, biology, and finance.

At its core, spectral analysis aims to characterize the frequency content of a signal or dataset. By representing data in the frequency domain, analysts can identify dominant patterns, periodicities, and trends that may not be readily apparent in the time or spatial domain. This decomposition facilitates the extraction of meaningful information, enabling researchers to discern underlying patterns, detect anomalies, and make informed predictions.

Spectral analysis is a common tool for condition monitoring

in wind turbines (Z. Zhang, Verma, & Kusiak, 2012; Xiao et al., 2020). Vibration data are typically collected from sensors placed in correspondence to moving elements in turbine generators and gearboxes, subject to wear and mechanical failure. Data are analyzed to identify anomalies and expose drift and changes in the data that can be associated with a degradation of the system health and, inturn, lead to its mechanical failure (Tchakoua et al., 2014; Q. Wang et al., 2022; Stetco et al., 2019).

One of the key advantages of spectral analysis lies in its ability to unveil hidden relationships and structures within data. Through techniques such as Fourier transform, wavelet analysis, and singular value decomposition (SVD), analysts can disentangle complex signals into simpler components, each representing a distinct frequency or mode of variation. This spectral decomposition forms the basis for a wide range of applications, including signal filtering, noise reduction, feature extraction, and system identification.

3.2. Topological data analysis

Topological data analysis allows the interpretation of the spatial arrangement of data. This approach has been developed in the last decade and successfully applied to the analysis of data in several fields of engineering, fluid mechanics (Casolo, 2022), physics and biology (Wasserman, 2018). Here we will present a brief introduction to the topic: for a full exposition of this approach, we recommend the excellent articles from Perea and Harer (Perea & Harer, 2015), Chazal et al. (Chazal & Michel, 2021) and Smith et al. (Smith, Dłotko, & Zavala, 2021).

A common assumption in data analysis is the hypothesis that there exists a suitable space of parameters where data happen to form a manifold. In this case, it would be fair to assume that the shape of such a manifold would contain information about the data. TDA is one of the tools that can be used to interpret such information. Univariate time series of a scalar signal is not immediately suitable to be analysed with TDA. The signal is therefore embedded with a time-delay approach to form a high-dimensional space via a procedure known as Takens embedding(Takens, 1981). This method embeds a time signal into a vector without loss of information, by defining two parameters: the time-delay τ and the embedding dimension d. Then, the time series $\mathbf{x}(t)$ is sampled in d-points, each separated by a time τ. The embedded d-dimensional vector is then built as:

$$\mathbf{x}(t) = \{x(t), x(t-\tau), \ldots, x(t-d\tau)\} \tag{1}$$

As the time series evolves in time, it can be sampled repeatedly to build a series of vectors, which are accumulated to form a point cloud in d-dimensions. This cloud samples the manifold on which the data lays.

Once the data are represented in the d-dimensional space of the embedding, this can be analyzed by using algorithms developed in algebraic topology. To build the manifold, it would be required to connect each vector, *i.e.* point in the cloud within a given radius around each point, to form a network or a cell complex. This process is performed by connecting points lying within a given radius via the creation of Vietoris-Rips complexes: a simplicial (cell) complex representing the connectivity between data points in a dataset. To encode the complexity of the point cloud, we then compute a nested series of complexes that are formed at every point increasing the value of the radius in a process known as filtration. The construction of the complex involves considering all possible subsets of data points and connecting those that are within a specified distance threshold. Overall, the point cloud generated from the time series is a sampling of the shape of the data, and the filtration process generates several simplicial complexes which are the computational descriptions of the shape of the data. As the filtration parameter increases, the Vietoris-Rips complex captures increasingly complex topological features, ranging from individual points to higher–dimensional structures such as loops and voids. Typically, these features are unique to the data manifold (Attali, Lieutier, & Salinas, 2011) and are the topological structures we consider when analyzing the data.

The presence of loops, voids, etc. is encoded in the concept of homology. Persistent homology analyze the development of data sets by considering the evolution of topological features across different scales. It quantifies the persistence of these features as they emerge, merge, or disappear, providing a robust framework for capturing and characterizing the essential topological structure of complex datasets. Each structure then has a birth and a death value at a given radius of the filtration process, which can be recorded in a diagram known as a persistence diagram, unique for the analyzed shape. Each point in the diagram corresponds to a topological feature per each dimension (connected components in dimension 0, loops in dimension 1, voids in dimension 2, etc.) with its coordinates indicating the scale at which the feature is born and dies (see Figure 2 for an example of a persistence diagram). The persistence of a feature is measured as the difference between its death (d) and birth (b) scales. Naturally, persistence diagrams are non-empty only above the diagonal as the death of a feature would occur only after its birth, and the more 'persistent' a feature is, the further this would lay from the diagonal line. By analyzing persistence diagrams, it is possible to identify persistent features that are robust across multiple scales and distinguish them from transient noise or artefacts in the data. Topological indicators in each homology dimension H_k can be extracted from persistence diagrams and used to analyze data.

While TDA can be applied to uncover the shape of the data manifold for a signal of an arbitrarily long time, it can also be applied to a sequence of short time windows, sliding forward in time and partially overlapping (Perea & Harer, 2015). This sliding windows approach can be used to uncover the lo-

cal structure of data and their evolution and it has been used successfully to study the dynamics of mechanical systems.

3.3. Topology of vibration signals

Topological methods are expected to work particularly well for analyzing periodic time signals and their changes. Mathematically, it can be shown that periodic signals which can be approximated with a trigonometric function of a given frequency, can be embedded into a point cloud of elliptical shape, hence in a loop that should be detected by a high persistence signal of dimension 1 (H_1) (Perea & Harer, 2015). When the signal is instead composed of combinations of more frequencies these give rise to more complex manifolds such as tori and higher dimensional structures (Perea, 2016).
In the case of oscillating systems, according to the Arnol'd-Liouville theorem in dynamical system theory, systems of n harmonic oscillators give rise to trajectories on a n-dimensional torus. This phenomenon emerges due to the conservation of action variables, which characterize the system's motion in phase space. In a system of harmonic oscillators, each oscillator contributes a set of action-angle variables, representing the oscillation's amplitude and phase in each dimension. These variables remain constant over time, preserving the system's dynamics. As a consequence, trajectories in phase space form closed loops, tracing out toroidal surfaces (Arnol'd, 1989). This behaviour stems from the periodicity of harmonic motion, enabling the system's state to return to its initial configuration after completing a cycle. The toroidal topology of these trajectories reflects the periodicity and conservation of action variables, illustrating a fundamental principle of dynamical systems theory.
When a vibrating mechanical system such as the gearbox of a wind turbine oscillates, it is reasonable to expect, accounting for deviation and noise, a behaviour similar to that of a harmonic oscillator, hence a trajectory in phase space spanning a manifold similar to a torus. In this case, it would be reasonable to expect some homology signatures that should be visible from the persistence diagrams, making persistent homology a good candidate method for characterizing the dynamics of vibrations at the gearbox and, hopefully, spotting the appearance and evolution of abnormal behaviour from sensors' time series.

3.4. Analysis strategy

In this work, we have chunks of high-frequency data sparsely collected, each a few weeks or months apart. Every chunk of data is sampled with $25.6\,\mathrm{kHz}$ for a period of $10\,\mathrm{s}$, allowing for spectral, spectral-temporal or topological data analysis. We assume that any changes happen on time scales of days or weeks, and hence the data is stationary over each of those $10\,\mathrm{s}$ segments. Therefore, the main strategy of our analysis focuses on finding trends between time segments as we get closer to the failure time.

The key challenge in this work is the lack of ground truth, as we do not know the onset of the damage that eventually led to the failure of the gearbox. Therefore, we use the early stages of data as a baseline, assuming that the damage developed later. In other words, we are looking for systematic deviations from the early state which is assumed to be *healthy*. Topological data analysis was performed with the Giotto-TDA code suite (Pérez, Hauke, Lupo, Caorsi, & Dassatti, 2021). Time series from vibration sensors were embedded using Takens embedding with the optimal time delay and embedding dimension chosen by the built-in standard heuristics based on mutual information (Fraser & Swinney, 1986; Abarbanel, Kennel, & Brown, 1992). Persistence diagrams D were then compiled from the Vietoris-Rips complexes obtained from the filtration and used to compute the following topological indicators:
The maximum persistence, defined as the infinity norm for each homology dimension:

$$\mathcal{P}_{\infty}^{\mathrm{H}_k}(D_{\mathrm{H}_k}) = \max_{\{b,d\}\in D} |d-b| \tag{2}$$

This is a useful shape indicator as noise gives rise to points in D with a short lifetime, while relevant features of the points cloud (*e.g.* loops) are expected to have high persistence.
The normalized persistence entropy is another measure of complexity (Atienza, Gonzalez-Diaz, & Rucco, 2019; Atienza, Gonzalez-Díaz, & Soriano-Trigueros, 2020), $\overline{\mathrm{E}}_{\mathrm{H}_k}(D)$, expressed as a measure of the distribution of points along the diagram based on Shannon's entropy formula:

$$\overline{\mathrm{E}}_{\mathrm{H}_k}(D) = -\frac{1}{\log_2 \mathcal{S}(D)} \sum_{\{b,d\}\in D_{\mathrm{H}_k}} \frac{|d-b|}{\mathcal{S}(D)} \log_2\left(\frac{|d-b|}{\mathcal{S}(D)}\right)$$

where the amplitude $\mathcal{S}(D_{\mathrm{H}_k})$ for a given dimension is defined as:

$$\mathcal{S}(D_{\mathrm{H}_k}) = \sum_{\{b,d\}\in D} |d-b| \tag{3}$$

Betti curves are another informative topological indicator, which measures the amount of k-dimensional topological features *i.e.* the Betti number, β_k (Hatcher, 2002), at each value of the filtration parameter. In practice, these "count" the number of k-dimensional holes of a space: β_0 represents connected components, β_1 circles, β_2 voids, etc. As an example, for a two-dimensional circle the set of Betti numbers $\{\beta_0, \beta_1, \beta_2\}$ are $\{1, 1, 0\}$, for a filled disk $\{1, 0, 0\}$, a hollow sphere $\{1, 0, 1\}$, for a filled ball $\{1, 0, 0\}$, for a torus $\{1, 2, 1\}$, etc.
Other indicators are the **f-family of indicators** defined here, as proposed by Adcock et al. (Adcock, Carlsson, & Carlsson, 2016) and used in TDA for the anomaly detection in rotating equipment for manufacturing (Yesilli, Khasawneh, & Otto, 2022b; Khasawneh & Munch, 2016) as they combine

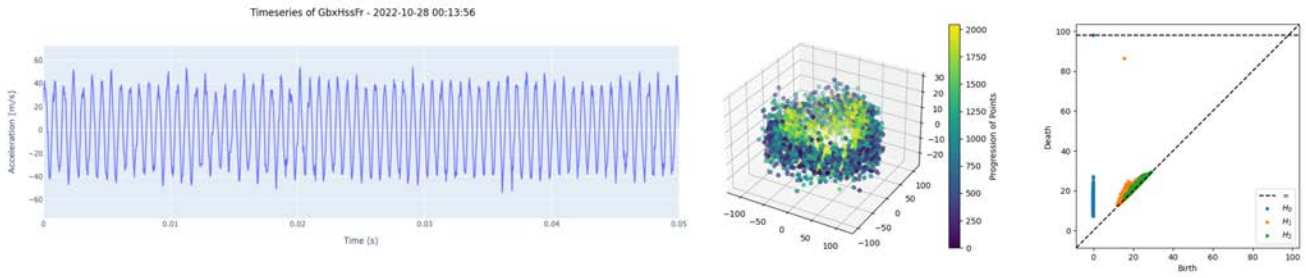

Figure 2. Left to right: Raw time-series signal, embedded point cloud and persistence diagram for GbxHssFr sensor at normal operation state. Note the toroidal point cloud, resulting from the embedding of the periodic time series. The loop structure is revealed in the persistence diagram as a point (yellow) far from the diagonal, where points created by signal noise tend to accumulate.

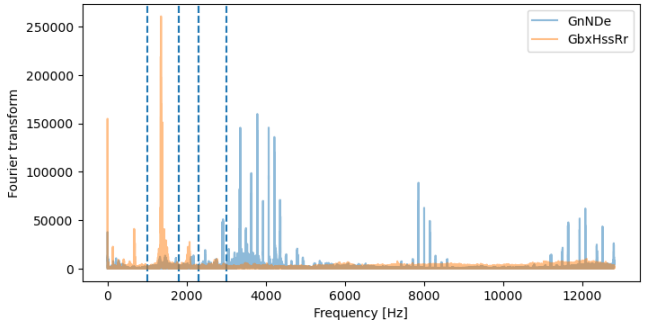

Figure 3. Fourier transform (normalised to counts) of the signal recorded on 2023-10-28 for GnNDe-BBF and GbxHssFr-BBF. The vertical lines indicate the frequency intervals for which the most dominating peaks are investigated for GbxHssFr.

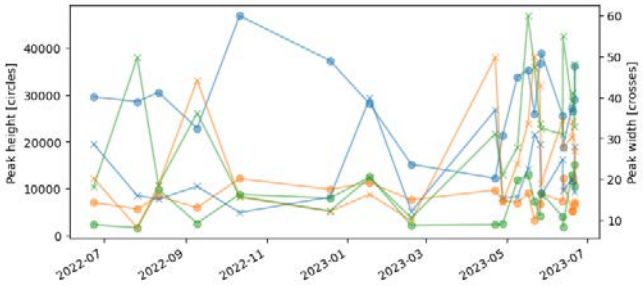

Figure 4. Peak height (left axis, circles) and width (right axis, crosses) for three frequency signatures (most dominant peak in the frequency ranges [1000, 1800], [1800, 2300], [2300, 3000] Hz) for GbxHssFr in the bearing failure case.

the highest persistence with amplitude information:

$$\begin{aligned} f_1 &= \textstyle\sum_i b_i \cdot (d_i - b_i) \\ f_2 &= \textstyle\sum_i (d_{max} - d_i) - (d_i - b_i) \\ f_3 &= \textstyle\sum_i b_i^2 \cdot (d_i - b_i)^4 \\ f_4 &= \textstyle\sum_i (d_{max} - d_i)^2 - (d_i - b_i)^4 \end{aligned} \tag{4}$$

4. Data Analysis

No data cleaning or pre-processing has been performed to the signal prior to the analysis described in Section 3, hereafter addressed as 'raw data'.

4.1. Bearing Failure

The bearing failure was reported at the non-drive end of the generator, corresponding to the location of the sensor labelled as "GnNDe" and the signal was recorded sporadically between October 2022 and the failure on November 11 2023. Each time series records acceleration data for the sensor and the corresponding frequency spectrum is computed from the raw signal through a Fast Fourier Transform (FFT) approximation. Figure 3 shows the spectrum for the signal recorded at the GnNDe (blue) and at the earliest available timestamp, 28-10-2023. We assume this to correspond to a state of "normal operations".

Topological analysis shows the point cloud corresponding with GnNDe is not describing a torus, but rather a semi-uniform ball, indicating non-periodic or very noisy behaviour. As a consequence, the H_0 persistence can only be interpreted as a measure of how much clustered or diffused the data are in the parameters space, while H_1 and higher-dimensional homology signals are expected to be low and not significant. Indeed, the only noticeable trend in the topological indicators is a decrease in H_0 persistence and an increase in entropy, typically as a consequence of a progressively less structured and more noisy signal. At a closer look, other sensor signals seem more suitable for analysis. In particular, the intermediate and high-speed stage sensors (GbxIss and GbxHss, respectively) show a more periodic and regular behaviour. Indeed the high-speed front (GbxHssFr) sensor shows a clear oscillating signal and a frequency spectrum dominated by a peak at around $1400\,\mathrm{Hz}$ and its multiples (orange spectrum in Figure 4). The embedded signal clearly shows a toroidal shape, a "filled" torus consisting of one main loop induced by the main frequency com-

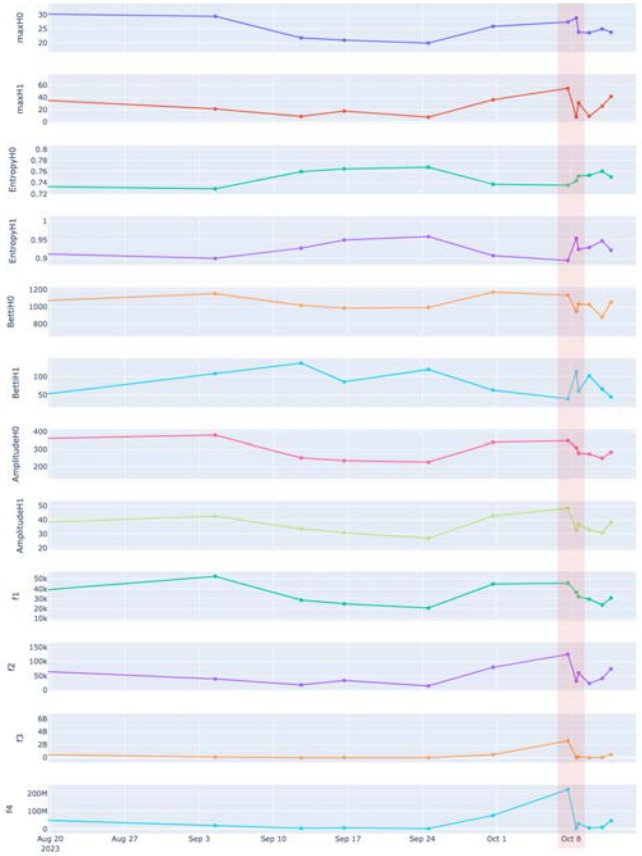

Figure 5. Topological indicators computed for the signal GbxHssFr in the bearing failure case. Highlighted the most significant anomaly, dated 2023-10-08.

ponent, and the direction orthogonal to the loop blown up by the noise. The corresponding persistence diagram then shows a high persistence point for H_0 and one at H_1 corresponding to the loop and proportional to its size.

The analysis of the evolution of the GbxHssFr signal is not trivial. Figure 3 shows the time development of the most dominant peak in each of the three frequency bands shown in Figure 4. We found that the frequencies do not shift significantly until the time of the failure (not shown). The corresponding peak heights and widths show a larger spread, especially at the lowest frequency. We also measure the evolution by computing the mutual distance between the vectors containing Fourier coefficients for each time series. This distance becomes more evident between the signal in the early timestamps (i.e. normal operations) and signals in a few specific days close to the failure, in particular at 2023-10-08 and 2023-10-10, one and three days from the failure, especially for the components included from 0 to $1800\,\mathrm{Hz}$.

We observe a similar behaviour in the skewness and kurtosis of the raw signal, which show a slow decreasing trend, with a very high spike in the latter at the timestamp 08-10-2023, 3 days from the point of failure, which was not evident from the spectra alone. The monitoring of kurtosis in the early detection of bearing failures is well-known in the literature and it is likely to be a good indicator in this case as well (H. Zhang, Chen, Du, & Yan, 2016; Chauhan et al., 2024; Sawalhi & Randall, 2004).

The development of TDA indicators over time are shown in Figure 5 for GbxHssFr. Indeed most indicators show a sharp change around 08-10-2023, particularly the indicators that include the maximum persistence in dimension 1, e.g. $\mathcal{P}_{\infty}^{\mathrm{H}_1}$, $f_2(H_1)$ and $f_4(H_1)$. When applying the sliding windows approach of TDA and focusing on the short-term dynamics of the signal, the topological indicators are computed for short time windows ($5\,\mathrm{ms}$) across one signal and then averaged (Figure 6). This deep dive allows us to expose the dynamics of the signal, how the topology of the point cloud changes on short timescales and, in turn, whether the signal frequencies are finely modulated. The sliding window anal-

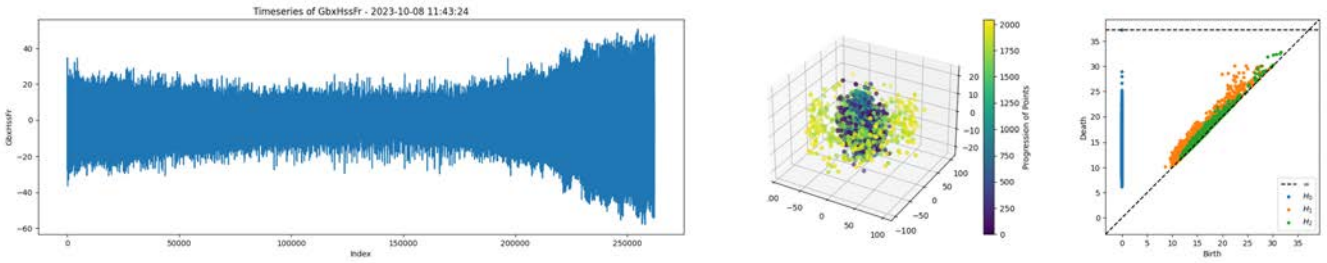

Figure 7. Left to right: Raw time-series signal, embedded point cloud and persistence diagram for GbxHssFr sensor recorded at 2023-10-08. Comparing the point and the persistence diagram with Figure 2 the loop structure of the point cloud has disappeared, together with the high persistence H_1 point in the diagram.

ysis is in perfect agreement with the Fourier analysis and the kurtosis signal, where a sharp change is visible on 2023-10-08. The change in the TDA results can be ascribed to a change in the average frequency of the signal, leading to a shrinkage of the toroidal point cloud to the point of almost closing the 'hole' of the torus (see Figure 7). This leads to a temporarily abrupt decrease in the persistence of the H_1 feature, and an increase in its entropy (entropy scales inversely with the smoothness of the manifold). There is also an apparent amplitude modulation of the raw signal which is hard to capture with TDA, but has been linked before with bearing failures in wind turbines (Jiang, Zhang, Xiang, Yu, & Xu, 2023).

4.2. Gear-tooth failure

A gear tooth damage event was reported on a different wind turbine in the same wind park in July 2023. The signal recorded for the sensor located closest to the failure, Gbx1Ps, has a frequency spectrum fairly similar to that of the high-speed sensor, GbxHssFr: dominated by few isolated frequency contributions. The only significant feature we could identify in the data is a drift in the peak width, similar to the case of the bearing fault, starting around May 2023 (see Figure 8).

Interestingly, when integrating the spectrum in the frequency range recommended by standard ISO 10816-3 (hereafter denoted Gbx1Ps.ECU2 where the signal is demodulated between 500-2kHz with the RMS broadband value between 1-150Hz). it appears more evident that a sudden jump in the signal of about 50% occurs between April and May 2023, as shown in Figure 8.

Following the same process as for the bearing fault, we focus on the high-speed gear sensor GbxHssFr, which shows a more regular oscillation pattern (see Figure 9). We apply both the Fourier and TDA analysis to uncover any possible failure signature in the data. Analogously to the bearing fault case, skewness and kurtosis show a drop, associated with an increase in the signal's median, starting from around May 2023.

The topology of the data is again that of a "filled" torus (Figure 9), which is topologically equivalent (homotopy equivalent) to a circle in 2 dimensions. This means that it should be possible to reduce the dimensionality of the Takens embedding to 2, without loss of information. We, therefore, focused on this reduced model for our analysis. The sliding windows processing for the GbxHssFr signal reveals a change in most of the topological indicators ($\mathcal{P}_{\infty}^{\mathrm{H}_{0,1}}$, $\overline{\mathrm{E}}_{\mathrm{H}_{0,1}}$, $\mathcal{S}_{H_{0,1}}$), etc.) at the same timestamp in April, and again more sharply only 2 days before the failure in July 2023, as visible from Figure 10. Close to the failure there is an increase in the persistence and a decrease in the entropy, signalling a change in the size of the loop when averaged across the 10 s of the signal at a given timestamp, but not in its shape as the Betti number indicator for dimension 1 remains stable.

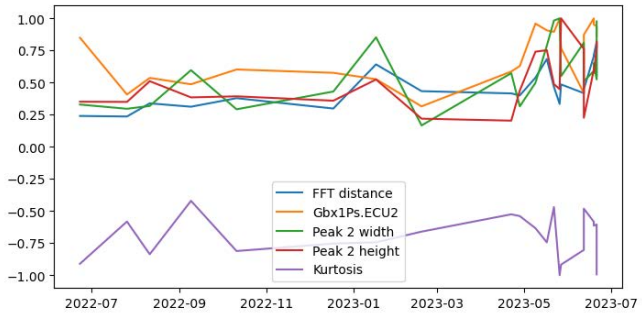

Figure 8. Selection of health indicators for the gear-tooth failure from sensor Gbx1Ps. FFT distance is the geometric distance between the average of the first three spectra in the dataset and each individual spectrum in the range [1800, 3000] Hz. Gbx1Ps.ECU2 is the indicator from standard ISO 10816-3. Peak 2 width and height are the characteristics of the dominating peak in the range [1800, 2300] Hz. Kurtosis is the kurtosis of the raw vibrations. All quantities have been normalised to their maximum value in the time interval.

In TDA, periodic functions get embedded in loops of a size proportional to the size of the sliding window (Perea & Harer, 2015), therefore, a change in the size of the torus loop should correspond to changes in the period of the gearbox vibrations or some kind of frequency modulation, close to the failure event. By looking at spectrograms for the GbxHssFr signal (Figure 11) it is possible to recover some of the dynamics of the peaks in the spectrum. On one hand, at timestamps far from the failure, the spectra shift only slightly across the 10 s of the recorded signal, and mostly the peaks tend to change

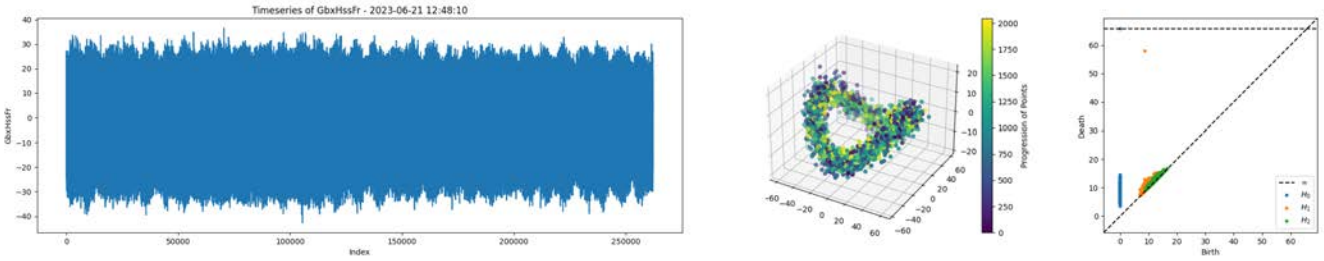

Figure 9. Left to right: Raw time-series signal, embedded point cloud and persistence diagram for GbxHssFr sensor in the gear-tooth failure case. Note the toroidal point cloud, resulting from the embedding of the periodic time series.

width with a timescale of a few seconds. On the other hand, close to the failure it appears that the two main peaks at 1350 Hz and 2700 Hz "jump" as their relative height tends to oscillate on a 3-4 Hz timescale, i.e. about 40 times across the measurement duration in a jittering fashion. This frequency modulation should also be noticeable in the TDA results, as the size of the loop in the point cloud should change as well. Indeed, this becomes evident when looking at the maximum persistence in dimension 1 ($\mathcal{P}_\infty^{\mathrm{H}_1}$) and in particular to the radius of gyration (R_{gyration}) for the point cloud, defined as:

$$R_{\text{gyration}} = \sqrt{\frac{1}{N}\sum_{i=1}^{N}(\mathbf{r}_i - \mathbf{r}_{\text{CM}})^2} \tag{5}$$

where N is the total number of points in the point cloud, $\mathbf{r}_i$ represents the position vector of the i-th point, $\mathbf{r}_{\text{CM}}$ denotes the position vector of the centre of mass of the point cloud.

The gyration radii for the data farther and closest in time to the gear tooth failure are shown in Figure 12 and manifests as a rapid oscillation in the gyration radius. This rapid modulation could indeed be a signature of imminent equipment failure. Interestingly, we notice this kind of modulation is common in other engineering disciplines, such as metal turning and machining, where is a signature of "chattering", a pathological resonance in the turning process (W.-K. Wang, Wan, Zhang, & Yang, 2022). Unsurprisingly, TDA has been successfully applied to chatter detection and it was shown to be useful in the early detection and the machine learning identification of such anomalies is several industrial settings (Khasawneh, Munch, & Perea, 2018; Yesilli et al., 2022b; Khasawneh & Munch, 2016; Yesilli, Khasawneh, & Otto, 2022a).

5. Conclusion

In this study, we have explored the application of topological data analysis (TDA) in conjunction with spectral analysis for condition-based monitoring (CBM) of wind turbines. Our investigation focused on analyzing vibration data aiming to detect and diagnose potential faults in gearbox components. Through TDA, we transformed raw vibration data into multi-dimensional point clouds and leveraged topological indicators such as Betti numbers, persistence diagrams, and entropy to characterize the underlying structure of the data. We compared TDA with traditional spectral analysis methods and observed that TDA offers complementary insights, particularly in identifying complex patterns and anomalies that may not be apparent through conventional signal processing techniques alone.

Our analysis revealed promising results in using TDA for fault detection and diagnosis. In the case of bearing failure, we observed significant changes in topological indicators, particularly in persistence and entropy, preceding the failure event. Similarly, for gear-tooth failure, TDA highlighted distinct changes in the structure of the point cloud, indicating the onset of damage. Furthermore, by integrating spectral analysis with TDA, we were able to uncover additional dynamics in the data, such as frequency modulation, which could serve as early indicators of equipment deterioration. These findings suggest the potential of TDA as a valuable tool for CBM in wind turbines, offering a complementary approach to monitoring and diagnosing faults and to proactive maintenance strategies in renewable energy generation. While TDA is only slightly more computationally demanding than the more traditional spectral analysis methods, it offers additional visual support by providing a manifold representing the data. Changes in the manifold of data in phase space correspond to changes in the vibration dynamics of the system, as is well known from dynamical system theory and therefore changes in the system's health may be more easily inferred by analyzing the shape of the data in addition to its spectral features.

Future research could explore the integration of TDA with machine learning techniques for more robust fault detection algorithms. Additionally, incorporating real-time monitoring capabilities could enhance the practical applicability of TDA in industrial settings.

ABSTRACT

Many articles have been published utilizing machine learning algorithms for condition-based maintenance through the analysis of vibration signals. One extensively researched topic is the classification of fault types in rolling bearings. There is a fairly widespread problem in the evaluation of these learning algorithms, where the separation of examples between the test and training sets is incorrect, leading to an optimistic conclusion about the algorithm's performance even when it is not the case. In this article, we will review this issue and explain how the data should be properly divided between the test and training sets to avoid this occurrence.

1. INTRODUCTION

Condition-based maintenance of rotating machinery, through the analysis of vibration signals, can significantly reduce maintenance costs and also help prevent catastrophic accidents (Matania et al., 2024; Randall, 2021). Over the years, a wide variety of machine learning algorithms have been developed to enhance traditional signal processing methods for vibration analysis (Lei, 2017).

One of the topics extensively explored in the field is the classification of fault types in bearings using machine learning algorithms (Lei et al., 2020). In this task, the algorithm is required to predict the fault type from four possibilities for a given input record: healthy condition (i.e., no fault), fault in the inner race, fault in the outer race, or fault in the rolling element. To achieve this, the algorithm is provided with examples of input records with various fault types during the training phase, and it predicts the fault type for new input records during the testing phase.

A wide variety of machine learning algorithms have been applied to this task. The first type comprises classical machine learning algorithms, where a domain expert extracts correlated features related to the fault, and the learning algorithm learns the relationship between these features and the fault type (Shalev-Shwartz & Ben-David, 2014c). The second type, developed later during the third wave of deep learning, utilizes deep neural networks to address this problem. Unlike classical algorithms, the neural network autonomously learns features that connect the vibration signals to the fault type, essentially eliminating the need for a domain expert (Goodfellow et al., 2016). In both types of learning algorithms, many studies incorrectly split the training set and the test set, leading to significant test-training leakage (Kapoor & Narayanan, 2023) that results in inaccurate, overly optimistic performance evaluations of the examined algorithms (Hendriks et al., 2022).

The first type of test-training leakage, which is also the more problematic of the two, involves splitting the same input record into different segments and randomly distributing them between the test set and the training set. Figure 1 illustrates this type of splitting. This splitting is fundamentally flawed, as many features in the same input may be unrelated to the fault type, causing the learning algorithm to inadvertently learn them. Often, when disassembling the test rig to change the tested bearing, there is a change in the vibration signature unrelated to the fault type at all. For example, researchers from the SKF group found evidence of this phenomenon in a study on fault severity assessment (Liefstingh et al., 2021). They demonstrated that the learning algorithm learned features from the vibration signature related to the transfer function of the test rig instead of information related to the fault. In such

[*]Equally contributed.

a case, when segments from the same record are divided between the training and test sets, the learning algorithm may seem to predict the fault type well, although it actually relates the segments from the same records based on the characteristics of the transfer function.

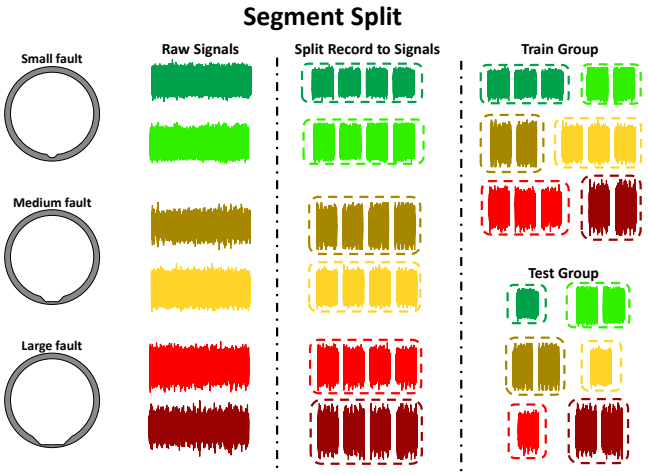

Figure 1. Illustration of random split of segments between the training and test sets.

The second type of test-training leakage involves the random separation of different records of the same fault type with the same fault shape precisely between the test and training sets. Figure 2 illustrates this type of improper separation. Each fault type can exhibit a wide variety of shapes. For example, a fault in the outer race can manifest in numerous different shapes and sizes, potentially even an infinite number. In practice, the likelihood that the exact shape of the fault in a real-world scenario matches one of the faults the algorithm learned from in the training set is very low. Many datasets record each fault multiple times. Randomly distributing these records between the test and training sets is incorrect and does not represent reality. In such a scenario, the algorithm may learn features related to the shape of the fault rather than its type, leading to overly optimistic evaluated performances. Furthermore, in some cases, the records of the same fault shape do not include the assembly of the test rig. Consequently, the algorithm may learn features from the vibration signature related to the transfer function of the test rig rather than information related to the fault, similar to the previous case of random segment split.

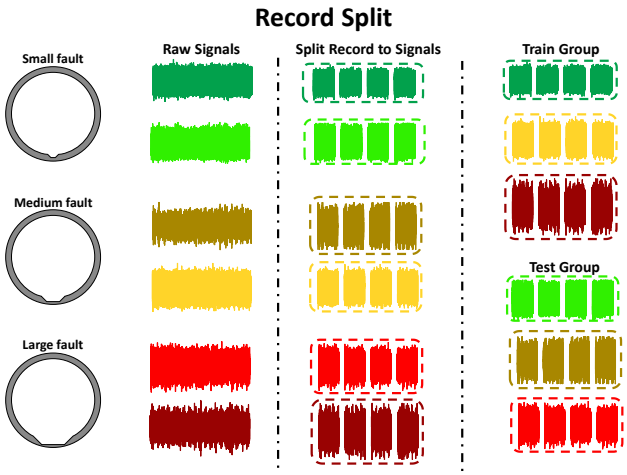

Figure 2. Illustration of random split of records between the training and test sets.

Figure 3 illustrates the correct splitting for evaluation learning algorithms: all records of each fault shape are either sent to the test set or to the training set. Following this separation, each record can be further divided into smaller segments if necessary. In this approach, to achieve an accurate estimation of performance, it is recommended to use K-fold testing. For example, in this study, performance evaluation in the test is implemented using the leave-one-out procedure, which is an extreme form of K-fold testing.

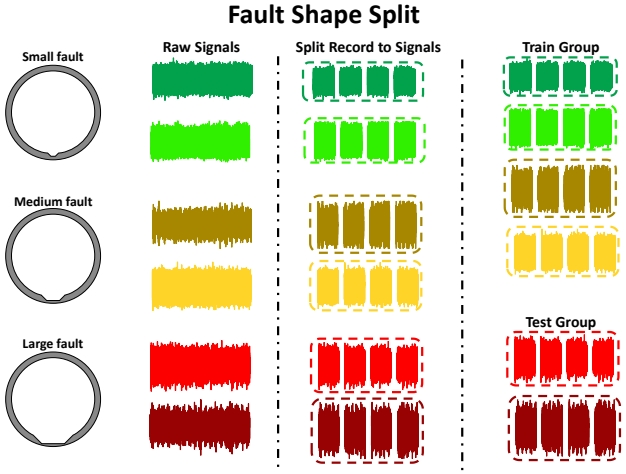

Figure 3. Illustration of split by fault shape between the training and test sets.

Section 2 will discuss the datasets analyzed in the article, and Section 3 will cover the learning algorithms. Section 4 will demonstrate that indeed, both segment split and record split lead to optimistic results compared to the correct way of fault shape split. Section 5 will summarize the article and present the conclusions.

2. TESTED DATASETS

Two datasets that are frequently used for evaluating machine learning algorithms for fault classification in rotating

machinery are discussed in the article. The first dataset, Case Western Reserve University dataset (CWRU), is accessible via the link (*Case Western Reserve University Bearing Data Center Website*, n.d.) and is extensively described in the work by Smith and Randall (Smith & Randall, 2015). It is important to note that this dataset has several issues, as explained by Smith and Randall, yet for unknown reasons it is still widely utilized. The CWRU test rig is illustrated in Figure 4. The CWRU dataset comprises a total of 416 distinct records, but in practice, only 12 truly different faults exist.

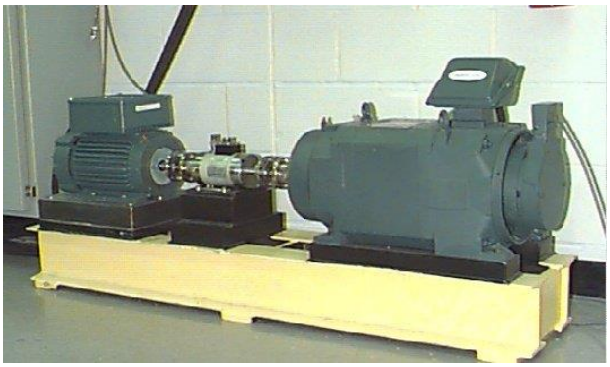

Figure 4. CWRU dataset test rig. Reproduced from (*Case Western Reserve University Bearing Data Center Website*, n.d.).

The Paderborn University (PU) dataset also serves for the evaluation of various learning algorithms and is extensively described in the study of Lessmeier et al. (Lessmeier et al., 2016). Our review of this dataset led to the conclusion that it also has several issues, such as unclear sources of interferences in the spectrum. In total, the PU dataset contains 2493 recordings, with 26 truly distinct faults in practice. Figure 5 depicts the experimental setup.

Figure 5. PU dataset test rig. Reproduced from (Lessmeier et al., 2016).

3. TESTED ALGORITHMS

In the current section, two learning algorithms will be described, which are used to demonstrate the effect of test-training leakage. The first is K-nearest neighbors (KNN) (Shalev-Shwartz & Ben-David, 2014a) and the second is Random Forest (Shalev-Shwartz & Ben-David, 2014b). All tested algorithms used the following features: mean, variance, kurtosis and absolute mean.

KNN operates by determining the class of a data point based on the majority class among its k-nearest neighbors within the feature space. The algorithm computes the distance between the given data point and its neighbors. The parameter K, denoting the number of neighbors taken into account, is a crucial factor that can significantly influence the model's performance. Small K values may result in overfitting, while large K values may lead to inadequate fitting of the training data. In the current study, K was set to 1 to prevent additional issues with training-validation splitting. Figure 6 provides a visualization of the KNN process for classification.

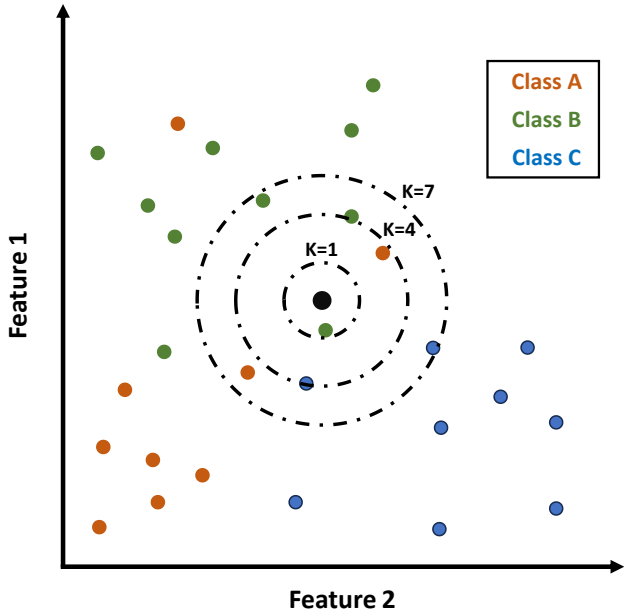

Figure 6. Illustration of KNN.

Random Forest stands out as a robust ensemble learning algorithm widely applied in machine learning for classification tasks. It generates numerous decision trees during training and outputs the mode of the classes. The key innovation of Random Forest lies in its incorporation of randomness—each tree is trained on a random subset of the data, and during each split, a random subset of features is taken into consideration. This randomness aids in mitigating overfitting and enhancing the model's generalization performance. Furthermore, for classification, the predictions from multiple trees are consolidated through majority voting, resulting in a resilient and accurate final prediction. In the current case, the number of trees was set to 300. This is a standard number of trees intended to prevent overfitting. Once again, this parameter was not set based on the validation set to avoid additional issues with training-validation splitting. Figure 7 provides a visualization of the random forest process for classification.

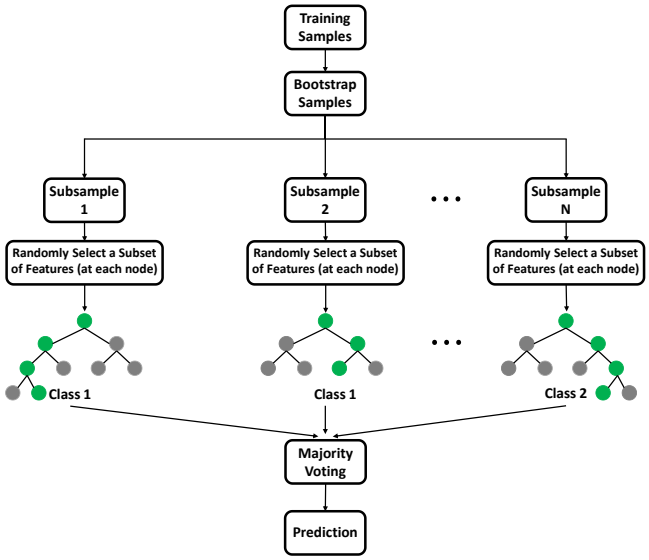

Figure 7. Illustration of random forest.

4. RESULTS

The results of KNN and random forest on the two tested datasets, CWRU and PU, are depicted in Figure 8 for the three types of splitting: segment split, record split, and fault shape split. The results of the segment and record splits were determined using a 10-fold cross-validation technique to calculate the average accuracy. The fault shape split results were obtained through a leave-one-out procedure. Furthermore, to compare the performance with a degenerated algorithm, two lines were added to the figure representing predictions of the test examples in the fault shape splitting for CWRU and PU, based on the most prevalent label in the training set. This degenerated algorithm disregards the features and, for any new unseen examples, returns the mode of the classes from the training set.

As can be seen from the figure, for the CWRU dataset, when changing from segment split to record split, the accuracy significantly decreases. For both datasets, when the correct splitting method is utilized, namely the fault shape split, the results are significantly worse. In the case of CWRU, they are even lower than the accuracy of the degenerated algorithm, which predicts the training mode constantly.

These results demonstrate that incorrect random splitting leads to overly optimistic conclusions. For the CWRU dataset, based on segment split, it seems that the very straightforward approach of using simple signal features and classic machine learning algorithms like KNN and random forest enable achieving good accuracy, close to 90%. However, when the record split is applied, the results are much less optimistic, and when the correct method is applied, the results are worser than constantly predicting the training mode, indicating that both algorithms probably learn nothing related to the fault type. For PU datasets, even when record split is utilized, the results are still optimistic, and only when the correct splitting of fault shape is utilized can we again conclude that the algorithm did not learn too much information related to the fault type.

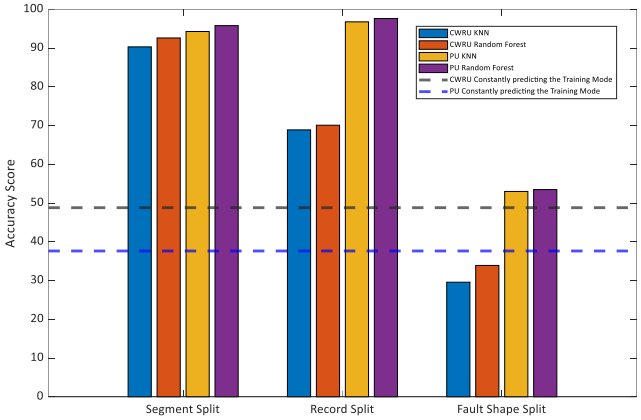

Figure 8. Accuracy score for bearing fault type classification on CWRU and PU datasets by KNN and random forest for different split approaches.

5. CONCLUSION

Many machine learning algorithms have been suggested for vibration analysis of rotating machinery for condition-based maintenance. As demonstrated in this paper, improper splitting of data between the training and test sets may lead to test-training leakage and, consequently, to an overly optimistic evaluation of the machine learning algorithm performances.

In the current study, this problem was tested on the prevalent task of fault type classification in rolling bearings. It was shown that when improper segment splitting is utilized, overly optimistic conclusions can be drawn regarding a simple approach that combines straightforward signal features with basic machine learning algorithms, as they achieve accuracy close to 90%. However, when the right splitting is utilized, reflecting the real scenario in which records of the exact same fault shape should not be present in both the training and test sets, the results are very poor and, in some cases, worser than constantly predicting the training mode, indicating that the algorithms have not learned anything.

Three further comments regarding machine learning studies in the vibration analysis field are worth discussing. First, most of the currently available datasets, such as CWRU and PU, contain many contaminated records. The research community would benefit greatly from newer datasets without contaminated records, which would also encompass a broader range of fault shapes. Second, it is not clear why so many papers attempt to solve the problem of fault type classification in bearings, as classic approaches in signal processing are adept at solving it (Randall & Antoni, 2011). We recommend that future papers focus on addressing fault

severity and estimating remaining useful life tasks (Matania et al., 2023), or alternatively, focus on fault classification of components that currently lack well-established classic approaches. Another option is to examine cases where the signal-to-noise ratio is so low that signal processing algorithms are unable to classify the fault type. The last comment worth noting is that a maintainer or operations manager doesn't really care if a bearing has a ball, inner, or outer race fault – as they will probably replace the entire bearing regardless. The more important issue is fault detection, determining whether the bearing is healthy or not. Fault classification is more interesting if it helps to better estimate severity or remaining useful life.

ABSTRACT

This study focuses on a critical aspect of implementing prognostics and health management (PHM) for assets: the creation of a descriptive dataset. In real-world applications, dealing with sparse and unlabelled big data is common, particularly in industries like production lines where complex subprocesses are monitored by multiple sensors. Moreover, selective application of quality control means that much of the data lacks information about end properties, making datasets provided by manufacturers unsuitable for PHM frameworks. This work aims to bridge the gap between raw production data and PHM frameworks, focusing on steel manufacturing management. In the context of steel manufacturing, compromised surface quality, characterized by thicker oxide layers chipping during milling, has been observed. We propose inferring compromised coils by analyzing temperature profiles directly before the coiling station to address this. Deviations from the goal temperature profile can indicate compromised surface quality, eliminating the need for tedious oxide layer thickness measurements, which are not feasible for continuous hot strip milling processes. The available dataset comprised multiple years of production, with no direct indication of the surface quality. Exploratory clustering analysis was the first step in the lack of labels. Even though indicative of the underlying pattern of the healthy/damaged coils distinction, three shortcomings were identified. Clustering was solely based on the similarity between the temperature profiles of the coils, so no domain knowledge was included regarding the goal temperature profile. Additionally, since different steel grades have different goal profiles, the model needs to be specifically trained for each grade. Also, a soft classification between healthy and damaged can provide more detailed information about the surface quality. Coils with low-confidence classifications can be identified and treated accordingly, thereby improving PHM framework performance by providing a dataset with only high-confidence samples. To tackle these issues, an expert-knowledge-based normalization technique and feature engineering, paired with synthetic labelling, contributed to the creation of a soft neural network classifier. This study presents the reality of handling real-world data for PHM applications and highlights the need for careful and informed feature extraction. This ensures the seamless integration of PHM frameworks into real-world systems, ultimately enhancing production yield by improving end-product quality.

1. INTRODUCTION

The 4^{th} industrial revolution led to a skyrocketing increase in the available data in production and manufacturing lines. Sensors were developed and installed throughout the processes, and computer-operated regulating devices were retrofitted to production equipment. This not only meant that the manufacturing process could be guided by preset rules that were constantly tailored to the real measurements of the system but also that an enormous amount of data became available. Manufacturers, suspecting these data's value, made sure to gather and store them in databases. However, the vast majority of the available data are unstructured and unlabelled, leading to their under-utilization.

The unstructured nature of big data gathered from multiple sources during production is one of the main challenges of applying prognostic health management (PHM) frameworks (Zio, 2022). Data quality greatly affects performance, especially for fault detection (FD), which is usually the first task during a PHM framework. The need to identify anomalies and deviations from the normal operating condition of the asset arises, but data are usually high-dimensional with non-smooth distribution densities. This makes their reconstruction and, in turn, the distinction between healthy and abnormal, challenging.

In order to tackle the high-dimensionality of the data, the challenge of informative feature extraction (FE) arises (Jardine, Lin, & Banjevic, 2006), in the hope of projecting the data into manifolds of lower dimensionalities, where the underlying classes become distinguishable. Traditional pre-processing techniques include statistical feature extraction in the time domain (Caesarendra & Tjahjowidodo, 2017), fast fourier transform (Z. Wang, McConnell, Balog, & Johnson, 2014), discrete wavelet transform (Z. Wang et al., 2014), continuous wavelet transform (Kankar, Sharma, & Harsha, 2011), morphology operators (Gush et al., 2018) and principal component analysis (Choi, Lee, & Lee, 2005). Adding to that, in the latest years, due to the ever-increasing applications of machine learning (ML) and deep learning (DL) in computer science, numerous successful applications for FE for PHM frameworks have been demonstrated. Categorical adversarial autoencoders (Liu et al., 2018), stacked autoencoders (Y. Wang, Yang, et al., 2020), generative adversarial networks (Jiang, Hong, Zhou, He, & Cheng, 2019; Xia et al., 2022), deep convolutional networks (Wu & Zhao, 2018) and deep belief networks (Y. Wang, Pan, Yuan, Yang, & Gui, 2020), are examples of ML and DL frameworks to extract lower dimensionality representations of big data.

However, it becomes apparent that DL does not provide a universal solution to FE (Zhao et al., 2019). Great effort and resources are associated with designing and training a successful DL model, and usually, the impressively performing but complex architectures make the DL networks task- and domain-specific. In this work, presented with a big real-world dataset from steel manufacturing, a data science and fundamental approach for feature extraction is followed. The aim is to showcase that even highly complex datasets with high variability, can be handled with expert-driven analysis, proving the discriminating power of informative features. The following sections will describe the issue under consideration and the available dataset (Section 2), followed by an overview of the applied methods (Section 3), the findings (Section 4), and a concluding discussion (Section 5).

2. Problem statement and dataset description

Steel strips are being widely used for numerous applications across multiple domains, such as the automotive industry, the aerospace industry, chemical equipment and light manufacturing, all of which, among others, have increasing demands considering surface quality. However, surface defects can appear during manufacturing, which significantly diminishes the end surface quality of the manufactured steel strips. Known root causes of surface quality defects are material defects, process defects and corrosion defects (Z. Wang, Wang, & Chen, 2020). Material and process defects can be more easily mitigated by tailoring the material's composition and manufacturing process (i.e. rolling forces, timely inspection and replacement of rollers). Unfortunately, corrosion defects are, by nature, more challenging. The low stability of the typical three-layer oxide composition of steel (hematite Fe_2O_3, magnetite Fe_3O_4 and wustite $Fe_{1-y}O$) at the low coiling temperatures, the presence of other elements in low-carbon steel, the presence of inclusions, the continuous cooling conditions, the temperature gradient across the width of the strip, the absence or lack of oxygen in the centre regions, all affect the oxide evolution (Chen & Yuen, 2001; Deng et al., 2017). The extensive study of Min K. et. al. (Min, Kim, Kim, & Lee, 2012) revealed a correlation between the thickness of the oxide layer and the surface quality. This is attributed to the fact that a thicker oxide scale is more brittle and, thus, more prone to chip off.

As demonstrated by Min K. et al. (Min et al., 2012), measuring the oxide layer thickness during production is not feasible. Production must be halted, and the oxide layer formation must be frozen (i.e., by spraying molten glass on the surface). This process can quickly become costly and counterproductive for a real-world application. This fact, combined with the fact that practical scale differs from lab-grown (Deng et al., 2017), led our team to try to develop a way to infer it indirectly from production measurements.

The first step towards achieving this goal is creating a labelled dataset from historical data containing coils with deteriorated and pristine surface quality. We theorize that, by observing the steel strip's coiling temperature (CT) profile, major deviations from the goal temperature and, more importantly, rapid fluctuations, can indicate a chipped-off oxide layer. The reasoning behind this is that when the oxide layer chips off, some parts of exposed steel appear on the surface that have drastically different emissivity than the oxides, throwing off the pyrometer temperature measurements. Thus, the need to distinguish faulty cases from normal ones from sequential data arises.

The dataset in hand consists of the process parameters, the CT profiles and the material properties of the manufactured steel strips from the hot strip milling (HSM) process of Tata Steel Europe ©. Due to the great variability in the CT profiles as well as the goal temperatures, a single steel grade was chosen, considering its observed troublesome behaviour during milling (the details of which will not be disclosed due to confidentiality). After data cleaning, the remaining dataset consists of 3768 CT profiles, that will in turn, be used for the development of the classification algorithm.

3. METHODS

Given the dataset's unlabelled nature, an exploratory clustering analysis was the first step towards processing the dataset to discover the expected underlying pattern of healthy and damaged coils. Afterwards, a domain-specific normalization was introduced to the sequential data to assist towards creating a universal framework independent of the steel grade. This is of high importance since a great number of different steel grades are produced. Therefore, if the developed framework is grade-specific, it will need to be trained for each grade specifically, making it counter-productive. Two different FE techniques were realized and contrasted: a domain-agnostic one and an expert-knowledge-based one. Finally, synthetic labels were created to facilitate the training of a neural network (NN) soft classifier to discriminate the produced coils into healthy and damaged ones (meaning with chipped-off oxides and pristine surface quality, respectively).

3.1. K-means with Dynamic Time Wrapping

Clustering analysis is one of the first steps in processing unlabelled data, due to its ability to uncover underlying patterns and connections in the dataset without requiring any prior knowledge. A well-known and established clustering algorithm is the k-means algorithm (Lloyd, 1982). The k-means algorithm strives to partition the n available observations into k clusters, where each observation belongs to the cluster with the nearest mean, referred to as the centroids. The original algorithm works by minimizing the squared Euclidean distances between the centroids and the observations. An immediate issue can be observed when the algorithm is tasked with clustering sequential data. The Euclidean distance between two points A and B can be calculated by Eq. (1), with δ being the distance between the elements.

$$D(A,B) = \sqrt{\delta(a_1,b_1)^2 + \cdots + \delta(a_T,b_T)^2} \qquad (1)$$

If A and B are sequences with $A = \langle x,y,x,x\rangle$ and $B = \langle x,x,y,x\rangle$, their Euclidean distance according to Eq. (1), will be great, even though intuitively, they sequences are similar. This is attributed to the inability of the Euclidean distance to capture similarities that are shifted in time. For that reason, the dynamic time wrapping (DTW) metric is introduced. Its main attribute is that it can capture similarities between sequences independently of the velocity (Sakoe, 1971). The way to achieve this is by aligning the coordinates inside the sequences by minimizing Eq. (2), where A_i is the subsequence $\langle a_1,\ldots,a_i\rangle$.

$$D(A,B) = \delta(a_i,b_i) + \min\left\{\begin{matrix} D(A_{i-1},B_{j-1}) \\ D(A_i,B_{j-1}) \\ D(A_{i-1},B_j)\end{matrix}\right\} \qquad (2)$$

Even though DTW can effectively find the optimal alignment between sequences and provide a single score for similarity, k-means requires the calculation of a cluster prototype (the centroid), which is the average of the assigned observations. Petitjean et al. (Petitjean, Ketterlin, & Gançarski, 2011), proposed the DTW barycenter averaging (DBA) algorithm, which iteratively calculates the barycenter of a set of sequences for the k-means algorithm. Later on, a differentiable function for computing the soft minimum of all of the alignment costs increases performance and reduces arithmetic complexity, referred to as soft-dtw algorithm (Cuturi & Blondel, 2018). For the aforementioned reasons and considering the large size of the dataset, the soft-dtw algorithm is chosen.

3.2. Domain-specific Normalization

One of the main issues with the given application for the distinction between good and bad coils is the great difference between the goal CT profiles for different steel grades. The difference lies not only in the temperature but also in the shape of the wanted goal CT profile. Some steel grades require a coffin-shaped CT profile where the head and the tail of the coil are hotter than the middle section. Adding to that, steel strips that belong to each coil are not manufactured equally. The manufacturer provides a range of properties for each grade, and thus, the final goal CT profile depends on the exact needs of the specific order. This inevitably leads to the inability to generalize any realized framework since it would need to be redesigned and explicitly trained for each available steel grade. The authors try to alleviate this dependency by normalizing the CT profiles with the goal CT. Let $traj_1 = \langle t_1,t_2,\ldots,t_F\rangle$ and its respective goal CT $goal_{ct} = \langle g_1,g_2,\ldots,g_F\rangle$. The normalized CT profile is calculated with the following:

$$traj_1{}^j_{norm} = \frac{t_j - g_j}{g_j}, j = [1,F] \qquad (3)$$

For the remaining of the analysis, the normalized trajectories $traj_{norm}$ will be used.

3.3. Feature Extraction

For the good/bad coil distinction, a NN classifier will be utilized (as explained in Sec. 3.5). NNs are generally unable to handle and interpret sequential data as inputs, excluding recurrent NNs (RNN) (Amari, 1972). RNNs come with their own set of limitations with lengthy sequential data, namely the high computational complexity, the vanishing gradient problem and the often-required tedious hyper-parameter tuning. To partially tackle said limitations, one can choose to split the sequential data into overlapping windows, but the choice of the length and overlap of the windows adds to the complexity of choosing optimal hyperparameters. For the aforementioned reasons, traditional fully connected layers (FC) will be used, and thus, the CT profiles need to be represented with fea-

tures. Two different techniques for FE are being contrasted: A domain-agnostic approach where a plethora of features is being extracted (statistical, temporal and spectral) and filtered automatically, and an expert-knowledge-based one.

3.3.1. Domain-Agnostic FE

Given sequential data, a domain-agnostic FE refers to the process where a variety of features are extracted without considering the nature of the data in the hope of capturing as many characteristics as possible. In this study, the features extracted were:

- Statistical: max, absolute max, min, kurtosis, standard deviation, variation, mean, median, min, quantile, sum of values, length, variance, variation coefficient, count of values above/below mean value, first location of min and max, length of longest strike above/below mean, root mean square, sum of reoccurring values,
- Autocorrelation values (Yentes et al., 2013) for $lag = (1, 2, \ldots, 10)$ and descriptive statistics on the aggregation function (mean, variance, median, standard deviation) over the autocorrelation,
- Approximate entropy (Yentes et al., 2013) with $(m = 2, r = 0.1), (m = 2, r = 0.3), (m = 2, r = 0.5), (m = 2, r = 0.7), (m = 2, r = 0.9)$ with m the length of the compared run of data and r the filtering level,
- Non-linearity measure with c3 statistics (Schreiber & Schmitz, 1997) with $lag = (1, 2, 3)$,
- Complexity-invariant distance (CID) with and without normalization (Batista, Keogh, Tataw, & De Souza, 2014),
- Coefficients $(0, 1, \ldots, 14)$ of continuous wavelet transform with Ricker wavelet for $widths = (2, 5, 10, 20)$ (Mallat, 1999),
- All the coefficients (real and imaginary part, angle and absolute) of the fast Fourier transformation (FFT),
- Statistics of the absolute FFT (mean, variance, skew and kurtosis),
- Binned entropy of the power spectral density with the Welch method (Welch, 1967) ,
- Friedrich polynomial coefficients (Friedrich et al., 2000) for order of 3,
- Value of the partial autocorrelation function (Box, Jenkins, Reinsel, & Ljung, 2015) for $lag = (1, 2, \ldots, 10)$,
- Permutation entropy (Bandt & Pompe, 2002) with $dimension = (3, 4, \ldots, 7)$,
- Sample entropy (Richman & Moorman, 2000),
- Time reversal asymmetry statistic (Fulcher & Jones, 2014) with $lag = (1, 2, 3)$.

(The values chosen for the parameters of the aforementioned features are the commonly used values since tuning their values would require domain knowledge, defeating the purpose of a domain-agnostic framework).
After all of the features are extracted, to limit the number of irrelevant features, the FRESH algorithm (Christ, Kempa-Liehr, & Feindt, 2016) is deployed. It first performs the Kolmogorov-Smirnov test (Massey Jr, 1951) independently for every feature and calculates the p-value. Then, the FRESH algorithm utilizes the Benjamini-Yekutieli (Benjamini & Yekutieli, 2001) procedure under correction for dependent hypotheses to decide which null hypothesis H_0 to reject. Only the features for which the H_0 is rejected are kept. Finally, a Pearson correlation analysis is performed to remove features that are correlated with a value greater than 0.6, as this would indicate that they are (weakly) linearly correlated. Correlated features will get overweighted during the training, thus creating biased models whose results and generalizability can be compromised.

3.3.2. Expert-knowledge-based FE

Contrary to the first FE method, where a plethora of well-known features for sequential data are automatically extracted and filtered, for the expert-knowledge-based FE, as the name would suggest, a closer look at the data is required. After examining a normalized sequence for both a known good and a known bad coil (Figure 1), it becomes evident that the discrepancy between the two different classes is apparent in the time domain. Thus, the features that will be extracted are going to be limited to the time domain, meaning that no transformations to the data will be performed. The prominent characteristics of coils with a compromised surface quality are that they overshoot the upper and/or lower bounds of the accepted temperature range, that they present drifts from the goal temperature and, more importantly, they present abrupt peaks of high amplitude.
Based on the above observations, we choose to extract the features presented on Table 1. On the left column, the name of the feature is presented, while on the right are the values of the parameters that are used for their calculation. It is worth noting that the values of 0.05 and -0.05 were chosen for the threshold of the $count\_above$, $count\_below$ and $number\_crossing\_m$ features since the acceptable temperature range for the chosen steel grade is $\pm 5\%$.
The $number\_high\_peaks$ feature was engineered by the authors for this specific use case. The appearance of high-amplitude peaks is deemed detrimental to the classification of the coils, so a new feature is introduced to identify the peaks that have a standard deviation larger than 2 and return their count. The pseudo-code for the implemented feature can be found in Appendix.

3.4. Synthetic Labelling

Classification tasks are, by nature, handled by supervised algorithms. Supervised algorithms depend on labelled data to learn the decision boundary of the multidimensional manifold upon which the data points lie. To that end, the Tata Steel experts provided a set of 14 sequences of the steel grade under

Table 1. Features extracted for expert-knowledge-based FE.

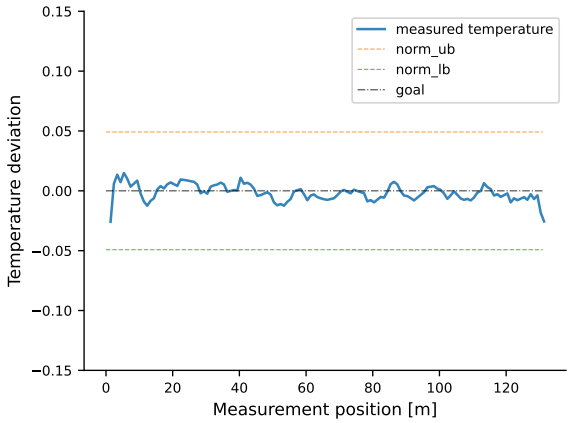
consideration that were identified to have low surface quality (one of which is shown in Figure 1b). Since the amount of labelled data is deemed inadequate to train a classification algorithm, the need to populate them arises. Upon inspection, and due to its use in the clustering analysis (Section 3.1), the DTW similarity metric is utilised. An ideal coil's CT profile would be identical to the goal CT profile. Leaning on that idea, the DTW similarity of each coil to the goal CT is calculated using Eq. (2). 76 coils with the highest score (indicating the **highest** dissimilarity to the goal CT) combined with the 14 expert-annotated ones comprise the bad coils labelled dataset. The 90 coils with the lowest DTW score form the good coils dataset.

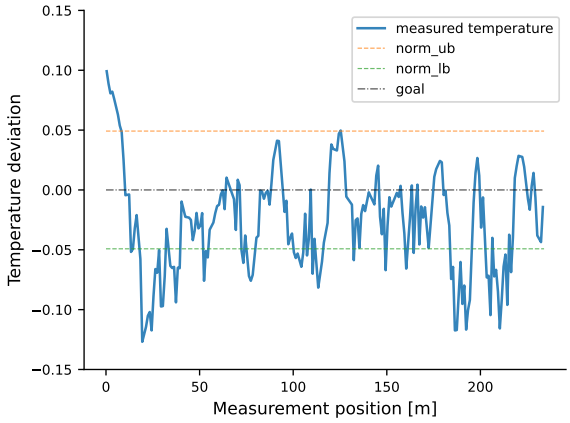
To guide the learning of the decision boundary, aside from providing examples of the extreme cases of both classes, we devised a labelled dataset of an extra 20 coils with intermediate DTW scores, half of which are used for training and half for testing. (this dataset will be referred to as manually annotated). This aims to not only provide information about the more ambiguous cases during training but also to provide a challenging test dataset that will assist in the evaluation of the performance of the classification algorithm. Figure 2 shows two of these coils. In conclusion, the final training dataset is constructed by performing an 80/20 % random split on the initial 180 coils and then adding half of the manually annotated dataset. The test dataset consists of the remaining data.

3.5. Neural Network classifier

A simple multilayer perceptron (MLP) is employed for the classification task. MLPs are fully connected feedforward NNs with non-linear activation functions. For the architecture of the model, typical design guidelines were followed. It consists of:



(a)



(b)

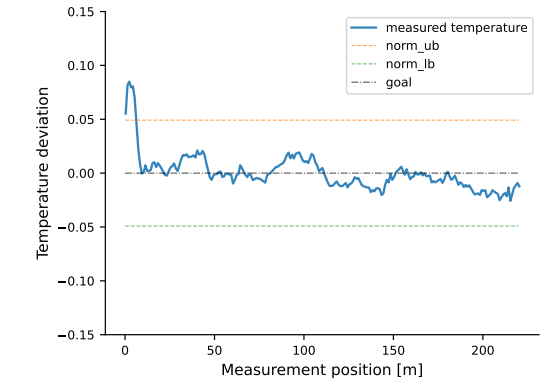
Figure 1. Normalized CT profile examples of a (a) good and a (b) bad coil

- **Input Layer:** where each feature is used as input for one input node,
- **Hidden Layer:** with $size = 64$, $relu$ activation function and to avoid overfitting, a dropout layer (Srivastava, Hinton, Krizhevsky, Sutskever, & Salakhutdinov, 2014) with a dropout probability equal to 0.5,
- **Output Layer:** where, according to standard binary classification practice, it has $size = 2$ and a $softmax$ activation function, which will output the membership probability of each sample to each class.

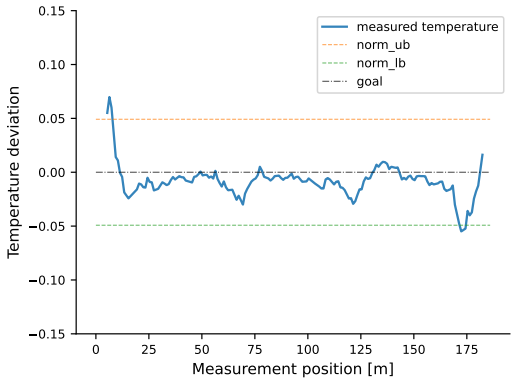
The simple and shallow architecture of the NN was chosen not only due to its decreased computational cost but also to avoid the tedious tuning and training of deep architectures.

4. Results

As previously discussed, the clustering analysis is performed on the raw data, while the classification is performed on the features extracted from the normalized sequences as described



(a)



(b)

Figure 2. Normalized CT profile examples of ambiguous coils. The spike in the beginning is observed on most coils, so it's not an indication of bad surface quality. Thus, (a) is labelled as good and (b) as bad (due to the peak at the end)

in Section 3.2. All of the code is written in Python, and the NN model was developed using Pytorch. Prior to the training of the NN, the training data are z-normalized. To avoid data leakage, the test data are z-normalized separately from the training data, utilizing the calculated scaling parameters of the training data. Models are trained for 200 epochs or until there is no improvement in the test accuracy. After the models have converged, they are tasked with classifying the entire dataset with all of the coils produced for the steel grade under consideration. The entire dataset follows the same FE procedure as the training set and is z-normalized with the pre-trained scaling parameters. Coils with a membership probability of less than 0.6 to either class are manually incorporated into the bad coils class to enhance our confidence in the models' predictions. Since the good/bad coil classification is the first step towards applying a PHM framework, we can tolerate false negatives, but we would like to avoid false positives. Since the good coils are of no interest to the analysis, a more inclusive bad coil class is preferred. First, the results of the clustering analysis on the raw data will be showcased, followed by the classification results with the introduced FE techniques.

4.1. K-means wth DTW

With the K-means algorithm, the number of cluster centres needs to be chosen a priori. To ensure the best fit, the elbow method is applied utilizing the silhouette coefficient (Rousseeuw, 1987). The results can be found in Table 2. As expected, the optimal number of clusters is two, confirming the prior assumption that the coils are split into good and bad ones. Figure 3 shows the results from the clustering and the calculated barycenters from the DBA algorithm. It becomes apparent that the majority of the coils in cluster 1 stay inside or close to the temperature boundaries, while bigger deviations are observed in cluster 2. This leads to the conclusion that the first cluster represents the good coils while the second cluster, the bad ones. However, the clustering is far from perfect since coils with high deviations and rapid fluctuations can be observed in the first (good) cluster. Given that the clustering analysis is the first exploratory step towards separating the data in hand, the results are satisfactory in that the expected underlying pattern of the data is actually observed. The high number of miss-clustered coils and the lack of soft-assignment capabilities means that it cannot be used as an end-to-end way to separate the data.

Table 2. Results of elbow method for DTW k-means.

Clusters	Silhouette Score
2	**0.2556**
3	0.1938
4	0.1844
5	0.1947
6	0.1454

4.2. Classification with domain-agnostic features

After following the procedure of the domain-agnostic FE and filtering explained in Section 3.3.1, 111 features are left. The mean achieved accuracy of the NN is 0.8274 over the test data with 0.0180 standard deviation for 10 runs. The results can be seen in Figure 4. It can be observed that while the coils assigned in the bad class show a greater overall deviation from the goal CT, a lot of misclassified coils can be observed in the good class with highly fluctuating temperatures. This performance was to be expected, considering the rather low classification accuracy. To comprehend the low performance of the classification model, a principal component analysis (PCA) was performed on the extracted features with the goal of projecting the samples in a two-dimensional space. The calculated decision boundary is also drawn to enhance this visualisation's information. In order to achieve acceptable classification performance, the different classes need to present minimal overlap on the PCA space so that the classifier can find a way to separate them. This visualization can be seen in Figure 4c. A high overlap between the good and bad coils can be seen, meaning that no possible decision boundary can correctly separate the two classes, regardless of the choice of the model.

Figure 5. Classification results with expert-knowledge-based FE

4.3. Classification with expert-knowledge-based features

Following the FE method described in Section 3.3.2, 20 features are extracted. The same NN classifier architecture is used with the only change in the number of input nodes, which is altered to 20 to match the number of extracted features. The mean achieved accuracy is 0.9636 over the test data with 0.0075 standard deviation for 10 runs. The results can be seen in Figure 5. It becomes pretty apparent that the classification of the coils is superior to all of the previously presented methods. The healthy coils present minimal deviation from the goal temperature, with only a few coils that have a single abrupt temperature fluctuation in their CT, attesting to the high accuracy of the classifier. This means that there is a very limited number of false positive coils, which is highly important, as discussed at the beginning of the current section. The same visualization procedure is followed as before and presented in Figure 5c. It can be seen that there is a clear separation between the two classes and that the decision boundary lies optimally between them. This clear separation of the two classes explains the high performance of the rather simple classification model.

5. Discussion

The presented results pave the way for an important discussion when it comes to handling real-world complex and big data. After the clustering analysis was performed, the two expected different classes of coils could be identified, that is, the good and the bad class (referring to the CT profile and, in turn, the surface quality). However informative the clustering was in providing insight into the dataset, its performance was far from acceptable, with a lot of misclassified (or rather miss-clustered) coils. This is attributed to the fact that the K-means with DTW distance metric is clustering coils strictly by comparing their shape to each other. No information regarding the acceptable temperature range, the goal CT or what good and bad coils are, is included. Adding to that, the k-means algorithm does not provide a way to soft-assign clusters to data points. Naturally, the next step would be to increase the classification's performance will achieving soft-classification capabilities. The most obvious idea is to create a representation of the data to train a soft ML classifier. Due to the increasing popularity of DL FE methods, a researcher would most probably invest their time in developing complex and computationally heavy models. These models' task would be to try and learn on their own latent representations of the data that would effectively separate the different classes. With this study, we would like to emphasize that traditional FE can be as (if not more) effective for some datasets while reducing the complexity, the computational load, and the overall time invested in developing the FE method.

This is not to say that traditional FE can be applied universally, without effort. This is the main takeaway from comparing an automated traditional FE method that is domain-agnostic with features that are specifically picked or engineered for the application. For the domain-agnostic FE, a plethora of famous and commonly used features for sequential data were automatically extracted and filtered utilizing hypothesis tests and correlation analysis. However, the resulting features fail to capture the distinctive features of the data. This becomes evident by the high overlap of the two classes presented in Figure 4c, and is the culprit of the wrong classification of the data. Spending the effort of manually labelling a small fraction of coils and choosing the right features to represent the data, successfully separates them and achieves the required classification performance.

The next step for this framework is to verify that it works universally for multiple steel grades, with minor or even no modifications at all. After generating the healthy/damaged coils dataset, the process parameters that lead to the damaged state are intended to be identified. The end goal is to apply a PHM framework that will be able to predict quality deterioration and provide alternative parameter settings to mitigate the damage to the surface quality of the produced steel strips.

6. Conclusions

In this study, a real-world data set of manufactured steel strips raises the importance and effectiveness of traditional FE, but only if done appropriately, as described in Section 3.3.2 and paired with manually annotated samples. Automated FE techniques are deemed ineffective; thus, the extracted features must be chosen carefully. This is achieved by keeping in mind that they should capture the characteristics that associate them with their corresponding class. The authors are by no means undermining the importance of deep learning FE methods. Their increasing popularity mainly stems from their successful application in extracting latent representations of big data. They would instead highlight that for some datasets, the effort needed to develop them is unjustified; that is when a correctly defined traditional FE method can solve the task.

APPENDIX

Algorithm 1 Pseudocode of number_high_peaks feature

Inputs:
x (list): the input sequence
n (int): the support of the peak (a peak of support n is defined as a subsequence of x where a value occurs, which is bigger than its n neighbours to the left and to the right)
std_t (int): the number of standard deviations that the peak's value needs to surpass
Procedure:
$x\_reduced = x[n : -n]$
$res = None$
for $(c = 0; c < n + 1; c + +)$ **do**
  $result\_first = x\_reduced > numpy.roll(x, c)[n : -n]$
  if $res = None$ **then**
    $res = result\_first$
  else
    $res \mathrel{+}= result\_first$
  end if
  $res \mathrel{+}= x\_reduced > numpy.roll(x, c)[n : -n]$
end for
$idx\_peaks = np.where(res)[0] + n$
$h_peaks = 0$
for $idx : idx\_peaks$ **do**
  if $|x[idx]| > mean(x) + std\_t * std(x)$ **then**
    $h\_peaks \pm 1$
  end if
end for
Output:
h_peaks (int): the amount of peaks of support n with maximum value higher than std_t times the standard deviation of x

Towards a Hybrid Framework for Prognostics with Limited Run-to-Failure Data

ABSTRACT

The introduction of cyber-physical systems with increased availability of sensor data creates a lot of research interest in prognostic algorithms for predictive maintenance. Although a lot of algorithms are successfully applied to benchmark case studies based on simulated data and experimental set-ups, deployment in industry lags behind. From a comparison between three benchmark case studies with two real-world case studies based on prognostic metrics (monotonicity, prognosability and trendability), two main issues are observed: 1) the lack of run-to-failures and 2) low prognostic metrics due to a low signal-to-noise ratio of degradation trends, as a result of unexplained physical phenomena. To make prognostics feasible, a hybrid framework is proposed that focuses on improving system knowledge. The framework consists of a quantitative diagnostic assessments, guided by (modular) system models in which damage is induced. This quantitative damage assessment provides input for prognostics based on Bayesian filtering, enabling prognostics for assets in varying operational conditions. Implementation and validation of the framework requires investments, but modularity within the framework can accelerate development for new systems.

1. INTRODUCTION

During the fourth industrial revolution, cyber-physical systems are being introduced where sensor data communicates between machinery and with operators (Pinciroli et al., 2023). This sensor data can be used to find characteristics of failures within the systems which can be used to develop models that predict the remaining useful life (RUL) (Yan et al., 2017), giving new opportunities for implementation of *predictive maintenance*. When failures can be predicted, catastrophic accidents are prevented, unexpected downtime can be reduced, components are used until the end of their actual lifetime and maintenance logistics can be optimized (Fernandes et al., 2022).

The recent increasing interest in *predictive maintenance* is clearly visible by observing the amount of published scientific papers in this field. Only the number of review papers is already growing significantly, as the number of counts in the Scopus database on article titles with (*survey* or *review*) and (*predictive maintenance*) grew from a total of 20 published documents up to 2020 to a total of 84 published documents up to 2023.

The increasing number of sensors and data availability, specifically increase the interest in *data-driven* prognostic approaches (Pinciroli et al., 2023). This type of approach requires sufficient historical run-to-failure data. However, in safety-critical systems (Chao et al., 2021) or when availability of assets is more important than costs (Tinga et al., 2021), failures are sparse and as a consequence the required historical run-to-failure data are rarely being collected. Also for new types of machinery, no historical data are available (Calabrese et al., 2021). If historical data are available, they are often unlabeled and unorganized, lacking context such as operating conditions and maintenance recordings (Calabrese et al., 2021; Lukens et al., 2022).

In contrast to data-driven approaches, physics-based approaches considering Physics-of-Failure (PoF) models have less strict data requirements. They provide a relation between usage and degradation rates (Tinga, 2013b). This yields benefits compared to purely data-driven approaches, specifically when failures are rare and when future operating conditions (and consequently degradation rates) are different from historical operating conditions (Tiddens et al., 2023). However, these models are expensive to develop and are component or system specific (Elattar et al., 2016). Also, the relation between usage and degradation rates should be known and must not be too

complex.

To overcome issues with purely data-driven or purely physics-based prognostics, combinations of them (i.e. hybrid approaches) are often proposed as a solution (Elattar et al., 2016; Guo et al., 2020). Still, many hybrid methods use data-driven models to estimate the degradation behavior (Pugalenthi et al., 2021; Borutzky, 2020) or only use physics to improve input parameters of a data-driven prognostic algorithm (Gálvez et al., 2021; Chao et al., 2022). This yields improved results compared to purely data-driven approaches, but the relation between usage and degradation rates are generally not considered, still limiting applicability in cases of rare historical failures and varying operating conditions.

Fernandes et al. (2022) described that in many studies, real-world challenges are often overlooked and additional research to address these real-world challenges is needed. This suggests a gap between science and industry. This suggestion is strengthened by a survey in 280 companies in Belgium, Germany and the Netherlands, showing that only 11% are actually implementing predictive maintenance techniques in 2017 (Mulders & Haarman, 2017). Although a similar survey showed that this number increased to 17% in 2023, mainly attributed to original equipment manufacturers (OEMs) and sectors with large numbers of the same assets (van der Velde et al., 2023), a large majority of developed methods is still only being applied to experimental or simulated data sets (Ferreira & Gonçalves, 2022) such as C-MAPSS (Saxena & Goebel, 2008).

In this paper, issues with implementation of prognostics in two real-world cases are pinpointed. The case studies are performed by two organizations within the Netherlands who try to implement predictive maintenance for military assets. The case studies are challenging, as availability of these assets is more important than costs (Tinga et al., 2021), fleets are relatively small and the assets operate in varying operational and environmental conditions. Prognostic metrics defined by Coble (2010) (monotonicity, prognosability and trendability) are calculated for the two real-world case studies, and also for three well-known benchmark cases to compare the potential for application of prognostic algorithms. Based on observed issues in the real-world cases, a possible solution is proposed in the form of a hybrid framework.

The remainder of the paper is organized as follows. Section 2 starts with calculating prognostic metrics of features from three benchmark cases: the Virkler crack growth data set, the NASA milling data set and the C-MAPSS data set. Then, metrics are calculated for features from the two real-world case studies, concerning condition monitoring of Apache helicopter engines and a naval main diesel engine respectively. Following from the issues observed in the case studies, section 3 proposes a hybrid framework for prognostics. Lastly, section 4 discusses the results and concludes the paper.

2. Prognostic Potential of Case Studies

2.1. Prognostic Metrics

Coble (2010) developed three metrics to assess the suitability of features as input for a (data-driven) prognostic algorithm. The suitability is evaluated based on monotonicity (M), prognosability (P) and trendability (T). The range of the scores is from 0 (unsuitable) to 1 (perfectly suitable). The weighted sum of the three metrics gives the prognostic score, and features with the highest score are most suitable to be used as the input for a prognostic algorithm. So, data sets from which features with high scores can be derived, have high potential for prognostics.

The first metric is monotonicity, assessing the extent to which run-to-failure trajectories are purely increasing or decreasing. It is calculated as follows:

$$M = \text{mean}\left(\left|\frac{N^+ - N^-}{n-1}\right|\right) \tag{1}$$

with N^+ the number of increments in the run-to-failure trajectory of the feature (i.e. $n_{i+1} - n_i > 0$), N^- the number of decrements in the trajectory (i.e. $n_{i+1} - n_i < 0$) and n the number of data points in the trajectory. The absolute mean monotonicity of all considered run-to-failure trends yields the final monotonicity.

Prognosability estimates how similar the start values and the values at failure are for the features when comparing different run-to-failure trajectories. It is calculated as follows:

$$P = \exp\left(-\frac{\text{std}(\mathbf{f}_{end})}{\text{mean}\left(|\mathbf{f}_{end} - \mathbf{f}_0|\right)}\right) \tag{2}$$

with $\mathbf{f}_{end}$ a vector with all values of the features at failures and $\mathbf{f}_0$ a vector with all values of the features at the start of the run-to-failure trajectories. Std refers to the standard deviation.

Trendability describes similarity between the shapes of run-to-failure trajectories. It is calculated as follows:

$$T = \min\left(\left|\boldsymbol{\rho}_{ij}\right|\right) \tag{3}$$

with $\boldsymbol{\rho}$ a vector with the correlation coefficients between each run-fo-failure trajectory i and j of the feature. For trajectories with different lengths, linear interpolation is applied such that the lengths of the correlated trajectories match.

The final score S is calculated by:

$$S = W_m \cdot M + W_p \cdot P + W_t \cdot T \tag{4}$$

with W_M, W_P and W_T the weight factors for monotonicity, prognosability and trendability respectively. In many applications they can be set identically, but in some applications some metrics may be less relevant (Coble, 2010). In the case studies discussed in the next subsection, the weight factors are

all set to $\frac{1}{3}$, yielding prognostic scores ranging from 0 to 1.

2.2. Benchmark Data Sets

2.2.1. Virkler Crack Growth

The first benchmark data set considered is the Virkler crack growth data set. Virkler et al. (1979) performed 68 run-to-failure fatigue tests of 2024-T3 aluminium and measured the crack length directly. This yields the run-to-failure trajectories as shown in Fig. 1.

The data set contains crack lengths at specific numbers of stress cycles. As crack lengths already provide a direct indicator of the damage severity, no additional features need to be calculated and the prognostic metrics are directly calculated on the crack length measurements. As the crack length always increases monotonically, the monotonicity is 1. All trajectories have the same end value (50mm) and starting value (9mm), yielding a prognosability of 1. As all trajectories are monotonically increasing, all trajectories have a perfect positive correlation, yielding a trendability of 1. Consequently, the total prognostic score is 1.

A direct measurement of degradation can be considered as a perfect prognostic metric, as the nature of degradation (an irreversible process) makes it monotonic, a proper threshold can be defined based on system knowledge and the monotonicity yields also perfect trendability. As the underlying model is well understood, the Virkler data set is perfectly suitable for prognostic methods based on Bayesian updating (Sun et al., 2014; Baral et al., 2023), but also data-driven methods are well applicable (Eker & Jennions, 2012).

2.2.2. Milling Tool Wear

The Milling Data Set (Agogino & Goebel, 2007) contains data collected from an experimental setup for tool wear estimation. There are two operational settings for the Depth of Cut (DOC), feed rate and material. Two experiments are performed for each combination of operational settings, yielding a total of 16 experiments. Each experiment consists of a number of runs, lasting 72s. After each run, the actual tool wear (i.e. *VB*: the measured distance from the cutting edge of the tool to the end of abrasive wear on the flank (Agogino & Goebel, 2007)) is measured with a microscope. Experiments were terminated at a certain (not further specified) tool wear limit (and some beyond). As measuring tool wear with a microscope after each operation is not feasible in practical applications, measurements are also collected from sensors that can provide an online estimation of tool wear. A total of six sensor are installed which measure at a sampling rate of 250Hz: AC and DC motor current sensors of the spindle, and vibration and acoustic emission sensors at both the spindle and the table.

The data set is shown in Fig. 2. Fig. 2a shows the offline tool wear depth (*VB*) measurements. As most experiments run until $\approx 0.50 - 0.80$mm as shown by the gray band in the figure, it is expected that the tool wear limit is around this band. The gaps in the trajectories in Fig. 2a are due to missing measurements in between some of the runs. Note that only 14 out of the 16 experiments are displayed: for one of the experiments, only one run is available, making it unsuitable to calculate prognostic metrics. Both experiments in the corresponding

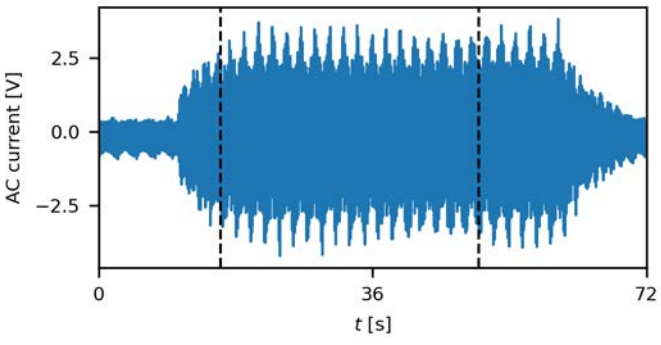
(a) All tool wear trajectories in milling data set. Each color corresponds to a set of operational settings (M = 0.95, P = 0.66, T = 0.78, S = 0.80)



(b) Example (AC motor current) measurements for one run in milling data set

Figure 2. Visualization of the milling data set

operational conditions are removed from the data set, such that seven pairs of experiments remain.

The trajectories for the *VB* measurements yield a monotonicity M of 0.95, prognosability P of 0.66, trendability T of 0.78 and S of 0.80. Although perfect metrics of 1 are expected for direct degradation condition measurements, as explained in subsection 2.2.1, some non-monotonic behavior can be observed in Fig. 2a (e.g. the dark green line before $t = 10$), reducing M and T. As wear is irreversible, this non-monotonic behavior is likely to be due to measurement errors. P is affected by the fact that some experiments were performed beyond the tool wear limit. Still, the prognostic metrics are high, and can be improved by reducing measurement error and running experiments until a fixed failure threshold.

A challenge is to estimate tool wear from the real-time sensor data. Fig. 2b shows an example of data from the AC motor current sensor for one run of an experiment. No clear trend can be observed in the raw sensor data, so features need to be calculated. As the start and run of an experiment yield no stable signal (i.e. magnitude increase and decrease as seen in Fig. 2b), only the stable period (defined to be 16-50s, indicated by the vertical dashed bars in Fig. 2b) is considered for feature calculation. For each sensor and each run, the mean, standard deviation, maximum, minimum, absolute maximum, absolute minimum, root mean squared and sum of values are calculated.

The standard deviation from the AC motor current measurements is found to have the highest prognostic score and its trajectories are shown in Fig. 3. M is 0.74, P is 0.57 and T is 0.84, yielding a score of 0.72. The different operating conditions clearly yield different feature values, as only the start and end values of curves with the same operating condition have approximately the same start- and end values (i.e. the dark green, black, red and pink pairs). Prognostic scores can be further improved by compensating for operating conditions, by calculating the P and T for two experiments with the same

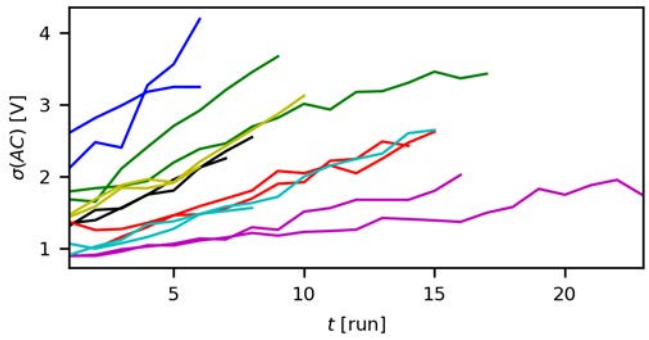


Figure 3. Feature with highest score from milling data set, color-coded by operating conditions (M = 0.74, P = 0.57, T = 0.84, S = 0.72)

operating conditions and taking the mean of the separately calculated P and T (note that M is unaffected). It is found that in this case, P increased to 0.78 and T increased to 0.86, yielding a final score of 0.79, which is almost the same score as for direct *VB* measurements.

This case shows that by calculating only a simple set of features, features with high prognostic potential can already be obtained. These characteristics make the data set applicable for prognostics. In literature, mainly quantitative diagnostic methods are applied, based on e.g. nearest neighbor-based approaches (Sheng & Zhu, 2020), Recurrent Neural Networks (Lu et al., 2022), Kernel Extreme Learning Machines (Zhou & Sun, 2020), particle filters (P. Wang & Gao, 2016) and Long Short-Term Memory Networks (Kumar et al., 2022). Subsequently, prognostics can be performed (J. Wang et al., 2015).

2.2.3. C-MAPSS

The Commercial Modular Aero-Propulsion System Simulation (C-MAPSS) (Saxena & Goebel, 2008) is a very popular benchmark data set due to the inclusion of sensor noise, different operating conditions and multiple fault modes (Ramasso & Saxena, 2014). Already in 2014, Ramasso & Saxena (2014) published a review paper on 70 different prognostic methods utilizing the data set. The data set is still being used and more recently a new version of this data set (N-CMAPSS) has been released (Chao et al., 2021). The data is generated with a simulator built in Matlab and Simulink. The operational settings are defined by three parameters and 21 (virtual) sensors are available.

In this paper, the FD001 and FD004 train data sets are evaluated. The FD001 set contains 100 degradation trajectories in one operating condition and one fault mode (High Pressure Compressor (HPC) degradation). The FD004 set contains 248 degradation trajectories in six operating conditions and two degradation modes (HPC degradation and fan degradation). As an example, Fig. 4 shows raw sensor data from one of the sensors (Φ, a fuel flow ratio) for five run-to-failure trajectories of FD001 and FD004. In Fig. 4a the degradation trends can be clearly observed, which is more difficult in Fig. 4b due to the effect of changing operating conditions on the data.

To reveal the degradation trend for the FD004 data set, a K-Nearest Neighbors regressor is trained on the first 40 data points to learn the (nominal) relation between the three operational settings and measurements. The regressor is built using the $sklearn$ Python package and uses two neighbors. Fig. 5 shows that the residuals (i.e. difference between measured and expected measurements) reveal similar degradation trends as was observed for the FD001 data set.

Although the raw sensor data of FD001, or the residuals for FD004, already reveal a strong degradation trend, better prog-

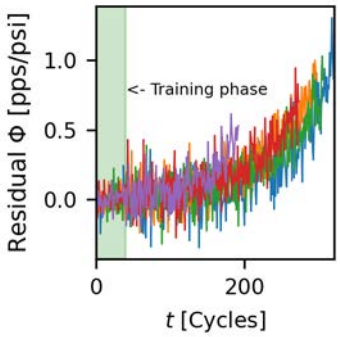

Figure 5. Five run-to-failure residual trajectories of Φ sensor in varying operating conditions (FD004)

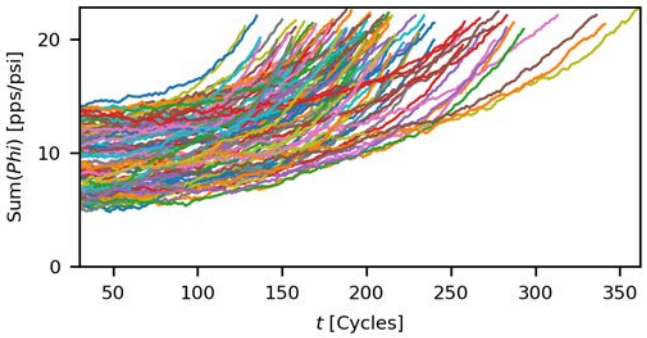
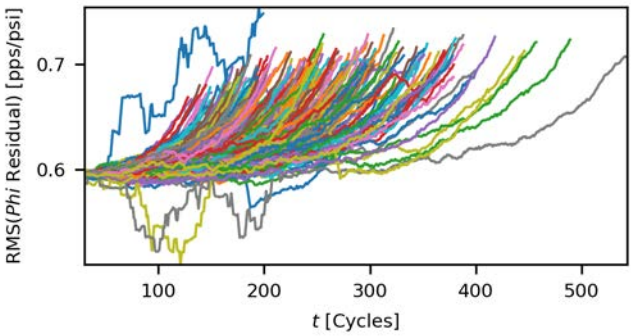


(a) Top feature of C-MAPSS FD001 data set (directly derived from sensor data) (M = 0.69, P = 0.88, T = 0.94, S = 0.84)



(b) Top feature of C-MAPSS FD004 data set (derived from residuals) (M = 0.55, P = 0.80, T=0.06, S =0.51)

Figure 6. Best features on CMAPSS data set

nostic metrics can be found by extracting features. This is done for both the FD001 raw measurements and the FD004 residuals using the Python package *tsfresh* (Christ et al., 2018) for automatic feature extraction. It first creates a rolling window over the data set and for each window, features are calculated. The window size is a trade-off between noise reduction and response time to signal changes, and is set to 30 by trial-and-error. To reduce noise in the calculated features, the prognostic metrics are calculated for each 5th data point.

The best performing feature for the FD001 and FD004 data set are shown in 6. For FD001 the sum of Φ measurements in the rolling window obtained the highest metrics, as shown in Fig. 6a: M=0.69,P=0.94 and T=0.84, yielding a score of 0.84. For FD004 the root mean square of the Φ residuals gave the highest metrics, which are significantly lower (i.e. M=0.55,P=0.80 and T=0.06, yielding a score of 0.47) compared to FD001. This is mainly caused by some outlying trajectories (e.g. the blue trajectory on the left in Fig. 6b) due to faulty residual calculations (e.g. because not all operating conditions are observed in the training phase of the KN-regressor). It is found that the mean of the correlation coefficients of all trajectories is 0.97, but the fact that T is determined by the lowest correlation coefficient between all trajectories yields the low trendability. Therefore, higher scores can be obtained when removing outliers and improving residual generation.

To conclude, it is found to be straightforward to retrieve features with high prognostic metrics, mainly for the FD001 data set. For the FD004 data set it is more challenging due to the varying operating conditions. However, features could be extracted which show similar run-to-failures trajectories, although additional effort is required to remove outliers and improve prognostic metrics further. The general characteristics of the data set make it feasible for data-driven prognostics, and methods such as Nearest-Neighbors, Random Forests, Extreme Gradient Boosting and Multilayer Perceptrons (Alomari et al., 2023), Convolutional Neural Networks-based approaches, Long-Short-Term-Memory-based approaches (de Pater et al., 2022) and others are widely found in literature.

2.3. Real-world Case Studies

This subsection introduces two real-world case studies. Despite an extensive search, only two cases were found to have sufficient measurements and meta data available to calculate metrics of run-to-failure trajectories. Organizations often do

not have, cannot or do not want to disclose the data necessary for a proper analysis. The authors thank NLR and the Royal Netherlands Navy gratefully for making these case studies available for evaluation.

It should be noted that the case studies concern the most complex cases for prognostics: they concern monitoring of individual assets in varying operating conditions, where future operating conditions can be different from historical operating conditions. This corresponds to the highest ambition level an organization can have, with high requirements on data availability or system knowledge (Tiddens et al., 2023).

2.3.1. Apache ETF Monitoring

The power level of helicopter turboshaft engines decreases over the lifetime due to wear of seals, vanes and blades or due to faults in other components (Vos, 2019). Engine performance is measured by the Engine Torque Factor (ETF), which is the ratio between the actual engine power and the rated engine power. If the ETF drops below 0.85, or if the combination of the ETFs of both tail engines of an Apache helicopter drops below 0.90, the Apache is not allowed to be used. The Netherlands Aerospace Centre (NLR) developed an algorithm to calculate the ETF from in-flight parameters, rather than from time-consuming manual Max Power Checks (MPCs) (Vos, 2019).

Vos (2019) selected the turbine gas temperature (TGT) as health indicator, and fitted a polynomial model using data from the Health and Usage Monitoring System (HUMS) to translate the in-flight TGT to the TGT at the reference condition (which in turn allowed to calculate ETF). The considered operational parameters are gas inlet temperature, outside air temperature, pressure altitude, speed, and engine torque.

For the development of a prognostic algorithm, run-to-failure trajectories are required. Although the engine needs an overhaul when the ETF reaches 85%, the data set does not contain any trajectory running till this threshold. Therefore, to calculate the prognostic metrics of trajectories, periods between (documented) engine replacements are selected. This does not fully represent run-to-failure, but no better option is available.

The rolling mean of these ETF trajectories is calculated over five ETF measurements, yielding the trajectories in Fig. 7. The calculated metrics over these trajectories are: M=0.09, P=0.19 and T=0, yielding the extremely low score of 0.12. This can be expected from Fig. 7, as the data are covered in low-frequency noise which make the actual degradation trend barely visible. This low-frequent wobbling behavior is caused by physical phenomena not explained by the polynomial model (Vos, 2019), i.e. by confounding factors. This noise yields a low signal-to-noise ratio (i.e. degradation to other external influences), and therefore low prognostic metrics.

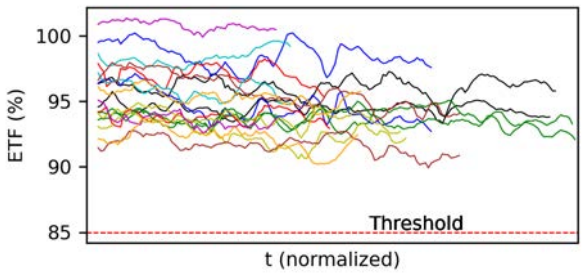


Figure 7. All ETF trajectories considered. Each color corresponds to the engines of a specific Apache. (M = 0.09, P = 0.19, T = 0, S = 0.12)

Real-time estimation of the ETF offers potential to replace expensive MPC by real-time ETF monitoring (i.e. additional inspections can be performed when the ETF drops below the threshold). However, the lack of actual run-to-failures and the low signal-to-noise ratio make the step towards prognostics extremely complicated.

2.3.2. Marine Diesel Engine Bearing Monitoring

The main diesel engine (MDE) of a naval vessel contains seven journal bearings that support the crankshaft. Failure of one of the bearings yields failure of the MDE and is therefore critical for availability of the vessel. Heek (2021) developed a monitoring method based on bearing temperature to detect failures timely. The underlying idea is that damage increases friction in the bearing and subsequently increases the bearing temperature.

Because the bearing temperature is also affected by operating conditions, Heek (2021) fitted data from the Integrated Platform Management System (IPMS) in a multiple linear regression model. This model estimates the bearing temperature in nominal conditions based on the RPM of the engine, RPM of the turbocharger, and the lube oil temperature at the outlet, which were found to have the highest predictive performance. Subsequently, the residual between the measured and the predicted bearing temperature is selected as a health indicator and is continuously monitored. Alarms can be raised when the measured temperature is higher than expected. The complete procedure of data selection and residual generation can be found in Heek (2021).

Heek (2021) evaluated three case studies, from which two concerned an actual failure. Cases 1 and 2, which concern failure cases, are visualized in Fig 8. The regression model is trained within the shaded areas (until $t = 993$ and $t = 1748$ respectively) and the residual monitoring is deployed after (note that case 2 runs longer than case 1). To evaluate prognostic metrics of these trajectories, every 10th data point is selected and the rolling mean over 10 data points is calculated. The calculated metrics are: M=0.06, P=0.92 and T=0.57,

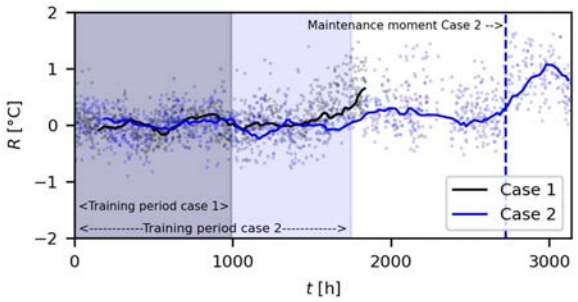

Figure 8. Trajectories of diesel engine temperature residuals with failure at the end ($M = 0.06$, $P = 0.92$, $T = 0.57$, $S = 0.52$)

yielding a score of 0.52.

The monotonicity of the trends is extremely low due to low-frequency oscillations over time. According to Heek (2021), this is caused by unobserved effects in the engines, probably caused by "*minor maintenance actions*", which again can be considered as confounding factors. P is relatively high due to the small difference between end values (i.e. 0.5 and 0.6 respectively), and a weak trendability is observed due to the increase in data points near the end.

However, the actual meaning of these high metrics is disputable. Heek (2021) described that in case 2, maintenance was performed around $t = 2700$h, as indicated by the vertical bar in Fig. 8. After this moment, the residuals make a jump of 1°C. This behavior is also visible when evaluating the third case study in which no failure was observed, shown in Fig. 9. Similar to case 2, maintenance was performed after which residuals make a jump (of approximately 0.6°C) as indicated by the vertical bar around $t = 1200$h.

Again, this yields a gradually increasing trend, but it is unrelated to degradation. Heek (2021) proposed to retrain the regression model after maintenance is performed to reduce the number of false positives, which may provide a solution for

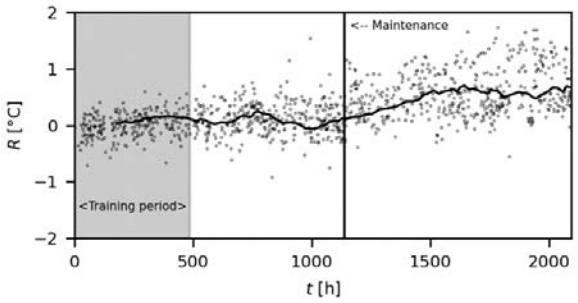

Figure 9. Trajectories of diesel engine temperature residuals without failures

anomaly detection. However, this way the physical relations and meaning of the residuals is inconsistent, i.e. there is no clear link between the residuals and the quantitative amount of damage. This makes it difficult to isolate maintenance actions (or other external confounding factors) from degradation, i.e. the signal-to-noise of the residuals can be considered to be low.

Real-time monitoring the residuals offers potential for early fault detection. However, similar to the ETF case study, it is still extremely complicated to implement prognostics due to the limited number of run-to-failure trajectories and a low signal-to-noise ratio due to limited physical understanding of the data. An additional problem in this case, is that the lack of physical understanding of the residuals complicate threshold definition, and without a threshold it is impossible to estimate the RUL.

2.4. Discussion and Conclusion Case Studies

A first observation of the case studies is that a good direct measurement of the degradation severity (e.g. crack length) can be considered as a perfect prognostic feature. As degradation is in general an irreversible process, it is monotonic and yields perfect trendability. Also thresholds can be defined based on phyical knowledge, yielding perfect prognosability. However, in practice it is complicated or impossible to obtain direct measurements of the actual degradation severity and real-time sensors should provide monotonic, prognosable and trendable run-to-failure trajectories. It is found to be relatively easy to extract such trajectories from well-defined benchmark data sets with labeled data (i.e. milling data set (Agogino & Goebel, 2007)) or many historical run-to-failures (i.e. C-MAPSS (Saxena & Goebel, 2008)).

However, both real-world case studies suffered from two main issues: 1) the number of failures is extremely low, or even non-existent, and 2) low prognostic metrics due to a low signal-to-noise ratio between the health indicator (i.e. the signal) and other confounding factors such as maintenance actions and environments (the noise). The low number of failures, with low prognostic potential in the derived feature, make training of data-driven prognostic algorithms infeasible. Furthermore, the low signal-to-noise ratio makes it complicated to distinguish nominal operating conditions from faulty behavior, such that estimation of the onset of degradation, as well as identifying the degradation trends are difficult.

Note that the latter issue is mainly contributed to confounding factors affecting system behavior, originating from varying operating conditions. This shows the main difference between the benchmark and real-world data sets: in benchmark data sets, either an experimental setup or a simulation is used to generate data, in which external factors influencing system behavior can easily be excluded (lab experiment) or by definition do not exist (simulation). However, in real-world cases

such factors are not always well understood or measured such that they are not included in the developed models. Note that available prognostic algorithms can work if data requirements are met (e.g. as found by van der Velde et al. (2023), chances are higher for assets in large fleets, and requirements are less strict in constant operating conditions (Tiddens et al., 2023)), but a solution needs to be found for these complex real-world cases in varying conditions.

3. Proposed Framework

The lack of run-to-failures and the lack of physical understanding of the monitored signal complicated prognostics in the real-world case studies. Following the decision framework proposed by Tiddens et al. (2023), two solutions are possible: 1) improving the data set or 2) improving the system knowledge. Collecting more run-to-failures is not a realistic option as the failures are critical and therefore prevented by performing preventive maintenance actions. Worldwide data sharing may help (Coelho et al., 2022), especially for similar assets existing in large fleets, such as industrial machinery (Peng et al., 2022) and wind turbines (Li et al., 2021). However, data sharing is often complicated due to standardization and different data structures (Coelho et al., 2022). Furthermore, the military applications bring additional challenges regarding confidentiality of data, but also companies may not be keen on sharing data as they can consider it as intellectual property.

Therefore, the focus in development of the framework (Fig. 10) is on improving system knowledge. System knowledge can be improved in two ways: 1) learning the relation between usage and the degradation rates (i.e. with PoF-models) and 2) and quantifying the relation between measured signals and damage severities. The first part (part I in Fig. 10) is already explored by previous work of the authors (Tinga, 2013a; Keizers et al., 2021, 2022). The second part (part II in 10) focuses on improved quantitative diagnostics to obtain features with higher prognostic metrics, as found to be required for the real-world case studies discussed in section 2.

Degradation can vary heavily between assets used in varying operational conditions (Tiddens et al., 2023), and in absence of historical run-to-failures, the quantitative relation between usage and degradation is essential for accurate prognostics. Therefore, PoF-models are used in part I of the framework. Such models are often tuned for prognostics of specific assets with Bayesian filters (Jouin et al., 2016). However, in literature the effect of actual loading conditions is often simplified, e.g. by substituting loads with a constant model parameter (Zio & Peloni, 2011). This takes away one of the main strengths of a PoF-model, as handling the loads as a model parameter only makes extrapolation of the latest trend possible, yielding wrong RUL for changing future usage profiles, as was shown in Keizers et al. (2021).

To achieve PoF-based prognostics (i.e. part I of the framework) it is proposed to use the method described in Keizers et al. (2021), taking loads as separate input for a Bayesian filter and for prognostics. Loads are first monitored (for $t \leq t_p$, with t_p the time of prediction) to update the PoF-model. Then, expected future loads (for $t > t_p$) are substituted in the updated PoF-model for prognostics (see the lower input of the PoF-model in Fig. 10). This enables RUL prediction based on expected future operating conditions, or adaptation of system usage to extend the RUL.

A conceptual example can be given in the form of the Apache ETF case: it is observed that the ETF decreases faster in sandy environments Vos (2019), which can be explained by increased wear of vanes, blades and seals due to the increased number of sliding sand particles over the components. Erosive wear is already studied for decades (Sundararajan, 1991) and can be modeled by Archard law (Archard, 1953) or by more detailed empirical models that also take characteristics (e.g. hardness, size) of sand particles into account (Gülich, 2020). Such models can be used to estimate degradation rates in specific (and varying) operational and environmental conditions.

The update of the PoF-model requires corresponding degradation measurements. In the studies described in Keizers et al. (2021) and Keizers et al. (2022) direct condition measurements (i.e. measurement of the parameter calculated by the PoF-model) were assumed, which can be the available in some practical applications. For example, in case of fatigue crack growth, DC Potential Drop Methods can measure crack lengths directly (Bär, 2020) and in case of corrosion, electrochemical measurements can measure corrosion rates directly (Homborg et al., 2014). Such direct condition measurements are preferred, as they can be considered to be a perfect prognostic metric as discussed in section 2. However, in many practical applications, such as the real-world case studies of section 2, these types of direct condition measurements are expensive or impossible to obtain. Therefore, monitoring options are used that measure (indirect) consequences of the actual degradation, e.g. vibrations or temperatures.

Here, part II of the framework is introduced. It considers a quantitative diagnostic block, linking indirect condition measurements in specific operating conditions (the right-side input of the block) to the direct condition (i.e. damage severity). However, as illustrated by the case studies in section 2 the features derived from the real-world data sets have low prognostic metrics, and are unlabeled. Therefore, the relation between measured data and degradation severity is unknown, and quantitative diagnostic algorithms cannot be trained. Experimental set-ups could help to gather training data to learn this relation, but it is economically infeasible to collect data for all fault types and locations in all possible operating conditions (Sawalhi & Randall, 2008). Here, the second way of including system knowledge is relevant, which is positioned below the quantitative diagnostic block in Fig. 10. By introducing faults

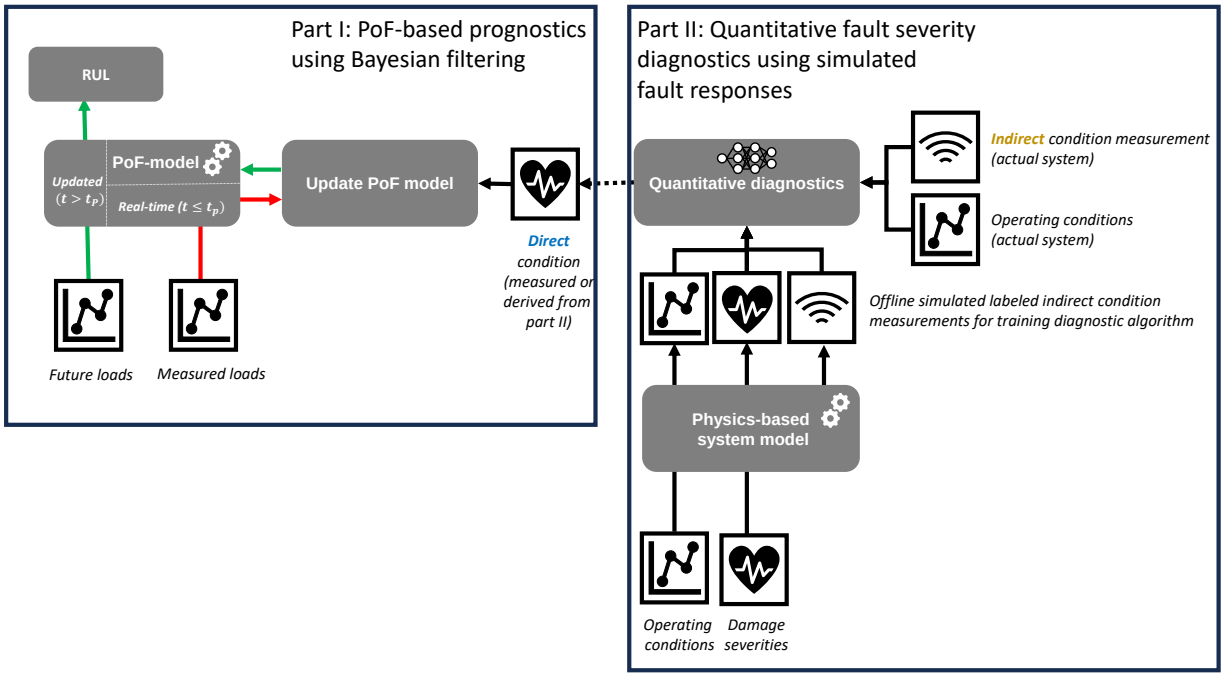

Figure 10. Proposed framework

in physics-based system models and (virtual) measuring the system response of degradation, a better understanding of the effect of faults with varying sizes on measured signals in different operating conditions can be obtained. In the conceptual example of erosive wear in the Apache components, a system model should reveal the efficiency loss for different amounts of material removal. Subsequently, the required additional power, and forthcoming turbine gas temperature, need to be modeled in different operational conditions.

Indeed, developing such a model brings major challenges. First, building an extensive physics-based model for each component or system is time-consuming and expensive. Second, damage induces responses in different physical domains (i.e. mechanical wear yields increased temperature). For these reasons, a modular modeling method that is relatively easy to reuse, adapt and scale, and which is applicable in multiple domains is proposed. Bond graphs are such models (Mkadara et al., 2021). It will be profitable to develop models of standard equipment (e.g. bearings) that can be easily reused in other system models, accelerating development for new machinery.

As an example, Nakhaeinejad & Bryant (2011) showed that different types of bearing faults and their vibration response can be modeled using these types of models. Note that bond graphs are proposed more often in hybrid prognostic frameworks for determining residuals from a nominal system model (e.g. (Medjaher & Zerhouni, 2013)) or for tracking faulty parameters (e.g. Borutzky (2020)), but the link with an actual PoF-model and its corresponding direct condition measurement is missing, limiting prognostic capabilities in cases of varying operating conditions.

To conclude, part II of the framework can help to create a quantitative damage assessment, acting as an input for part I in the likely scenario where direct condition measurements are unavailable. Subsequently, prognostics can be performed, and the RUL can be predicted based on assumed usage profiles. This not only improves prognostic performance in cases of varying operating conditions, but also offers the possibility to adapt usage profiles to extend the RUL.

4. Discussion and Conclusion

The paper showed that prognostic metrics of data from real-world data sets are extremely low compared to benchmark data sets. The main issues observed are unavailability of run-to-failure trajectories and low signal-to-noise ratios of the available trajectories due to always present confounding factors. As a consequence, developed data-driven prognostic methods are often not applicable in practical cases.

The criticality of discussed real-world cases make it unlikely that much run-to-failure data will be collected in the future, so the proposed solution is defined in a framework based on enhancing and utilizing system knowledge. The limited un-

derstanding of measured signals in the real-world cases make trending complicated, so system models with induced damage are proposed to increase understanding of the effects of damage on measured signals. A quantitative diagnostic algorithm can improve the signal-to-noise ratio of measured signals, providing the input for a Bayesian filter that quantifies the relation between usage and degradation rates. Subsequently, prognostics can be performed based on expected system usage.

The framework has strict requirements on system knowledge (i.e. PoF, load monitoring, system models with induced damage), but low data requirements as no historical run-to-failures are needed. To accelerate development for application to new systems, usage of modular system models such as bond graphs is proposed. The framework still needs to be implemented and validated for a real application and the strict requirements on system knowledge requires investments. However, it enables better RUL predictions (or RUL extension by usage adaptation) which can yield great benefits. Before moving to complex cases such as the Apache ETF or the marine diesel engine, it is proposed to start with relatively simple standard equipment such as bearings to validate the benefits of the method. This will be presented in a future publication.

ACKNOWLEDGEMENTS

This work is carried out as a part of the PrimaVera Project, funded by the NWO under grant agreement NWA.1160.18.238. The authors thank the NLR and Royal Netherlands Navy gratefully for making their case studies available for evaluation.

BIOGRAPHIES

Luc S. Keizers received his MSc degree in Mechanical Engineering at the University of Twente in 2020. He graduated on "Structural Fatigue Analysis using Flexible Multibody Dynamics" in the research chair of Applied Mechanics and Data Analysis. Shortly after, he started his PhD at the same university in the chair of Dynamics Based Maintenance in collaboration with the Netherlands Royal Navy. His research interest is in prognostics that combine his engineering background with data-driven models.

Richard Loendersloot received a MSc degree in Mechanical Engineering (2001) and a did his PhD research at the University of Twente, on thermoset resin flow processes through textile reinforcements during composite production process Resin Transfer Moulding and obtained his PhD degree in 2006. He worked in an engineering office on high-end FE simulations of a variety mechanical problems to return to the University of Twente in 2008 as assistant professor for Applied Mechanics. His research started to focus on vibration based structural health and condition monitoring, being addressed in both research and education. He became part of the research chair Dynamics Based Maintenance upon its initiation in 2012. His research covers a broad range of applications: from rail infra structure monitoring, to water mains condition inspection and aerospace health monitoring applications, using both structural dynamics and ultrasound methods. He is involved in a number of European and National funded research projects. He became associate professor in 2019, currently in charge of the daily lead of the Dynamics Based Maintenance group.

Tiedo Tinga is a full professor in dynamics based maintenance at the University of Twente since 2012 and full professor Life Cycle Management at the Netherlands Defence Academy since 2016. He received his PhD degree in mechanics of materials from Eindhoven University in 2009. He is chairing the smart maintenance knowledge center and leads a number of research projects on developing predictive maintenance concepts, mainly based on physics of failure models, but also following data-driven approaches.

Towards a Probabilistic Fusion Approach for Robust Battery Prognostics

ABSTRACT

Batteries are a key enabling technology for the decarbonization of transport and energy sectors. The safe and reliable operation of batteries is crucial for battery-powered systems. In this direction, the development of accurate and robust battery state-of-health prognostics models can unlock the potential of autonomous systems for complex, remote and reliable operations. The combination of Neural Networks, Bayesian modelling concepts and ensemble learning strategies, form a valuable prognostics framework to combine uncertainty in a robust and accurate manner. Accordingly, this paper introduces a Bayesian ensemble learning approach to predict the capacity depletion of lithium-ion batteries. The approach accurately predicts the capacity fade and quantifies the uncertainty associated with battery design and degradation processes. The proposed Bayesian ensemble methodology employs a stacking technique, integrating multiple Bayesian neural networks (BNNs) as base learners, which have been trained on data diversity. The proposed method has been validated using a battery aging dataset collected by the NASA Ames Prognostics Center of Excellence. Obtained results demonstrate the improved accuracy and robustness of the proposed probabilistic fusion approach with respect to (i) a single BNN model and (ii) a classical stacking strategy based on different BNNs.

1. INTRODUCTION

Batteries are key components in the transition towards a sustainable carbon-free economy. In this transition, the development of remaining useful life (RUL) prediction of batteries is a crucial activity. The accuracy and reliability of the RUL prediction models is essential to build trust in the predictions (Liu et al., 2023). In this context, robust and reliable battery prognostics models support the development of accurate monitoring strategies and cost-effective solutions.

The estimation of the state-of-health (SOH) of batteries is a key activity for the design of RUL prognostics models. SOH-based prognostics models focus on capturing the run-to-failure ageing dynamics and battery health state estimation (Toughzaoui et al., 2022). It is frequently used to determine age-related degradation that reduces energy capacity and rises safety risks, including overheating and explosions (Wang et al., 2022). Therefore, accurate SOH monitoring and forecasting are key activities to design and operate safe, reliable and effective battery-powered systems (H. Zhao et al., 2023).

SOH estimation is an ongoing area of research (Yang, Chen, Chen, & Huang, 2023). SOH refers to the ratio of the current maximum capacity relative to its original specified capacity (X. Zhao, Wang, Li, & Miao, 2024). SOH can be quantified through different factors, including resistance and maximum power. However, discharge capacity is the most common definition (Vanem, Salucci, Bakdi, & Alnes, 2021), and this is adopted in this research.

Recent data-driven approaches have focused on modeling the capacity degradation of lithium-ion (Li-ion) batteries. (Lee, Kwon, & Lee, 2023) used convolutional neural network (CNN) to estimate the future SOH value of Li-ion batteries, transforming the capacity degradation data into two-dimensional images. Estimates of the SOH and RUL are commonly found together in the literature. For example, (Toughzaoui et al., 2022) developed a CNN-LSTM architecture, and (Wei & Wu, 2023) presented a graph CNN complemented by dual attention mechanisms for the estimation of SOH and RUL of batteries. However, due to the variability inherent in battery manufacturing process, it is essential to quantify this uncertainty to ensure robust and reliable prognostics predictions

(Abdar et al., 2021; Nemani et al., 2023).

There are different sources of uncertainty present in the design, operation and maintenance of batteries (Hadigol, Maute, & Doostan, 2015). (Y. Zhang, Zhang, Liu, Feng, & Xu, 2024) introduced a SOH assessment method that estimates uncertainty through the quantile distribution of deep features, which are inferred from a Residual Neural Network (ResNet) architecture. This approach generates SOH values accompanied by confidence intervals. However, the proposed ResNet architecture lacks probabilistic layers, overlooking the uncertainty inherent in the model parameters. (Che et al., 2024) developed a prognostic framework to assess battery aging, using a CNN-LSTM Bayesian neural network. However, this approach limits the uncertainty to the final dense layers, which are the only components modeled probabilistically.

With the aim of capturing uncertainty associated with complex processes, recent studies in the broader machine learning (ML) community have focused on ensembles of probabilistic models. (Fan, Olson, & Evans, 2017) introduced a Bayesian posterior predictive framework for weighting ensemble climate models. (Cobb et al., 2019) present a new ML retrieval method based on an ensemble of Bayesian Neural Networks (BNNs). In this scenario, the overall output from the ensemble is treated as a Gaussian mixture model. However, models are equally weighted with no adaptation to the observed data. (S. Zhang, Liu, & Su, 2022) present a Bayesian Mixture Neural Network (BMNN) for Li-ion battery RUL prediction. The BMNN framework incorporates a Bayesian Convolutional Neural Network as feature extractor and a Bayesian Long Short-Term Memory to learn degradation patterns over time. However, the absence of a weighted model combination limits the analysis of individual model contributions.

Alternatively, (Bai & Chandra, 2023) described a Bayesian ensemble learning framework that uses gradient boosting by combining multiple Neural Networks trained by Markov Chain Monte Carlo (MCMC) sampling. Finally, (Dai, Pollock, & Roberts, 2023) demonstrate the robustness of Bayesian fusion by embedding the Monte Carlo fusion framework within a sequential Monte Carlo algorithm.

In this context, inspired by the use of probabilistic ensemble models to capture model uncertainty, the main contribution of this research is the development of a novel probabilistic model fusion approach for battery SOH predictions. Bayesian convolutional neural networks (BCNNs) are used as base models for SOH prediction, and the fusion approach integrates individual BCNN probabilistic predictions. The fusion strategy balances between precision and reliability of individual predictions, adopting an optimal tradeoff between accuracy and uncertainty of predictions through the proposed stacking approach.

The proposed approach has been compared with (i) individual BCNN models and (ii) fusion strategies focused on stacking of BCNN models using point prediction information. Obtained results confirm that the proposed framework infers accurate, well-calibrated, and reliable probabilistic predictions, which improve predictive performance and contribute to estimate uncertainty in a robust and reliable manner in complex data-driven tasks. The proposed approach has been tested and validated with the publicly available NASA's battery dataset (Saha & Goebel, 2007).

The remainder of this article is organized as follows. Section 2 outlines our probabilistic fusion approach for robust battery prognostics. Section 3 describes a case study to demonstrate the application of our methodology. Section 4 presents and analyzes the results obtained from the case study. Section 5 discusses the implications of these findings. The article concludes with Section 6, summarizing our main conclusions and suggesting avenues for future work.

2. Probabilistic Fusion Approach for Robust Battery Prognostics

The proposed probabilistic fusion framework integrates BCNNs with probabilistic ensemble strategies. The main objective of the integration is to generate accurate predictions with robust uncertainty quantification, thanks to the uncertainty quantification of Bayesian modelling (Blundell, Cornebise, Kavukcuoglu, & Wierstra, 2015) and the robustness and accuracy of ensemble strategies (S. Zhang et al., 2022).

The approach is divided into offline and online stages. Starting from a set of battery datasets, in the offline process, data pre-processing and model training steps are completed. In the online process, trained models are stacked in an ensemble model according to computed weight and stacking criteria. The outcome of the approach is a one-step-ahead probabilistic capacity estimate. Figure 1 shows the high-level block diagram of the proposed approach.

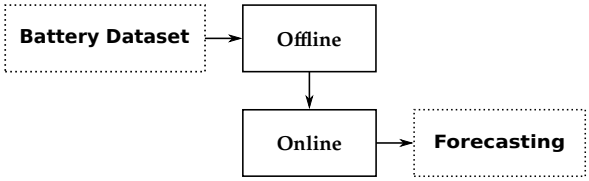

Figure 1. High-level block diagram of the proposed approach.

The high-level concepts in Figure 1 are implemented through the detailed model architecture shown in Figure 2.

The base models are BCNN models, which are trained (offline) through a leave-one-out cross validation (LOOCV) process. The probabilistic results of individual BCNN models are aggregated through a stacking process that includes accuracy and uncertainty metrics. In the testing (online) phase, each BCNN model weights are computed using learned mod-

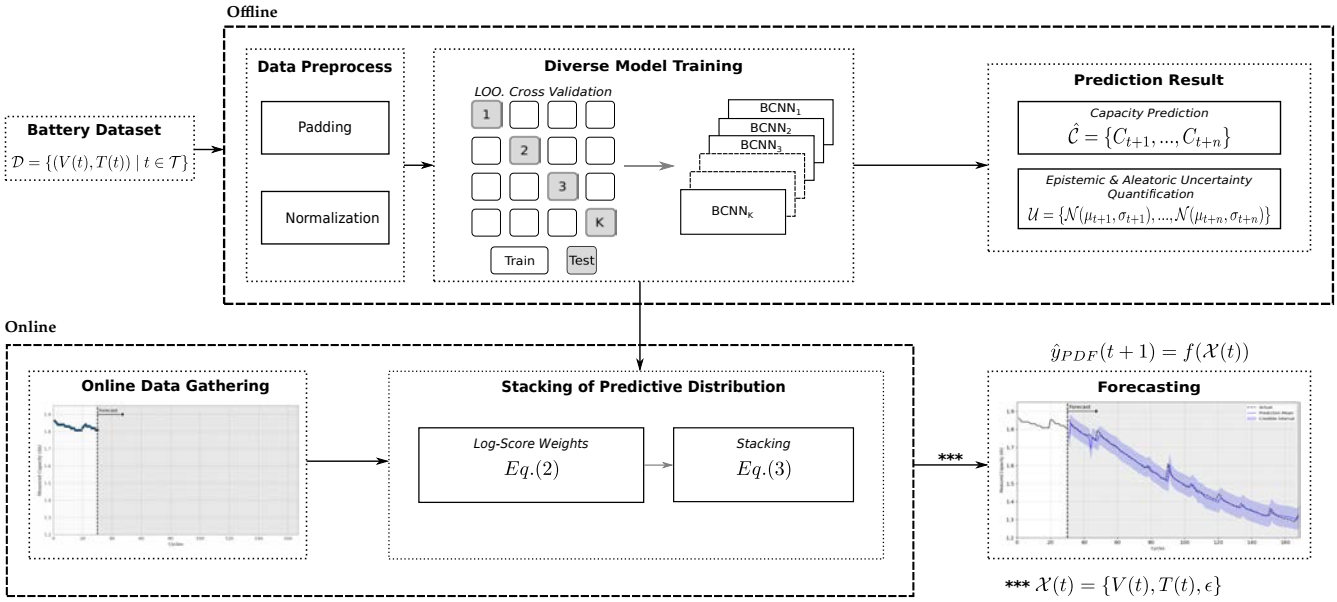

Figure 2. Block diagram of the proposed approach.

els (log-score weights) and the stacking model is designed to combine them and generate a distribution from a mixture model. The following subsections explain in detail the main parts of the approach.

2.1. Offline Phase

During the offline phase, starting from a battery dataset with different run-to-failure trajectories on the same type of batteries, different base models are designed through a training strategy which seeks diversity in the training set to develop complementary predictive models.

2.1.1. Ensemble Base Models: BCNNs

BCNN models are a Bayesian extension of the classical CNN models to include uncertainty associated with parameter estimation. This requires modification of the classical backpropagation algorithm through Bayesian techniques that involves incorporating uncertainty into the model by treating weights as random variables, and applying variational inference to approximate posterior distributions. This results in a more robust model that predicts the complete probability density function (PDF).

Consequently, BCNN models have been selected to improve the robustness and accuracy of model prediction. To this end, BCNNs make use of probabilistic distributions to model parameters and the uncertainty related to their training process, and prior distributions to incorporate previous knowledge, generate uncertainty estimations and mitigate over-fitting (Blundell et al., 2015). In contrast, the classical learning models, e.g. non-Bayesian CNN models, focus on maximum likelihood estimation (MLE) and they overlook prior and posterior distributions. This leads to increasing error and decreasing model robustness in high uncertainty contexts, e.g. out-of-distribution data or manufacturing drifts.

The proposed approach utilizes data pre-processing techniques to standardize the length of discharge cycles through padding. This technique involves repeating the last discharge value until the desired cycle length is reached, ensuring consistent input dimensions for all models. Additionally, normalization is carried out scaling the discharge values between 0 and 1.

The architecture of the BCNN models is shown in Figure 3 defined as follows:

- Input data: the input data for the BCNN is structured in a tensor format. The rows represent data samples of discharge cycles, and columns that correspond to features, such as the voltage and temperature over time. Notably, the input does not include the current discharge as it remains constant in this scenario.
- Convolutional 1D Reparametrization: this layer creates a convolution kernel that is applied to the input data. During the forward pass, kernel and bias parameters are drawn from a Gaussian distribution. It uses the reparameterization estimator to approximate distributions through Monte Carlo trials, integrating over the kernel and bias.
- Global Average Pooling 1D: this layer performs average pooling specifically for temporal data. It reduces the spatial dimensions of the input data to a single value per channel by calculating the average over the temporal dimension.
- Flatten: this layer reshapes input data into a one dimensional array, enabling compatibility between Bayesian

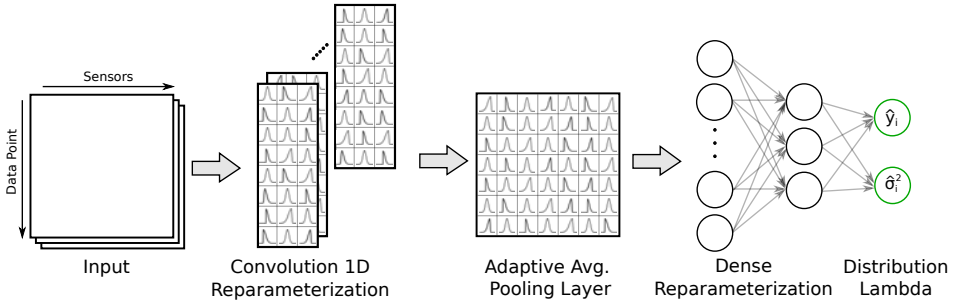

Figure 3. Schematic of the Bayesian convolution neural network.

convolutional layers and Bayesian dense layers.

- Dense Reparameterization: this layer implements a reparameterization estimator for Bayesian variational inference. It implements a stochastic forward pass via sampling from the kernel and bias distributions. This approach improves the robustness of the model, allowing uncertainty estimation in parameter values and supporting probabilistic modeling in deep learning.
- Distribution Lambda: this layer is responsible for producing the final results given the inputs and the learned weights from the previous layers. The output layer consists of two neurons representing the mean, $\hat{y}$ and variance, $\hat{\sigma}^2$, in order to quantify the expected value and its associated uncertainty. To ensure a positive variance, the neuron is activated using an exponential function.

BCNN combines feature extraction capabilities of classical CNN models with the uncertainty quantification of Bayesian theory. The proposed architecture is built using the Bayesian layers of `TensorFlow Probability` in Python (Dillon et al., 2017).

2.1.2. Training for Diversity

Model diversity is a key concept for effective ensemble models (Nam, Yoon, Lee, & Lee, 2021). Accordingly, in this case, the training set for each battery model is modified to learn different battery aging properties. Historical capacity fading data are used to build aging models for each battery in the dataset.

Namely, using the LOOCV strategy, if K run-to-failure trajectories are available, K diverse BCNN models are built changing the training set in each iteration (cf. Figure 2). That is, the model is trained on all batteries except one, which is held as a test set. This process is repeated so that each battery serves as a test set exactly once. Thus, all available data are used for training, maximizing the diversity of training scenarios.

Training the BCNN models through LOOCV strategy, enhances the ability of individual models to generalize across different battery types and manufacturing conditions.

This stage completes the offline training process, which results in a set of BCNN models:

$$\mathcal{M} = \{BCNN_1, BCNN_2, \ldots, BCNN_K\}, \qquad (1)$$

which are used in the subsequent online inference process to build ensemble models.

2.2. Online: Stacking of Predictive Distribution

During the online phase, the proposed stacking of predictive distribution strategy is designed and tested. The proposed approach takes as input individual base models [cf. Eq. (1)] and monitored data up to the prediction instant t, which is used to forecast the probability density function (PDF) of the capacity at $t+1$, $\hat{y}_{PDF}(t+1)$. The objective of the stacking process is to integrate the predictive distributions of different base models and propagate all the information end-to-end.

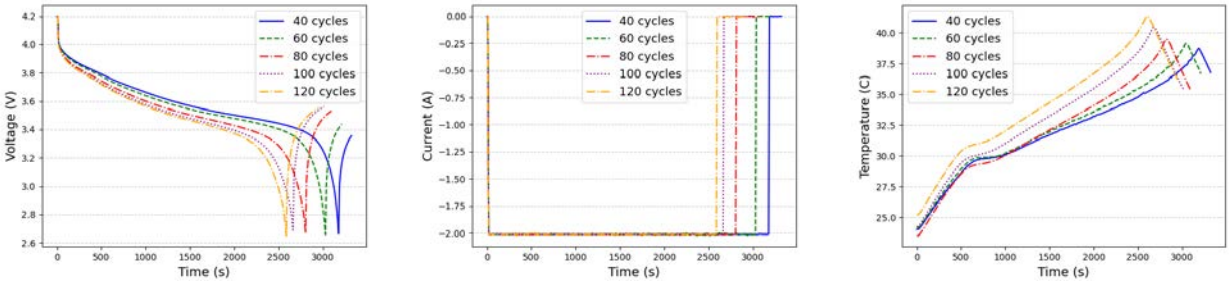
For comparison and benchmarking purposes, an alternative stacking approach is also implemented named stacking of point prediction (cf. Subsection 3.3).

Log-Score Weights

The optimal way to combine a set of Bayesian posterior predictive distributions is by using the logarithmic score (Yao, Vehtari, Simpson, & Gelman, 2018). This method maximizes the average log-likelihood of the observed data, which is a proper scoring rule used to evaluate the accuracy of probabilistic forecasts. It measures the accuracy of a forecast and penalizes overconfidence and underconfidence in the predicted probability. The logarithmic score is defined as follows:

$$\hat{w} = \arg\max_{w} \frac{1}{N} \sum_{i=1}^{N} log \sum_{k=1}^{K} w_k p(y_i \mid y_{-i}, M_k) + \lambda_{reg} \sum_{k=1}^{K} w_k^2 \quad (2)$$

where N denotes the total number of data points and K denotes the total number of base models. The leave-one-out predictive distribution for each model, *i.e.* $p(y_i \mid y_{-i}, M_k)$, is used to compute the model's prediction for the data point i. To avoid overfitting, a regularization term λ_{reg} is added to the likelihood function, penalizing large weights.



(a) Voltage variation (b) Current variation (c) Temperature variation

Figure 4. Feature variations due to an increasing number of discharge cycles in battery #5.

Stacking

Stacking is a method to average point estimates from several models (LeBlanc & Tibshirani, 1996). In its simplest form, it can be seen as a weighted average method. Through the weighted average, it facilitates the construction of ensembles that incorporate predictions from multiple models. In the proposed framework, the goal of weighted average ensemble is to leverage the predictive capabilities of K pre-trained BCNN models [cf. Eq. (1)]. It seeks to mitigate forecasting errors by assigning weights to the linear combination of these models, thereby enhancing the accuracy of predictions.

In the Bayesian framework, stacking extends beyond the limitations of averaging point predictions by combining multiple Bayesian posterior predictive distributions. This approach develops a *stacking model* that leverages the strengths of various predictive models, enhancing overall predictive accuracy. The stacking of the predictive distribution enables the fusion of uncertainties from various models into a unified predictive framework. This approach improves the accuracy of forecasts and offers a comprehensive evaluation of the uncertainty associated with these forecasts, providing advantages across diverse decision-making scenarios. The fundamental equation governing this process is defined as follows:

$$\hat{p}(\tilde{y}|y) = \sum_{k=1}^{K} \hat{w}_k p(\tilde{y}|y, M_k) \tag{3}$$

where $\hat{p}(\tilde{y}|y)$ represents the aggregate probability estimation based on the ensemble model, ω_k denotes the weight assigned to the k-th component within the ensemble, and $p(\tilde{y}|y, M_k)$ refers to the probabilistic forecast generated by each base model, denoted as BCNN_k, given the observed data y.

This probabilistic prediction indicates the likelihood of observing the predicted outcome $\tilde{y}$, dependent on the specific base model employed.

2.2.1. Forecasting

Online forecasting is computed for one-step-ahead predictions. In order to forecast battery capacity at instant $t+1$, previous data until the instant t is used, plus an uncertainty factor expressed as noise:

$$\mathcal{X}(t) = \{V(t), T(t), \epsilon\} \tag{4}$$

where $\{V(t), T(t)\}$ denote the values of voltage and temperature at instant t, and ϵ denotes the Gaussian noise term, $N(0, \sigma)$ with $\sigma = 0.1$, that introduces variability in the progression of X over time.

The one-step-ahead capacity distribution prediction is thus defined as follows:

$$\hat{y}_{PDF}(t+1) = f(\mathcal{X}(t)) \tag{5}$$

where $f(.)$, denotes the designed ensemble model, $\hat{y}_{PDF}(t+1)$ is the distribution of the capacity estimate at $t+1$.

It is possible to perform SOH predictions for longer prediction horizons through a recursive forecasting strategy. However, due to the accumulation of individual forecasting errors, this approach may lead to decrease long-term forecasting performance. Long-term SOH forecasting activities are left open for future work.

This approach allows the model to learn continuously and adapt to changing conditions. Online forecasting is particularly beneficial in environments that require immediate decision making based on the latest available data.

3. CASE STUDY

3.1. Dataset description

The effectiveness of the proposed method has been tested using a battery dataset from the NASA Ames Prognostics Center of Excellence (Saha & Goebel, 2007).

A subset of available battery data has been selected, focusing on batteries #5, #6, #7 and #18. Each battery is operated under various conditions including charging, discharging, and impedance analysis. Throughout the charge and discharge cycles, temperature, current, and voltage were meticulously recorded. During charging, a constant current mode at 1.5 A was maintained until the voltage reached 4.2 V, followed by a switch to constant voltage mode until the current dropped to 20 mA. Discharge cycles involved a constant load mode at 2 A until the voltage levels reached 2.7 V, 2.5 V, 2.2 V and 2.5 V for batteries #5, #6, #7 and #18, respectively. The experiment ended once the battery capacity decreased by 30%. These batteries had a maximum capacity of 2Ah with an end-of-life capacity set at 1.4Ah.

Figures 4(a), 4(b) and 4(c) show the evolution of voltage, current (constant), and temperature measurements with the increment of discharge cycles for the battery #5. Figure 5 shows variations in capacity degradation rates for identical batteries. This is an indicator of uncertainty inherent in the manufacturing process, which affects SOH estimates.

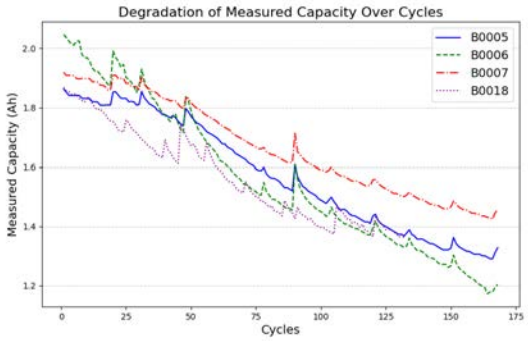


Figure 5. Capacity degradation data of Li-ion batteries.

3.2. BCNN structure and hyperparameters

The design of the base BCNN model structure is developed through experimentation. The BCNN architecture for SOH forecasting is detailed in Table 1, where 'None' is indicative of the batch size. The input for the model comprises 371 data points per discharge cycle, with each point aggregating 3 features: voltage, temperature, and time.

The proposed structure encompasses a total of 1300 trainable parameters, designed to extract features from battery discharge cycle data for forecasting purposes. Figure 3 details the convolutional layer hyperparameters, which includes 16 kernels, each with a dimension of 3, adopting a Laplace distribution for the prior and employing a ReLU activation function. In addition, the model incorporates Bayesian dense layers with 16 units, Adam optimizer, a learning rate of 0.01, and Evidence Lower Bound (ELBO) as its loss function (S. Zhang et al., 2022).

Table 1. BCNN model architecture

Layer	Description	Output Shape	# Param.
-	Input	(None, 371, 4)	0
1	Conv.1D Reparameter.	(None, 369, 16)	416
2	Conv.1D Reparameter.	(None, 368, 8)	528
3	Global Average Pooling	(None, 8)	0
4	Flatten	(None, 8)	0
5	Dense Reparameter.	(None, 16)	288
6	Dense Reparameter.	(None, 2)	68
7	Distribution Lambda	(None,1),(None,1)	0
	Total params: 1300 (5.08 KB)		

3.3. Benchmarking

In order to compare the designed stacking approach with alternative stacking strategies, another stacking approach has been designed using point prediction information instead of the full distribution.

Stacking of Point Prediction

An effective method for determining the weight of each model in the stacking process is by minimizing the leave-one-out mean squared error with a L_2 regularization term, λ_{reg}. The purpose of this term is to penalize large weights, thus preventing overfitting and balancing individual model contributions. The weights are obtained through the following optimization problem:

$$\hat{w} = \arg\min_{w} \sum_{i=1}^{n} \left(y_i - \sum_{k=1}^{K} w_k \hat{f}_K^{(-i)}(x_i) \right)^2 + \lambda_{reg} \sum_{k=1}^{K} w_k^2 \quad (6)$$

where $\hat{f}_K^{(-i)}(x_i)$ represents the predicted value of the k-th model, when the i-th observation is left out of the training set. The regularization parameter, λ_{reg}, controls the strength of the regularization applied. To ensure a feasible solution, the weights are restricted to $w_k \geq 0$ and $\sum_{k=1}^{K} w_k = 1$.

Accordingly, the stacking of point prediction approach is defined as follows:

$$\hat{y} = \sum_{k=1}^{K} \hat{w}_k f_k(x|\theta_k) \quad (7)$$

where $\hat{y}$ represents the prediction of the ensemble for the test battery capacity, $\hat{w}_k$ denotes the weight assigned to the k-th battery base model, and $f_k(x|\theta_k)$ is the prediction made by the corresponding base model (BCNN_k).

3.4. Evaluation criteria

The accuracy of the regression is measured by Mean Squared Error, while Negative Log Likelihood assesses model perfor-

mance by quantifying prediction probabilities. Finally, The correctness of probability predictions is assessed through the CRPS.

Mean Square Error (MSE) is a metric for measuring the quality of an estimator. It is a measure of the average squared differences between the estimated values and what is estimated. MSE is calculated by taking the average of the square of the differences between the predicted values and the actual values (Hodson, 2022).

$$\text{MSE} = \frac{1}{n}\sum_{i=1}^{n}(Y_i - \hat{Y}_i)^2 \tag{8}$$

where, n represents the number of observations, Y_i denotes the actual value for the ith observation, and $\hat{Y}_i$ signifies the predicted value for the ith observation.

Coefficient of Determination (R^2) is a metric used to assess the goodness of fit of the model. It provides a measure of how well the observed outcomes are replicated by the model, based on the proportion of total variation of outcomes explained by the model (Barrett, 1974).

$$R^2 = 1 - \frac{\sum_{i=1}^{n}(Y_i - \hat{Y}i)^2}{\sum_{i=1}^{n}(Y_i - \bar{Y})^2} \tag{9}$$

where, n is the number of observations, Y_i is the actual value, $\hat{Y}_i$ the predicted value for the i-th observation and $\bar{Y}$ the mean of Y. R^2 of 1 implies perfect model predictions, while 0 means no explained variability.

Continuous Ranked Probability Score (CRPS) can be formally expressed as a quadratic measure of discrepancy between the predicted Cumulative Distribution Function (CDF), $F(\cdot)$, and the observed empirical CDF for a given scalar observation y (Zamo & Naveau, 2018):

$$CRPS(F, y) = \int (F(x) - \mathbb{I}(x \geq y_i))^2 dx, \tag{10}$$

where $\mathbb{I}(x \geq y_i)$ is the indicator function, which models the empirical CDF.

To obtain a single score value from Eq. (10), a weighted average is calculated for each individual observation of the test set (Gneiting, Raftery, Westveld, & Goldman, 2005):

$$CRPS = \frac{1}{N}\sum_{i=1}^{N} CRPS(F_i, y_i) \tag{11}$$

where N denotes the total number of predictions.

Negative Log Likelihood (NLL) metric assesses probabilistic models by using the likelihood concept, which indicates how likely the observed data is given model parameters (Bosman & Thierens, 2000). Likelihood ($\mathcal{L}$) is the product of each observation's probability density function (PDF), expressed mathematically as

$$\mathcal{L}(\theta \mid X) = \prod_{i=1}^{N} f(x_i|\theta) \tag{12}$$

where θ denotes model parameters and X includes N data points. NLL is preferred for optimization since minimizing NLL is equivalent to maximizing the log-likelihood, facilitating the discovery of model parameters that best explain the observed data, represented by

$$-\log \mathcal{L}(\theta \mid X) = -\sum_{i=1}^{n} \log f(x_i \mid \theta) \tag{13}$$

Calibration refers to the statistical consistency between the predictive distributions and the actual observations. It represents a joint property of forecasts and empirical data (Jung, Jo, Choo, & Lee, 2022). Namely, it is stated that the model is calibrated if (Kuleshov, Fenner, & Ermon, 2018):

$$\frac{\sum_{t=1}^{T} \mathbb{I}\{y_t \leq F_t^{-1}(p)\}}{T} \rightarrow p \text{ for all } p \in [0, 1] \tag{14}$$

In this expression, T refers to the total number of data points, while the indicator function $\mathbb{I}\{y_t \leq F_t^{-1}(p)\}$ takes a value of 1 when the condition $y_t \leq F_t^{-1}(p)$ is true, and 0 otherwise. Given this condition, y_t express the observed outcome at time t, and $F_t^{-1}(p)$ is the inverse of the CDF for the forecast, evaluated at probability p. Therefore, the condition represents the threshold below which a random sample from the distribution would occur with a probability p.

Sharpness means that the confidence intervals should be optimized for minimal width around a singular value. That is, the goal is to reduce the variance, denoted as $var(F_n)$, of the random variable characterized by the cumulative distribution function F_n (Kuleshov et al., 2018; Tran et al., 2020):

$$sha = \sqrt{\frac{1}{N}\sum_{n=1}^{N} var(F_n)} \tag{15}$$

4. RESULTS

To evaluate the proposed approach, firstly, different ensemble strategies are compared to evaluate their strengths and identify the most suitable approach. Subsequently, a sensitivity analysis is developed with respect to the contribution of individual base-models to the overall ensemble.

4.1. Probabilistic Ensemble Strategies

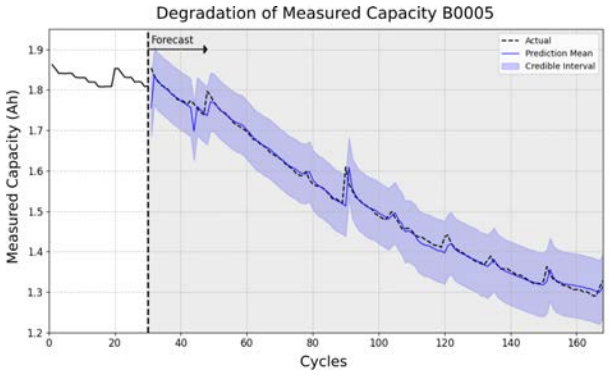
This section focuses on the comparison between (i) the baseline model, *i.e.* BCNN model trained with all available data, (ii) ensemble of point prediction and (iii) proposed ensemble method (cf. Figure 2) to further evaluate the improvement of ensemble strategies over baseline model.

Table 2 presents a comparative analysis in terms of accuracy and probabilistic metrics. This comparison highlights that, for different test scenarios, the ensemble methodologies enhance the performance of the baseline model.

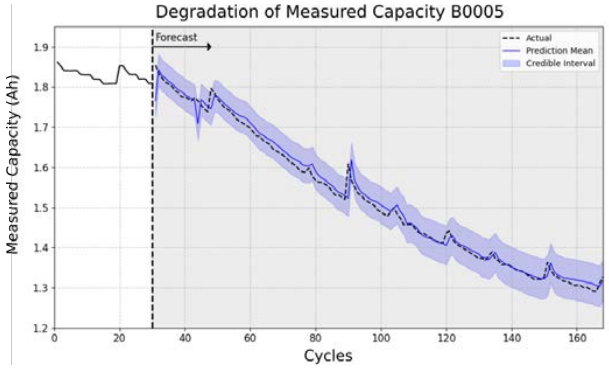
A notable observation from the results in Table 2 is the variance between the proposed ensemble approach (cf. Figure 2) and the benchmarking ensemble model (cf. Subsection 3.3) in specific scenarios. For batteries #5 and #6, the proposed approach exhibited superior outcomes, particularly in probabilistic metrics (NLL and CRPS). This suggests that within a Bayesian framework, prioritizing likelihood maximization, leads to accurately modelling uncertainty, and therefore, it is more advantageous than focusing on MSE minimization (as in Subsection 3.3).

The model optimization criterion has a direct impact on the performance of the tested methods and on the effectiveness of the ensemble approach. However, for batteries #7 and #18, no significant differences were observed between the tested ensemble approaches, which indicates that the results are associated to the prior models. That is, it is possible that the same prior model minimizes the MSE and maximizes the likelihood at the same time.

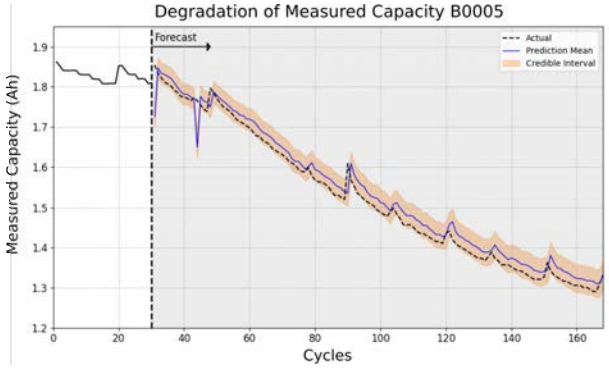
Figure 6(a) shows the comparison between the ensemble model generated by stacking point predictions (cf. Subsection 3.3), Figure 6(b) shows the ensemble model generated through stacking of predictive distributions (cf. Figure 2), and Figure 6(c) shows the individual BCNN trained with the entire dataset, e.g. for the battery #5, train with batteries #6, #7, and #18, and test with #5.



(a) Stacked point prediction method (cf. Subsection 3.3)



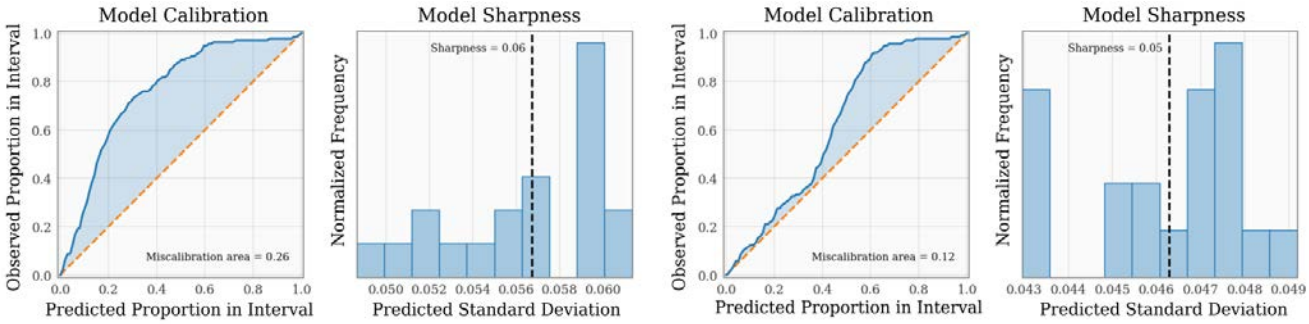
(b) Stacked predictive distribution method (cf. Figure 2)



(c) Baseline model

Figure 6. Battery capacity degradation forecasting results.

It is observed that the ensemble models enhance the performance of baseline model in terms of accuracy and uncertainty



(a) calibration and sharpness for the benchmarking ensemble model

(b) calibration and sharpness for the proposed ensemble model

Figure 7. Evaluation of calibration and sharpness for battery #5.

quantification. This is indicated by the positioning of the ground truth (dashed lines) at the limit of the lower boundary in Figure 6(c), which means that the uncertainty does not accurately cover the observed values. That is, the uncertainty bounds are not well-calibrated, compromising the model's ability to accurately represent the underlying variability in the data and in the model compared to ensemble strategies.

Figure 6(a) shows an improvement in the prediction accuracy. However, it simultaneously introduces a higher level of uncertainty compared to the proposed ensemble method in Figure 6(b). This is reflected in the NLL and CRPS metrics, where the stacking of the predictive distribution demonstrates superior performance (cf. Table 2). Such probabilistic metrics indicate that the model parameters make the observed data more probable, indicating a good fit to the observed data.

The evaluation of the shape of the PDF is a crucial aspect of uncertainty quantification. Accordingly, the calibration and the sharpness assessment of PDFs is performed through a python toolbox for predictive uncertainty quantification (Chung, Char, Guo, Schneider, & Neiswanger, 2021). Figure 7 shows the calibration and sharpness of the analysed ensemble methods designed for probabilistic forecasting for the battery #5.

The calibration plot for the point-prediction ensemble model [cf. Figure 7(a)] reveals a miscalibration area of 0.26, indicating a gap between predicted probabilities and actual outcomes, generally overestimating event probabilities. On the contrary, the proposed ensemble model [cf. Figure 7(b)] shows better calibration with a miscalibration area of 0.12, aligning closer to the ideal, especially in midrange probabilities.

In terms of sharpness, the predictions of the point-prediction based ensemble model have a mean sharpness value of 0.06 and are right-skewed, reflecting higher uncertainty. However, the proposed ensemble model has a mean sharpness value of 0.05, with a slightly left-skewed distribution, indicating more predictions with lower uncertainty and greater confidence.

4.2. Sensitivity of the Ensemble Strategy with Base-Models

To evaluate the contribution of each individual BCNN model to the ensemble approach, a sensitivity assessment has been performed. Namely, the performance of the different leave-one-out iterations has been evaluated, sequentially training with different battery datasets and testing with the leave-out battery dataset. This has been compared with the proposed ensemble approach results to identify individual contributions from different models. Table 3 displays the obtained results.

Table 3. Performance evaluation of BCNN models and the ensemble approach.

Test[1]	Model	*MSE* (↓)	R^2 (↑)	*NLL* (↓)	*CRPS* (↓)

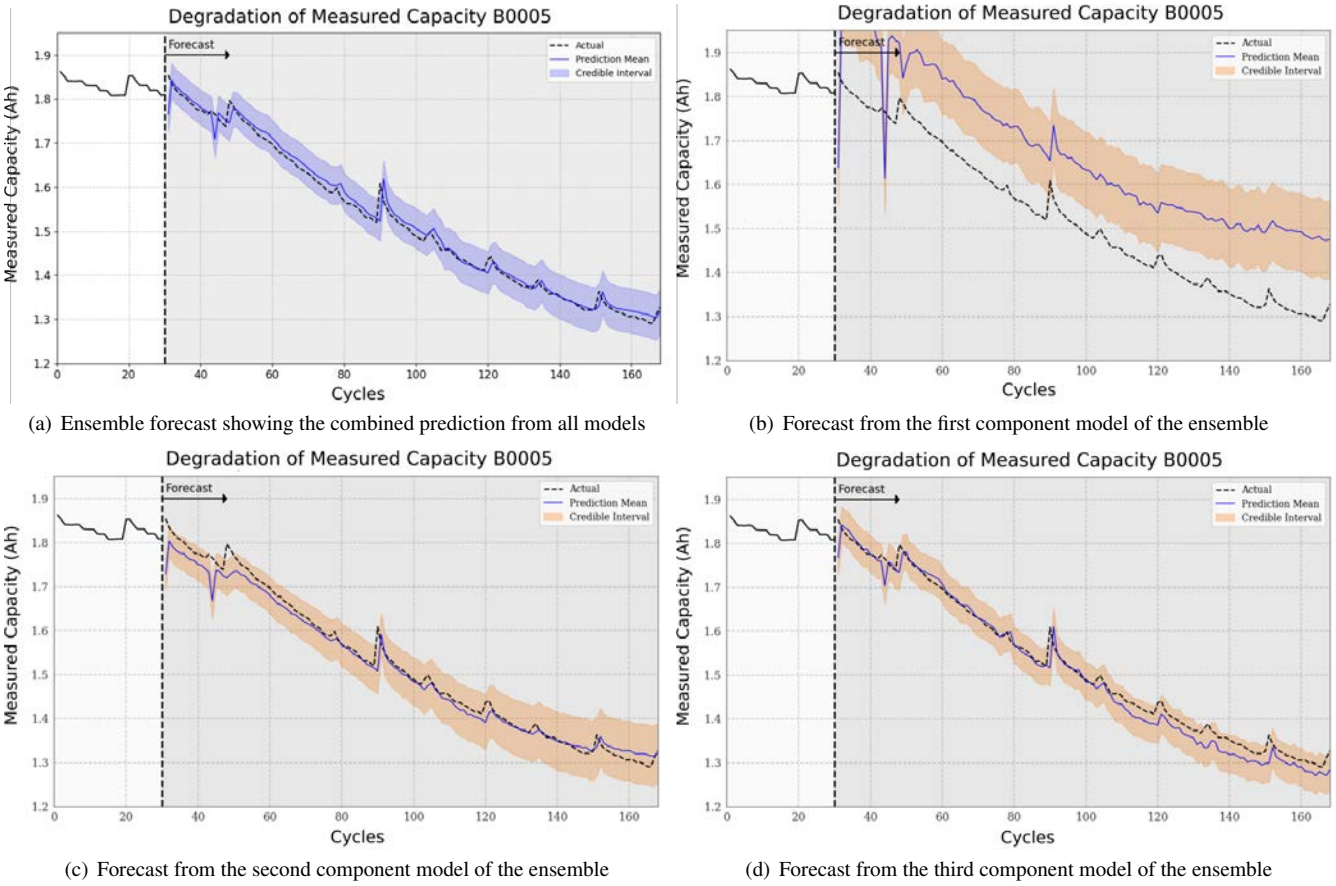
[1] Battery identifier used for testing.
[2] BCNN [#A,#B]: BCNN trained with batteries #A and #B.

The ensemble BCNN model demonstrates significantly higher accuracy and predictive power than individual BCNN models, as evidenced by its superior performance across multiple metrics. It achieves the lowest MSE in every testing battery, indicating more precise predictions, and the highest R^2 score, showing its ability to explain a greater proportion of variance.



(a) Ensemble forecast showing the combined prediction from all models

(b) Forecast from the first component model of the ensemble

(c) Forecast from the second component model of the ensemble

(d) Forecast from the third component model of the ensemble

Figure 8. Capacity fade forecasting for battery #5 employing an ensemble of BCNN models.

The ensemble model also shows a notable improvement in the NLL metric, suggesting a more reliable uncertainty estimation. Additionally, by achieving the lowest CRPS, it emphasizes its proficiency in probabilistic forecasting and precise uncertainty quantification. Overall, the ensemble method outperforms individual models, highlighting its effectiveness in contexts that require high accuracy and reliability.

Figure 8 presents the forecasts generated by individual models for battery #5 (cf. Table 3). Figures 8(b)-8(d), show individual models and Figure 8(a) shows the combined forecast of the ensemble model.

It can be seen that the ensemble effectively combines the characteristics of models 2 and 3, thereby improving the overall performance of the final forecast of the ensemble.

5. Discussion

The proposed research work demonstrates that the stacking of predictive distributions based on a Bayesian framework improves the accuracy and robustness of predictions compared with stacking of point predictions. Furthermore, it has been observed that the use of an ensemble of BCNN models improves the modeling of uncertainty when compared to relying on a single BCNN model (baseline). However, before drawing definitive conclusions about the application of the proposed solution in real-world applications, further work is necessary testing the robustness, scalability, and sensitivity with respect to noise.

Robustness

Credible intervals reflect the uncertainty associated with the data and the model (cf. Figure 6). The robustness of the proposed approach is therefore directly dependent on model and data uncertainty. The reduction of credible intervals align with the objective of increasing robustness. To this end, increasing the number of observations would reduce the uncertainty attributed to the model, which results in more precise credible intervals. Additionally, employing priors like maximum entropy priors or weakly informative priors may further tighten credible intervals, thereby improving the reliability of the model predictions.

Scalability

To analyze larger fleets of batteries, instead of using leave-one-out methodologies, it may be more appropriate to de-

velop generalized training methodologies. In this direction, one approach would be to cluster batteries that exhibit similar operation and degradation conditions. This strategy would enable capturing data diversity, which is a key property for ensemble strategies. Alternatively, a hierarchical modelling strategy may be adopted. This method involves a global model for overall battery behavior, supplemented by smaller models for specific groups, enabling precise adaptations without the need for separate models per battery. This strategy ensures scalability and flexibility in handling various battery operation and degradation conditions efficiently.

Noise Sensitivity

The proposed approach assumes a Gaussian noise to model the variability of the modeled process and measurements [cf. Eq. (4)]. To analyze the impact of Gaussian noise levels on prediction results, a sensitivity analysis has been performed. Figure 9 shows the obtained results.

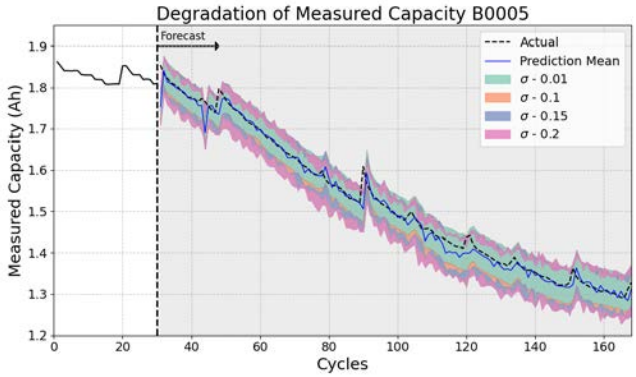


Figure 9. Impact of Gaussian Noise on Predictive Modeling of Battery Capacity Degradation.

Obtained results indicate that, when testing data diverges from training data, the epistemic uncertainty increases. The increase in Gaussian noise causes a greater deviation, and therefore, there is a significant rise in epistemic uncertainty. Analysing the model's behaviour in the presence of different types of uncertainty is crucial to evaluate the robustness of the model and determine if additional training stages are needed to enhance its reliability. Consequently, this research adopts a noise level of 0.1 as a trade-off decision between prediction accuracy and uncertainty.

Application Limits

Some of the adopted practices may limit the applicability of the proposed framework in real-world applications. The experimental setup, conducted in a controlled environment with specified load conditions, may not entirely replicate the diverse sources of uncertainty present in real-world applications. Such controlled conditions could potentially skew the understanding of uncertainty due to environmental and operational variabilities. Consequently, the predictive performance observed in this study may differ under less predictable conditions. In this direction, for controlled operation environments, the complexity of the proposed approach may be reduced. However, the proposed methodology complexity is designed to capture a wide range of uncertainties found in real operating systems.

6. Conclusion and Future Work

Batteries are key components in power and energy systems and ensuring a robust and reliable remaining useful life (RUL) prediction of batteries is crucial to develop accurate monitoring strategies, and build cost-effective solutions.

In this context, battery RUL prediction models generally focus on individual prediction models. They may be able to capture uncertainty associated with the battery ageing process, but the uncertainty modelling and capturing ability is also limited to the individual model. This research presents a probabilistic ensemble prognostics approach which combines Bayesian Convolutional Neural Network (BCNN) models in a probabilistic stacking strategy. The proposed framework leverages the probabilistic predictive information of individual BCNN models, which are integrated through a probabilistic stacking approach that calibrates between accuracy and robustness of probabilistic predictions.

The proposed approach has been tested on NASA's battery dataset. Obtained results show that the proposed probabilistic stacking approach improves accuracy and uncertainty of predictions with respect to other ensemble strategies and individual BCNN models.

This research study contributes towards understanding and predicting the capacity fade in Li-ion batteries. Namely, it highlights the role of probabilistic approaches and ensemble methods in modelling the uncertainties inherent in battery manufacturing and operation.

Looking forward, there are different opportunities to expand the scope and applicability of this work. On the one hand, the use of a larger battery dataset, which includes diverse environmental and operational conditions, would allow for a more comprehensive understanding of capacity fade across various scenarios. On the other hand, it may be possible to perform a more exhaustive comparative analysis of different fusion strategies, including Bayesian Model Averaging, Pseudo Bayesian Model Averaging, or Mixture Models. This comparative will provide further insights into the optimal approaches for integrating predictive models in the context of battery life prediction, enhancing both the accuracy and reliability of capacity fade forecasts.

ABSTRACT

To effectively compete with other renewable energy sources, there remains a critical need to further decrease the Levelized Cost of Energy of Wind Farms (WFs). A promising way to achieve this objective is by minimizing the downtime of wind turbines (WTs) through effective Inspection and Maintenance (I&M) activities. Conventionally, I&M plans have predominantly relied on CM/SCADA data obtained from the physical components of turbines, with data analytics and machine learning (ML) techniques being employed to predict their performance and maintenance needs. However, statistics indicate that nearly 40% of WT failures can be traced back to HFs. These include aspects such as skills, knowledge, communication, and even the broader organizational culture. This paper delves into the importance of integrating HFs in the I&M of WFs to optimize turbine performance, enhance safety, and reduce downtime.

Firstly, we briefly discussed various Human Reliability Analysis (HRA) methods with special emphasis on Performance Shape Factors (PSFs). We then identify key human factors (HFs) that are vital for performing O&M tasks. For this, we have prepared a questionnaire to get qualitative input from technicians and also done a thorough literature review. E.g., some of the HFs that stand out include the ergonomics of tools and workspace designs tailored to technicians' needs, the cognitive load placed on operators during system monitoring and diagnostics, continuous training to handle evolving challenges, effective communication channels, and safety protocols designed with human behavior in mind. We then propose a novel framework for developing a computer vision-based recommendation system that can guide the technicians to perform the maintenance effectively thus minimizing the HE.

1. INTRODUCTION

The wind industry, driven by a commitment to green energy generation, is at the forefront of research, technological innovation, efficiency gains, and cost reductions. With turbine sizes and capacity factors having tripled, there has been a monumental shift in the wind energy sector. Since 1990, generation costs have been reduced by 65% (KPMG, (2019)), underscoring the industry's dedication to developing sustainable and economical energy solutions for the future. For instance, breakthroughs in blade design and materials, backed by rigorous research, enable turbines to harness wind more proficiently, yielding higher energy outputs even in suboptimal wind conditions (Asim, T., Islam, S., Hemmati, A., & Khalid, M. (2022)). The adoption of various Prognostics and Health Management (PHM) technologies and predictive analytics has further improved the operation and maintenance (O&M) of (WFs), curtailing downtime and driving costs even lower (Haghshenas, A., Hasan, A., Osen, O., & Mikalsen, E. T. (2023)).

Rinaldi et al. (Rinaldi, G., Thies, P. R., & Johanning, L. (2021)) performed an exhaustive survey of the latest strategies governing the O&M planning and CM of OWFs. Their review delves into the benefits and limitations of current practices and looks ahead to emerging trends in robotics, AI, and data analytics. Key opportunities highlighted include the integration of diverse data sources to refine O&M strategies, precise inventory management, detailed uncertainty modeling, the urgent need for

standardized open data frameworks, and the development of essential reference software. In a related study, McMorland et al. (McMorland, J., Flannigan, C., Carroll, J., Collu, M., McMillan, D., Leithead, W., & Coraddu, A. (2022)) highlighted the significance of various factors in O&M modeling for OWFs, including weather dynamics, failure, and degradation patterns, vessel logistics, cost estimation, and maintenance tactics. Besnard et al. (Besnard, F., Patriksson, M., Stromberg, A. B., Wojciechowski, A., & Bertling, L. (2009)) introduced the 'opportunistic maintenance' concept for OWFs, which entails the fusion of multiple planned corrective and preventive maintenance tasks, either within a similar timeframe or even during a single visit. By capitalizing on wind forecasts and synchronizing corrective maintenance with periods of low power generation or unexpected failures, this approach has proven to yield a 43% reduction in preventive maintenance expenses (Fast, S., Mabee, W., Baxter, J., Christidis, T., Driver, L., Hill, S., McMurtry, J., & Tomkow, M. (2016)) However, as currently practiced, the PHM approach uses only machine-related quantitative data available from CM/SCADA systems to predict and manage the performance and maintenance needs of WFs. The biggest drawback of the overreliance on machine-related (MR) data is its inability to capture the full spectrum of operating conditions under which WFs function. A frequently undervalued metric in this context is human-related data, which offers additional insights into the system environment (Kiassat, A.C., (2013)).

Human technicians/operators are an essential part of the daily O&M activities of the WFs. It is highly probable that Human Error (HE), in one form or another, might infiltrate the design, manufacturing, operation, and maintenance phases of WFs. Morag et al. (Morag, I. et al. (2018)), identified the most common HE during a maintenance activity described in Table 1.

The HE may go unnoticed due to various reasons and can result in catastrophic accidents leading to severe consequences for the environment, society, and business. Statistics indicate, HE as one of the major factors for accidents across various sectors as shown in Figure 1. For instance, the infamous disasters within the oil and gas sector namely, the Piper Alpha and the BP Deepwater Horizon blowout occurred due to human and operational flaws. Likewise, the accident investigations of multiple aircraft crashes (such as of a Boeing 707-321C in 1977; Boeing 747-200, in 1992; and Airbus 380-842 Qantas Flight 32 in 2010) also point towards technical failures, HFs, and regulatory shortcomings as failure causes (Mathavara, K., & Ramachandran, G. (2022)). These statistics serve as a reminder that, while the hardware aspect is undoubtedly important, the human dimension also has a significant influence on the overall health and performance of the system.

Table 1. Most common causes of Human Errors

(Morag, I. et al. (2018))

HE Type	**Description**
Communication	Misunderstandings among technicians and operators, often stemming from inadequate leadership and management.
Fatigue	Tiredness due to overwork or working in enclosed environments.
Tools and equipment	Improper use of tools and equipment can augment risks and compromise worker safety. Additionally, the lack of proper tools may increase HE as workers resort to using unsuitable machinery for specific tasks.
Skills and expertise	The risk of HE increases in non-routine tasks that demand specific knowledge when workers assigned are unfamiliar with the activities.
Bad procedures	HE often arises from poor information and the lack of standardized procedures.
Documentation	Poor documentation handling can increase HE due to its impact on task performance and understanding of required work.
Procedure's usage	Lengthy procedures often lead workers to adopt informal methods and rely on personal experience to complete tasks.
Time pressures	Overtime and overwork often lead to more mistakes by workers, as they resort to shortcuts and simpler work methods.
Tool control and housekeeping	It concerns tracking the equipment used or removed from machinery.

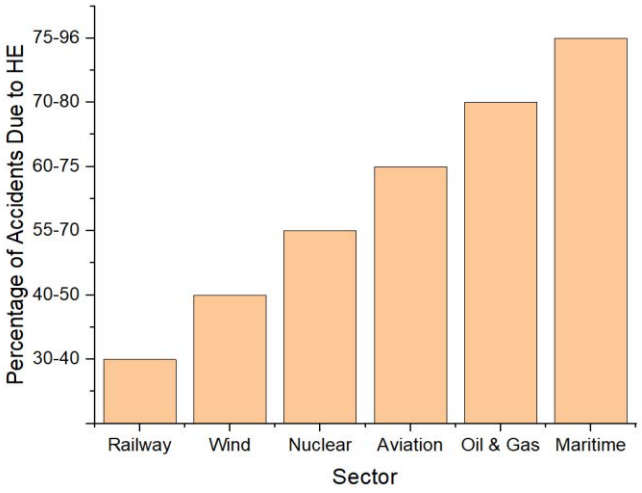

Figure 1. Accident percentage due to HE across various sectors

In this paper, the authors have highlighted the importance of integrating HFs within O&M of WFs. Firstly, we have briefly discussed various Human Reliability Analysis (HRA) methods with special emphasis on Performance Shape Factors (PSFs). We then discuss two scenarios of performance maintenance in the yaw deck and the nacelle of a typical WT. Thereafter we propose a framework for developing a computer vision-based recommendation system that can guide the technicians to perform the maintenance effectively thus minimizing the HE. We also propose the use of an eye-tracking device to measure the stress level of technicians.

2. HUMAN RELIABILITY ANALYSIS (HRA)

2.1. General

The origin of HRA is in probabilistic risk assessment (PRA), a discipline initially developed for understanding and quantifying the risks of serious accidents within the nuclear industry. HRA provides methods and tools for analyzing and assessing risks caused by operator's actions on a technical system, thus evaluating to operator's contribution to system reliability. The first fully developed HRA methods date back to the 1970s when systematic tools for analysis of the operator's contribution to risk were applied in the nuclear industry. There are now several HRA methods available for the nuclear sector, with some being adapted to other industries such as oil and gas, chemical, and aviation. Figure 2 illustrates the steps of a generic HRA process.

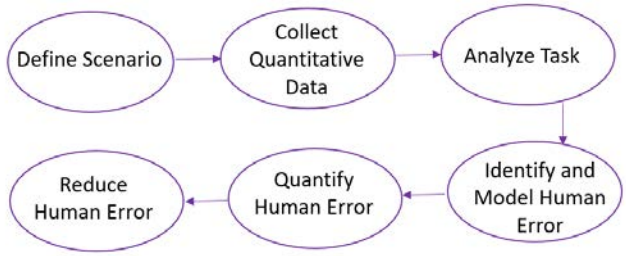

Figure 2. Generic HRA Process

2.2. HRA Methods

It is common to distinguish between first and second-generation HRA methods (Swain, A.D. (1990), Dougherty, E.M. (1990)). The list of first-generation methods is extensive and includes amongst others Technique for Human Error Rate Prediction (THERP) (Swain, A.D., Guttman, H.E. (1983)), the Human Cognitive Reliability method (HCR) (Hannaman, G.W., Spurgin, A.J., Lukic, Y.D. (1984)), the Human Error Assessment and Reduction Technique (HEART) (Williams, J.C. (1985)), Accident Sequence Evaluation Program (ASEP) (Swain, A.D. (1987), and Standardized Plant Analysis Risk – Human (SPAR-H) reliability analysis (Gertman, D., Blackan, H.S., Marble, J., Byers, J., Haney, L.N., Smith, C. (2005)).

Hollnagel (Hollnagel, E. (1998)), and Kim (Kim, I.S. (2001)) provide the following list of notable characteristics of first-generation methods: 1) Assumption that human reliability is similarly describable as hardware reliability. 2) HRA being limited to only the human actions that are included in the PSA event trees. 3) Binary representation of human action as either success or failure to carry out a given task. 4) Dichotomy of errors of omission (failure to perform an action) and errors of commission (unintended or unplanned action). 5) Focus on phenomenological aspects of human actions. 6) Little concern about the cognitive aspects of human actions. 7) Emphasis on quantification of human errors. 8) Indirect treatment of context, as the way in which PSFs exert their effect on performance is not described.

Second-generation HRA methods were developed based on cognitive architectures to unveil the causes of errors from a behavioral perspective; thus, solving the main deficiency of the first generation. Two basic requirements proposed by Hollnagel (Hollnagel, E. (1998)) are that second-generation approach "uses enhanced PSA event trees and that it extends the traditional description or error modes beyond the binary categorization of success-failure and omission-commission" (p.151). He further stresses the need for a more realistic type of operator model, as the approach must be explicit about the way in which performance conditions affect performance. Most authors critiquing first-generation HRA methods agree on the necessity of incorporating a cognitive model into HRA "that would enable a better understanding of human error mechanisms that were well described by Reason (Reason, J. (1990))". A Technique for Human Event Analysis (ATHEANA) (Cooper, S.E., Ramey-Smith, A.M., Wreathall, J., Parry, G.W. (1996)) and Cognitive Reliability and Error Analysis Method (CREAM) (Hollnagel, E. (1998)) are examples of well-known and widely utilized second-generation techniques. CREAM uses the contextual control model (COCOM) and provides a determination of the reliability of a person's performance based on an error taxonomy that contains both error modes and error causes.

Although addressing the main issue of first-generation HRA methods, one of the highlighted weaknesses of second-generation methods is that they do not provide sufficient consideration of the mutual influences between PSFs (De Ambroggi, M. (2011)). According to Griffith and Mahadevan (Griffith, C.D., Mahadevan, S. (2011)) the main sources of deficiencies in HRA methods include: "1) lack of empirical data for model development and validation, 2) lack of inclusion of human cognition (i.e., need for better human behavior modeling, 3) large variability in implementation (i.e., HRA parameters are different depending on the method used), and 4) heavy reliance on expert judgment in selecting PSFs, and use of these PSFs to obtain the HEP in human reliability analysis" (p. 1444).

HRA experts have more recently begun to look at potential improvements to existing methods. As an example, the

HEART method has been used as a basis for domain-specific approaches such as Nuclear Action Reliability Assessment (NARA) (Kirwan, B., Gibson, H., Kennedy, R., Edmunds, J., Cooksley, G., Umbers, I. (2004)), Controller Action Reliability Assessment (CARA) (Kirwan, B., Gibson, H. (2008)), Railway Action Reliability Assessment (RARA) (Gibson, W.H., Mills, A.M., Smith, S., Kirwan, B.K. (2013)) and Shipboard Operations Human Reliability (SOHRA) (Akyuz, E., Celik, M., Cebi, S. (2016)). Another example is a more recent article by He et al. (He, Y., Kuai, N.-S., Deng, L.-M., He, X-Y. (2021)), which builds on CREAM by adding Human Inherent Factors (HIFs) such as anti-fatigue ability, concentration ability, reaction ability, and personality traits.

In 2006, NASA Office of Safety and Mission Assurance (OSMA) published a technical report evaluating 14 HRA methods against a list of 17 attributes to highlight methods that are considered suitable for use in risk and reliability studies of NASA space systems and missions. The evaluation resulted in the selection of four methods: THERP, CREAM, NARA, and SPAR-H. The list of attributes used to compare the methods included: Developmental Context, Screening, Task Decomposition, PSF List and Causal Model, Coverage, HEP Calculation Procedure, Error-Specific HEPs, Task Dependencies and Recovery, HEP Uncertainty Bounds, Level of Knowledge Required, Validation, Reproducibility, Sensitivity, Experience Base, Resource Requirements, Cost and Availability, as well as Suitability for NASA Applications (Chandler, F., Chang, Y., Mosleh, A., Marble, J., Boring, R., Gethman, D. (2006)). Consideration of several of these attributes is essential when evaluating existing HRA methods for use in the context of O&M of WFs.

2.3. Human Factors

Our definition of HFs is from IEA: "Human Factors is the scientific discipline concerned with the understanding of interactions among humans and other elements of a system, and the profession that applies theory, principles, data, and other methods to design to optimize human well-being and overall system performance". HFs can be used either in accident investigations, or they can be used to enhance the performance of the technicians.

The aims of using HF in general and in accident investigations are to:

(1) Improve safety (i.e., reducing the risk of injury and death);

(2) Improve performance in safety-critical situations (i.e., increase quality, productivity, and efficiency);

(3) Support satisfaction/usability (i.e., increasing acceptance, comfort, and well-being).

The details of how to use HFs for accident investigation are well documented in the literature, however, in this paper, we shall focus more on the identification of the HFs (in particular PSFs) that can be managed such that the I&M activities are performed efficiently within given time with minimal HE.

2.4. Performance Shape Factors (PSFs) for OWFs

PSFs or Performance Influencing Factors (PIFs) are defined by the Health Safety and Executive (HSE) as “characteristics of the job (e.g. the working environment); the individual (physical capability to do the work), and the organization (e.g. time pressure) that influence human performance” (HSE RR01 (2002))

Relevant PSFs for OWFs include environmental conditions (e.g., high winds, rough seas, weather variability), ergonomic challenges (working at heights, confined spaces, awkward postures), organizational aspects (training, work culture, resource availability), technical and mechanical complexity, accessibility and logistics due to remote locations, communication and coordination for emergency response, and the use of specialized tools and predictive maintenance technologies. On a more personal level, psychological stressors such as time pressure and distractions, as well as physiological factors like fatigue and hunger, can impact inspection and maintenance quality and error rates, especially in confined spaces like nacelles and hubs.

Acknowledging PSFs and their impact on operational outcomes is essential for ensuring the safety, efficiency, and reliability of OWF’s O&M. For instance, the performance of technicians can significantly drop on a wet and windy day compared to more favorable weather conditions, increasing the risk of human error and injuries. Similarly, an overloaded technician may overlook early signs of wear, potentially causing unforeseen equipment failures. Additionally, a company that prioritizes proactive maintenance is likely to emphasize regular training, which can lead to fewer operational errors.

The I&M activities and corresponding PSFs differ depending on the location within the WTs. For example, tasks on the yaw deck, such as brake maintenance and friction pad replacement, present unique challenges. These include transporting items using the nacelle crane or manually from inside the tower. Operations in this area entail inspecting the deck, handling moving parts, setting up the workspace, conducting maintenance, and cleaning up (G+ Global Offshore Wind Health & Safety Organization, (2021)). Challenges specific to the yaw deck include difficult access, particularly through ladder hatches in older turbines, constrained working space, and the physical strain of maneuvering heavy items. These conditions require technicians to employ specialized tools and assume strenuous postures, which can adversely affect their well-being (G+ Global Offshore Wind Health & Safety Organization, (2021)).

Most service and maintenance tasks in WTs, such as routine inspections and part replacements, are carried out in the confined spaces of the nacelle and blade hub. Although newer, larger wind turbines provide a bit more space and improved accessibility, the areas remain constrained, frequently cluttered, and occasionally slippery due to oil spills. These conditions make it difficult to move safely and operate tools efficiently (G+ Global Offshore Wind Health & Safety Organization, (2021)). In the hub, accessing components like blade root bolts forces technicians into uncomfortable positions, compounded by the presence of grease and cramped, angled spaces. This increases the likelihood of injuries, equipment mishandling, and errors. More details regarding PSFs for working on OWT can be found in (G+ Global Offshore Wind Health & Safety Organization, (2021)).

A questionnaire was designed to collect feedback from technicians, the results of which are presented in Figure 3 (in the Appendix). The questionnaire's link is provided in (Questionnaire, (2024)). The responses indicate a consensus among technicians on most questions. For instance, regarding ergonomic challenges highlighted in question 3, one technician mentioned, "*Wind turbines are often not ergonomically designed, lacking laydown areas for bags and equipment, leading to obstacles and potential hazards. Restricted access, working in areas with significant grease or oil, and maintaining a clean environment pose substantial challenges.*" Another respondent highlighted the absence of adequate sanitary facilities for women on WTs.

A detailed analysis of the survey results suggests that conducting I&M activities on WTs is an exceptionally challenging task, which significantly increases the likelihood of HE. Moreover, the lack of real-time supervision at inspection sites reduces the opportunities to correct such errors. Consequently, the following section introduces a novel framework for a Computer Vision supervisory agent designed to monitor technicians during inspections and capable of raising an alarm if there is a risk of HE

3. COMPUTER VISION-BASED RECOMMENDATION AGENT

The steps involved in the framework that integrates multi-modal inputs like videos and images consist of the following steps:

1. Data Collection: Using high-resolution cameras, we will gather a comprehensive dataset of videos and images capturing expert technicians performing WT inspections.
2. Data Preprocessing: We will apply techniques like frame extraction, noise reduction, and image stabilization to the recorded videos and images to prepare the data for analysis. Next, we will manually annotate them with labels indicating correct and incorrect actions, focusing on key inspection points and common errors. Finally, we will augment the data using techniques such as rotation, scaling, and mirroring to increase the dataset's robustness against variations in real-world scenarios.
3. Model Development: We will use convolutional neural networks (CNNs) to extract features from images and video frames, and employ Long Short-Term Memory (LSTM) networks to analyze temporal dependencies in video data. We will then implement a fusion technique to effectively integrate features from different modalities, capturing a comprehensive profile of inspection activities. Lastly, we will develop a classification system using machine learning to distinguish between correct and incorrect inspection behaviors based on the labeled data.
4. Real-Time Monitoring System: We will install a monitoring device at strategic locations around the wind turbine. Each device will be equipped with a high-resolution camera and a speaker system. The camera will continuously capture video of the technician’s activities, allowing the system to visually monitor the inspection process from multiple angles. We will use edge computing devices integrated within the monitoring systems to process the data in real-time, significantly reducing latency and ensuring that any deviations or anomalies are promptly detected. The speaker will provide immediate audio feedback and recommendations to the technician based on the real-time analysis, including alerts about potential errors, reminders of inspection steps, or safety warnings.
5. Feedback Loop: We will integrate a feedback system where the model learns from new inspection videos over time, adapting to new techniques and evolving standards in turbine maintenance. We will regularly evaluate the system’s accuracy and reliability in detecting deviations and making iterative improvements based on real-world performance and feedback from technicians and supervisors. Furthermore, the technicians will also be able to interact with the system using voice commands. They will be able to respond to the audio cues by confirming receipt of messages or asking for further clarification. They will also be able to report issues, fetch information, or even tag certain observations without having to stop their work or remove their gloves, which can be particularly useful in harsh weather conditions.

The deployment of such a framework has the potential to lower the HE significantly within WT maintenance and it also aligns with the broader goals of the wind industry to reduce costs and improve the reliability and efficiency of green energy production. As the industry continues to evolve, the continuous refinement and adoption of such integrated frameworks will be essential for sustaining

growth and ensuring the safety and well-being of the human technicians at the heart of these operations.

4. CONCLUSION

This paper laid out the critical importance of integrating HFs into the O&M of WFs, with a particular focus on the potential to enhance safety and efficiency through advanced technologies and methodologies. We discussed various approaches that have been used in the past for performing HRA to estimate HEP. The important PSFs for maintenance activity on WFs, include environmental conditions, ergonomic challenges, organizational aspects, accessibility and logistics due to remote locations, communication and coordination for emergency response, the use of specialized tools, and psychological stressors. A questionnaire was designed to collect feedback on PSFs from WT technicians. For example, all the technicians agreed that the awkward positions required for accessing components like blade root bolts not only increase the risk of injury but also elevate the likelihood of mishandling equipment and making errors.

To address these issues, we proposed a computer vision-based supervisory agent capable of real-time monitoring. This system, which utilizes multi-modal inputs from high-resolution cameras and provides audio feedback, represents a significant leap forward in reducing HE. By continuously capturing and analyzing the technician's actions, the system offers corrective feedback and actionable recommendations, thereby ensuring adherence to best practices and enhancing overall safety.

BIOGRAPHIES

Arvind Keprate received his B. Tech in Mechanical Engineering (2007) from Himachal Pradesh University, M.Sc. in Marine & Subsea Technology (2014), and PhD (2017), in Offshore Engineering from the University of Stavanger, Norway. He is currently a Professor at Oslo Metropolitan University where he teaches Design related courses to Mechanical Engineering students. Besides this, he also teaches Machine Learning, Probability & Statistics at Kristiania University College in Oslo. He has been a visiting researcher at the Prognostics Center of Excellence, NASA Ames Research Center, USA. Currently, his research is focused on Digital Twins and PHM of complex Socio-Ecological-Technical Energy Systems such as Wind Farms.

Stine Skaufel Kilskar has an M.Sc. in Industrial Economics and Technology Management (2014) from the Norwegian University of Science and Technology, Norway, with a focus on strategic change management. She is currently a Research Scientist at SINTEF Digital in Trondheim. She has ten years' experience of working in safety-related research projects within various industries, such as construction, maritime, oil & gas, and energy. The research is mainly focused on safety management and human factors.

Pete Andrews qualified from the University of Sheffield with a Masters degree in Aerospace Engineering in 2005. Working within the power industry for the last 19 years he has delivered operational, engineering and leadership roles across a broad range of power generation assets and technologies. Previously he delivered a number of roles within leading utilities including Commercial Manager supporting major asset divestments and managing offshore wind services and Plant Manager accountable for a large offshore wind farm. Recognizing that the pace of innovation in offshore wind operations and maintenance was lagging compared to the rate of development in other aspects of the sector he founded EchoBolt, an organisation dedicated to deploying advanced technologies to improve the management of structural integrity of wind turbines.

Appendix

Fig 3. Response of Questionnaire

1. **Environmental Conditions:** How often do adverse weather conditions (e.g., high winds, rain, sea states) affect your ability to safely perform maintenance tasks?

2. **Ergonomic Challenges:** Do you face any physical difficulties while working on turbines. How do these challenges affect your work?

3. **Ergonomics Challenges:** Please describe any physical difficulties you encounter while working on turbines (e.g., working in confined spaces, at heights, or in awkward positions)

Latest Responses

"Working in awkward positions for long time"

"very hard for women to be there in case of periods "

"Wind turbines are often not ergonomically designed. No laydown areas for ...

4. **Psychological Stressors:** How often do you find that time pressure or distractions affect your focus during maintenance tasks?

5. **Physiological Factors:** How frequently do fatigue or hunger impact your ability to perform maintenance and inspection tasks effectively?

6. **Organizational Support:** How adequate do you find the training and resources provided for dealing with the specific challenges of offshore wind turbine maintenance?

7. **Technical Complexity:** Rate the level of difficulty you face in understanding and applying the technical knowledge required for turbine maintenance.

8. **Accessibility and Logistics:** How do the logistics and accessibility of offshore wind farms impact your maintenance work, particularly in emergency situations?

9. **Communication and Coordination:** Evaluate the effectiveness of communication within your team and with management, especially for coordinating maintenance activities and responding to incidents.

10. **Safety and Emergency Procedures:** How confident are you in the safety protocols and emergency response plans in place for offshore wind turbine operations? Have you identified any areas for improvement?

Towards Physics-Informed PHM for Multi-component degradation (MCD) in complex systems

ABSTRACT

This study seeks to address the challenge of limited degradation data in developing Fault Detection and Isolation (FDI) models for multi-component degradation (MCD) scenarios. Utilizing a small fraction (0.05%) of a previously utilized water distribution testbed dataset in a previous publication, a weighted ensemble hybrid approach is proposed and evaluated against more established modelling approaches used in the previous publication. The proposed approach combines heuristic approximation and Physics-Informed Neural Network (PINN) methods with a recurrent neural network (RNN) model to enhance diagnostic performance for predicting MCD scenarios. The hybrid model generally outperformed other algorithms when tested on an MCD dataset, demonstrating improved diagnostic accuracy in such scenarios. Future research aims to optimize ensemble weights based on model uncertainty, further enhancing diagnostic capabilities.

1. INTRODUCTION

Data has become the story of engineering design in recent times as the availability of system data provides insights into the dynamics of any complex system. This is particularly true for developing analytics in digital twin (DT) design for asset health management applications (Lu, Xie, Parlikad, & Schooling, 2020). Figure 1 shows the nexus between the analytics developed for PHM applications and a virtual representation of a physical asset highlighting how DTs can enable PHM applications. In exploring cost mitigation strategies, different maintenance data-driven models often rely on large amounts of data to train effectively (Maass, Parsons, Purao, Storey, & Woo, 2018). The more data is available, the better the model can learn patterns and relationships within the data, leading to more accurate predictions or insights (Barimah, Niculita, McGlinchey, & Cowell, 2023). This helps data-driven models generalise better to unseen data the more data is available (Duriez, Brunton, & Noack, 2017). This is particularly useful when it comes to asset health management where the availability of trainable degradation data is critical in the design and execution of Prognostics and Health Management (PHM) strategies for complex systems undergoing multi-component degradation scenarios.

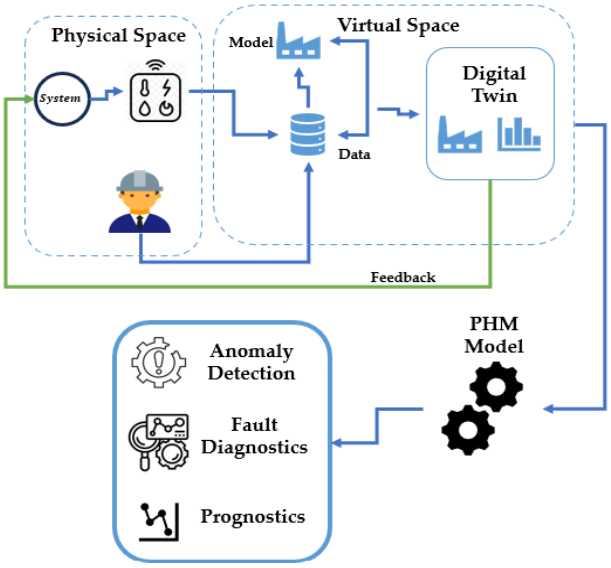

Figure 1. Relationship between DT and PHM applications.

However, obtaining asset degradation data can be expensive, time consuming, and often requires specialized equipment, sensors, or monitoring systems (Hu, Miao, Si, Pan, & Zio, 2022). Operators often rely on post-failure degradation data (Barimah, Niculita, McGlinchey, & Alkali, 2021) which enables the development of statistical-based techniques for

system-level anomaly detection. The statistical-based technique alone prevents an operator from isolating the sub-systems contributing to the anomaly in the larger system. The scenario becomes even more complex when two components of the same system degrade simultaneously (very often, at different rates). Simulated degradation data calibrated with the actual physical system (Higdon, Kennedy, Cavendish, Cafeo, & Ryne, 2004) can also be used to train predictive models. However, this approach becomes limited when MCD scenarios are being considered as degradation data from the different combinations of sub-systems undergoing degradation need to be simulated to generated the required data. For complex systems with a lot of sub-systems with different operating conditions, this approach becomes untenable.

To address the issue of limited data, several authors have suggested combining the insights given by data-driven models with some physical equations that govern the dynamics of a system. Physics-Informed Neural Networks (PINNs) integrate the physics of an asset into their training process, enforcing physical constraints alongside data-driven learning. PINNs can generalize well with limited data (Cai, Mao, Wang, Yin, & Karniadakis, 2021) and have applications in various fields (Huang & Wang, 2022), making them valuable for tackling complex, multi-physics problems (Bararnia & Esmaeilpour, 2022) by reducing computational costs and providing insights (Rizi & Abbas, 2023). The aim and objectives of this paper are presented in section 2 below.

2. OBJECTIVES OF STUDY

This paper aims to develop and benchmark an ensemble hybrid fault detection and isolation model for components (sub-systems) undergoing multi-component degradation (MCD) scenarios in a water distribution system.

- Identify a physical equation that represents the degradation severity level of either blockages or leakages in the system.
- Design a Fault Detection and Isolation (FDI) algorithm using a PINN-enabled Hybrid model for each component in the water distribution system.
- Train all FDI models on limited degradation data and test models on test multi-component degradation scenario data from the same system at different operating conditions.
- Identify areas of model improvement and potential research.

The paper is structured as follows: Section 3 covers the methodology. Sections 4 and 5 present and discuss the results of FDI model performance. Finally, the paper concludes with contributions and future research work.

3. METHODOLOGY

3.1. System Description

Data from the dynamic behaviour of a water distribution system undergoing multi-component degradation presented in Barimah et. al (2023) was used in this report. Figure 2 below shows the water distribution experimental testbed, where an external gear pump pumps water from a main supply tank. A variable speed drive (VSD) controls the rotational speed of the pump and the motor. The system also has five (5) direct proportional valves (DPV1 to DPV5) and a solenoid shut-off valve (SHV) that were included to support the emulation of deterioration phenomena affecting five different components in a controlled manner. Data is collected from five pressure transmitters (P1, P2, P3, P4, and P5), turbine flow meters (f1 and f2), and a laser sensor to gauge the pump's speed. Table 1 lists the control valves in the system's default operating states, their respective fault codes, and the fault emulation mechanism for each component on the testbed.

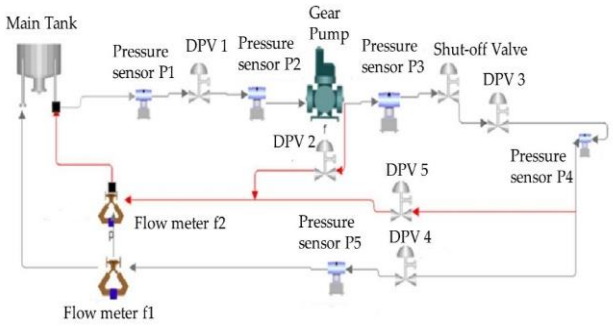

Figure 2. Water Distribution System Testbed Schematic (Barimah et. al 2023).

Table 1. Healthy condition operating state of the system's control valves and associated fault codes

Component/Fault Codes	Testbed Valves	Healthy State	Fault Emulation Mechanism
Filter/FC1	DPV 1	FO	DPV1 GC
Pump/FC2	DPV 2	FC	DPV2 GO
Valve/FC3	DPV 3	FO	DPV3 GC
Nozzle/FC4	DPV 4	FO	DPV4 GC
Pipe/FC5	DPV 5	FC	DPV5 GO

FO - Fully Open | FC - Fully Closed
GC - Gradually closing | GO - Gradually opening.

3.2. Process Data Capture

The degradation data used in the previous publication by Barimah et. al (2023) was recorded within four (4) weeks for healthy condition (HC), Single Component Degradation (SCD) and Multi-Component Degradation (MCD) scenarios between pump speeds of 700rpm and 950rpm in intervals of 50rpm. The SCD process data represents the degradation of individual components (See Table 2) with pressure and flow

measurements at $P_1, P_2 \ldots\ldots P_5$ and f_1, f_2 respectively. Data logging for each faulty condition scenario last between three (3) to four (4) minutes and also starts at least 10 minutes after the process reaches steady state conditions or when there is a step change in pump speed or a change in the failure condition scenario with each data file having different sample sizes. The degradation level of severity $(0 \leq S \leq 1)$ for each component on the testbed is determined by gradually closing or opening the respective direct proportional valve.

Table 2. Data capturing process with a sampling rate of 0.2s

Test period	4 consecutive weeks
Faulty Condition Scenarios (Total No of Tests)	FC0 – Healthy Condition (24) FC1–Clogged Filter (24) FC2–Degraded Pump (24) FC3–Blocked Valve (24) FC4–Blocked Nozzle (24) FC5–Leaking Pipe (24)
Pump Speed (rpm)	700/750/800/850/900/950

3.3. FDI Model Development

Sections 3.3.1 to 3.3.5 presents the process for developing physics informed fault detection and isolation (FDI) algorithms. Using limited training data, the paper also benchmarks the statistical process control (SPC), ensemble classification models and a recurrent neural network model presented by the author in a previous paper (see Figure 4) with the physics Informed FDI models presented in this paper. This is to determine the performance of FDI models in detecting multi-component degradation scenarios when limited degradation data is available for model training. The Statistical Process Control, the ensemble and neural network models were trained with full degradation dataset in Table 2 simultaneously, tagged as models $M_1, M_2 and\ M_3$ respectively and stored in a Fault Detection and Isolation model repository. The function $f_2(x)$ is then used to determine the proportion of accurate predictions of test degradation scenario data by $M_1, M_2 and\ M_3$.

A physics-informed Neural Network (PINN) enabled hybrid FDI algorithm is also developed in this report to detect multi component degradation scenarios. The hybrid model consists of a weighted average of a heuristic approximation model, a naïve recurrent neural network and a feedforward PINN model for each component in the water distribution system. The training of all models was done using randomly selected 0.05 % of the full degradation data from the original historical dataset used in Barimah et. al (2023) shown in Table 2. Figure 5 below shows the various cases in which the various randomly sampled degradation data can occur. Case A represents a scenario where part of the live process data from the system forms part of the distribution of the sampled random data. Case B is the non-ideal situation where the live process data is a subset of the sampled distribution while case C is the ideal case where the degradation data available is truly limited. The rationale for the random approach is to reduce the quantity and diversity of degradation data available for model training and development hence the limited nature. This is done to determine the impact of limited data conditions on the performance of FDI algorithms in MCD scenarios. The levels of severity are categorized into two (2) groups with below 0.21 defined as healthy and between 0.21 and 1.0 defined a faulty in both MCD and SCD scenarios (see Figure 3). The performance of the FDI algorithms is measured using the interval $(0 \leq Performance \leq 1)$ where 1 means the algorithm predicted correctly all the categorized severity states of the asset in operation while 0 means the algorithm failed to predict correctly any severity state of the asset.

3.3.1. Physics Informed Neural Network Model

As shown in Figure 2, five direct-acting proportional valves are used to emulate the dynamics of degradation patterns in the main components on the water distribution system. Equation (1) is used to determine the fluid flow through a valve where $f(V_0)$ is the function of valve opening with $0 \leq f(V_0) \leq 1$ as the interval for the valve opening and C_v is the valve coefficient (Knight, Russell, Sawalk & Yendell, 2013). Equations (2) & (3) are used to determine the level of severity $S(0,1)$ for blockages (Blocked Filter, degraded valve & Blocked Nozzle) and leakage (leaking pipe) respectively. For the pump, Eq. (4) is used to determine the severity level in a leaking pump degradation scenario for the gear pump on the testbed where N_v and N_m are the volumetric and mechanical efficiencies respectively. The maximum level of severity occurs when $S = 1$ with no fault condition being $S = 0$. Therefore, the interval of degradation for each component on the testbed is $0 \leq S \leq 1$ (see Figure 3).

$$flow = C_v f(V_0)\sqrt{\frac{\Delta P}{SG}} \quad (1)$$

$$S(0,1) = 1 - f(V_0) \quad (2)$$

$$S(0,1) = f(V_0) \quad (3)$$

$$S(0,1) = 1 - (N_m N_v) \quad (4)$$

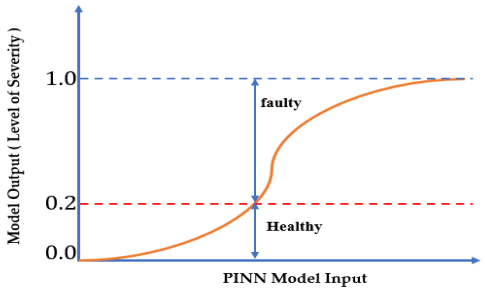

Figure 3. Change in component degradation severity level.

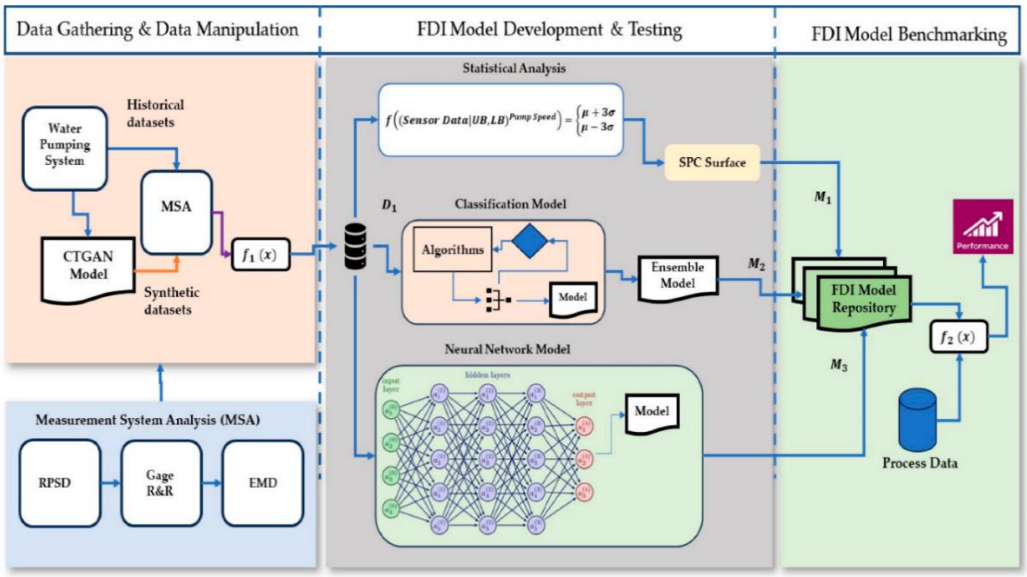

Figure 4. Proposed process for benchmarking the FDI algorithms (Barimah et. al 2023).

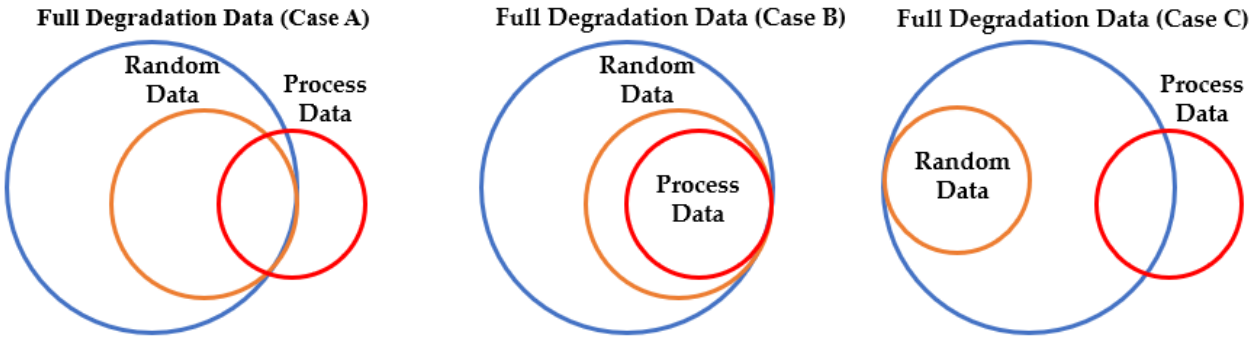

Figure 5. Random sampling of full degradation dataset for FDI model training.

Equations (2), (3) & (4) are used as physical constraints in constructing the loss function in the training process for the physics-informed neural network (PINN). Equation 2 is used for the filter, valve and nozzle all of which degrade via the gradual closing of DPV 1, DPV 3 and DPV 4 respectively. Since the gradual opening in DPV 5 represents a leakage in the main line, Eq. 3 is used to determine the extent of valve opening which represents the level of severity in the pipe. Equation (4) which represents the drop in gear pump volumetric efficiency when DPV 2 is opened is used in developing the loss function for the PINN model for the pump. The PINN model architecture used consists of a fully connected feedforward neural network with a Leaky version of the rectified linear unit (LeakyReLU) activation function to prevent any potential dying ReLU problem during the training process. The network has 1 input and output node, 3 hidden layers with 100 neurons in each layer. The Nadam optimizer is used for its good coverage and faster training time (Bera & Shrivastava, 2020). A Mean Squared Error (MSE) Loss function of the PINN model $L(\theta)$ used is shown below where λ is a hyperparameter manually set to 1. Figure 6 below shows the PINN model architecture for each component on the testbed. The total loss for the PINN model which consists of the data and physics loss is shown in Equation (5). Table 3 also shows the various parameters used for the PINN model and the associated loss functions in Eqs. (6), (7) & (8) where $\beta = \frac{flow \times \sqrt{SG}}{c_v}$ and N_m are treated as trainable parameters in the training process.

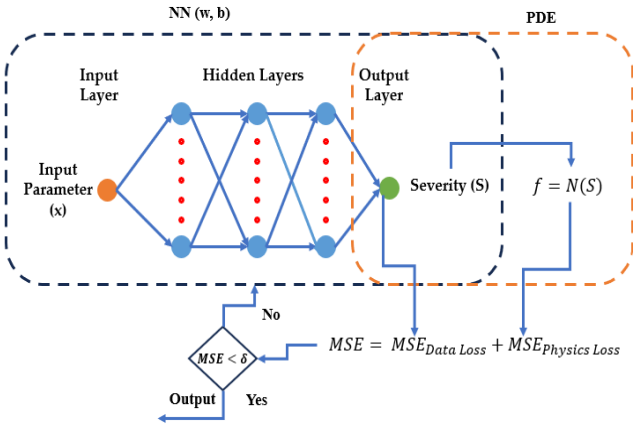

Figure 6. PINN Model Architecture for each component

$$Total\ Loss = (\lambda \times Data\ Loss) + Physics\ Loss \quad (5)$$

$$L_1(\theta) = \frac{\lambda}{N_b}\sum_{i=1}^{N_b}(S_{PINN}(x_i,\theta) - S_{obs}(x_i))^2 + \frac{1}{N_p}\sum_{j=1}^{N_p}\left(\left[V_0 - 1 + \left[\beta/\sqrt{\Delta P}\right]\right]S_{PINN}(x_j,\theta)\right)^2 \quad (6)$$

$$L_2(\theta) = \frac{\lambda}{N_b}\sum_{i=1}^{N_b}(S_{PINN}(x_i,\theta) - S_{obs}(x_i))^2 + \frac{1}{N_p}\sum_{j=1}^{N_p}\left([V_0 - 1 + N_m.N_v]S_{PINN}(x_j,\theta)\right)^2 \quad (7)$$

$$L_3(\theta) = \frac{\lambda}{N_b}\sum_{i=1}^{N_b}(S_{PINN}(x_i,\theta) - S_{obs}(x_i))^2 + \frac{1}{N_p}\sum_{j=1}^{N_p}\left(\left[V_0 - \left[\beta/\sqrt{\Delta P}\right]\right]S_{PINN}(x_j,\theta)\right)^2 \quad (8)$$

Table 3. Parameters used for the construction of the PINN Model

Component	Learning Rate	λ	Input	Output	$L(\theta)$
Filter	1e-3	1	$\Delta P = \lvert P_2 - P_1 \rvert$	$S(0,1)$	$L_1(\theta)$
Valve	1e-3	1	$\Delta P = \lvert P_3 - P_4 \rvert$	$S(0,1)$	$L_1(\theta)$
Nozzle	1e-3	1	$\Delta P = \lvert P_5 - P_4 \rvert$	$S(0,1)$	$L_1(\theta)$
Pump	1e-3	1	N_v	$S(0,1)$	$L_2(\theta)$
Pipe	1e-3	1	$\Delta P = \lvert P_5 - P_4 \rvert$	$S(0,1)$	$L_3(\theta)$

3.3.2. Approximation Model

A heuristic model $S(0,1) = 1 - x_{O.C}$ is used to approximate the level of severity of both blockages and leakages (see Eqs. 10 & 11) in the system with a domain of [0,1]. The variable x is the feature of the component which is sensitive to a change in degradation levels and it is defined as $x_{O.C}$ (see Eq. 9) with a domain of $x_{O.C}[0,1]$. The operating condition in this case is the speed of the pump.

$$x_{O.C} = \frac{Feature_{Operating\ Condition}}{Feature_{Healthy\ Condition}} \quad (9)$$

$$x_{O.C}(Blockage) = \frac{\left(Downstream\ Pressure/Upstream\ Pressure\right)_{Operating\ Condition}}{\left(Downstream\ Pressure/Upstream\ Pressure\right)_{Healthy\ Condition}} \quad (10)$$

$$x_{O.C}(Leakage) = \frac{\lvert Downstream\ Pressure - Upstream\ Pressure\rvert_{Operating\ Condition}}{\lvert Downstream\ Pressure - Upstream\ Pressure\rvert_{Healthy\ Condition}} \quad (11)$$

3.3.3. Recurrent Neural Network (RNN) Model

An FDI classifier based on a neural network architecture in a previous publication Barimah et. al (2023) which uses a recurrent neural network (RNN) architecture is used in this report. The RNN model comprises a single hidden layer with 150 neurons followed by a dense layer and a sigmoid activation function (see Figure 7 below). The model is compiled with binary cross-entropy loss and the Nadam optimizer. Early stopping is then employed to prevent overfitting during the training of the model.

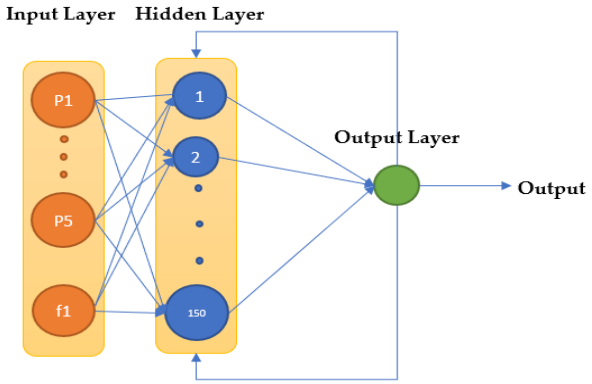

Figure 7. Recurrent Neural Network Architecture (Barimah et. al 2023)

3.3.4. PINN enabled Hybrid FDI Model

The physics-informed Neural Network (PINN) enabled hybrid FDI algorithm shown in Figure 8 is a weighted ensemble of the outputs of the RNN model, approximation model and PINN model. The weights of the model are skewed more towards the PINN model due to the limitations of purely data-driven model in the face of limited training data and its ability to generalize outside its training distribution. This PINN enabled hybrid model is then benchmarked against the other FDI algorithms, presented in Figure 4, for the system undergoing multi-component degradation scenarios. The model weights (W_D, W_P, W_A) for each component in the hybrid ensemble model are shown in Appendix B.

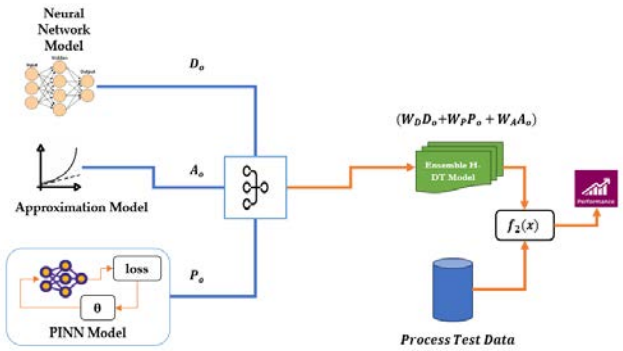

Figure 8. Ensemble Hybrid Framework for FDI models

3.3.5. Test Degradation Scenarios

Benchmarking is done using a series of test datasets recorded by Barimah et. al (2023) to assess the performance of FDI algorithms in the context of multi-component degradation. Table 3 below describes the nature of the test data with the components under consideration for the multi-component degradation scenarios, at different pump speeds, as well as their specific levels of severity.

Table 3. Test Degradation scenarios for FDI Model Testing

Dataset	Degradation (Component 1)	Degradation (Component 2)	Operational Speed Range (RPM)
T13	Pump (Medium-severity) at 45% DPV2 opening	Constant degradation of Nozzle: 30-70% DPV1 opening	700
T14	Pump (Medium-severity) at 45% DPV2 opening	Constant degradation of Nozzle: 30-70% DPV4 opening	950
T15	Filter (High severity) at 32% DPV1 opening	N/A	700 to 950
T16	Pump (Medium-severity) at 50% DPV2 opening	Nozzle (Medium-severity) at 40% DPV4 opening	700 to 950
T17	Constant degradation of Pump: 0-100% DPV2 opening	Constant degradation of Pipe: 0-100% DPV5 opening	800
T18	Intermittent faults for the pump between 45%-60% DPV2 opening	N/A	850
T19	Constant degradation of Pump: 0-100% DPV2 opening	Constant degradation of Valve: 30-70% DPV3 opening	850
T20	Pump (Medium-severity) at 55% DPV2 opening	Nozzle (High severity) at 30% DPV4 opening	700 to 950

4. RESULTS

4.1. Healthy Condition (HC) Scenario

The FDI algorithms showed very good performance in determining the healthy condition scenario in a situation where no fault had been injected into the system. Figure 9 shows the performance of all the FDI models in a healthy condition scenario with the pump speed at 700rpm and at 950 (see Appendix B). However, the performance of some of the models for components in a healthy state deteriorates once failure is introduced into the system. The performance of the FDI algorithms in faulty condition scenarios are presented in sections 4.2 to 4.4 showing the prediction of the conditions of various components on the testbed for the test scenarios.

4.2. Statistical Process Control (SPC)

The statistical process control (SPC) which relies on deviation from the mean of a process variable generally showed poor performance in the detection of the test MCD scenarios for components where faults were injected. For the test degradation scenario T13 which is has a leakage in the pump at DPV 2 of 45% opening and the gradual closure of DPV 4 which represents nozzle from 70% to 30%, the SPC model resulted in a 0.42 and 0.61 model performance for the pump and nozzle respectively (see Figure 9). In the case of T14 which has the same components under consideration but at a higher pump speed of 950rpm, the SPC showed an even poorer performance than in the case of T13 with 0.22 and 0.55 for the pump and nozzle respectively. However, for the components which had no failure injection, the SPC had a performance of 1.0 for the components not undergoing any form of degradation. This pattern of poor performance for components undergoing MCD scenarios and healthy components is seen in the rest of the test degradation scenarios T15, T16, T17, T18, T19 & T20 (see Appendix A).

4.3. Ensemble (Classifiers) and Recurrent Neural Network (RNN)

The ensemble classifier which uses the weighted outputs from logistic regression, support vector machine and decision tree classifier models also showed poor performance particularly for components not undergoing any form of degradation. This was revealed in T13 where it had a prediction performance of 0.42 for the pipe even though the pipe had no leak. This is also identified in T14 where the

model performance was 0.23 and 0.22 for the filter and pipe respectively. For components undergoing MCD scenarios the model showed some good performance for components (see Figure 10 &11). The recurrent neural network (RNN) also showed a similar pattern of prediction to the SPC model albeit slightly better than the former. The performance of the RNN model of the nozzle deteriorates from 0.81 for T13 (700rpm) to 0.45 for T14 (950rpm). This drop in performance is also seen in the pump where the performance reduces from 0.42 to 0.22. For the test degradation scenarios T15, T16, T17, T18, T19 & T20 (see Appendix), the RNN model showed very good prediction for the components not undergoing degradation. Nonetheless, for the components undergoing the MCD scenarios, the RNN model showed mixed model prediction performance.

4.4. PINN enabled Hybrid FDI Model

The performance of the PINN enabled hybrid FDI model on the test degradation scenarios in Table 3 above showed improved performance compared to the other algorithms in the context of the MCD scenarios. Although the PINN model performs better than the other FDI models in the hybrid model, it sometimes underperforms as seen in T17 (see Appendix A4) where the weighted ensemble hybrid model compensates for the limitations in the PINN model in predicting the degradation of the leak in the pipe due to the impact of the other models in the hybrid model. For all the test degradation scenarios, the hybrid approach showed a much better performance as seen in Figures 10 & 11 as well as for test scenarios T15, T16, T17, T18, T19 & T20 (see Appendix A).

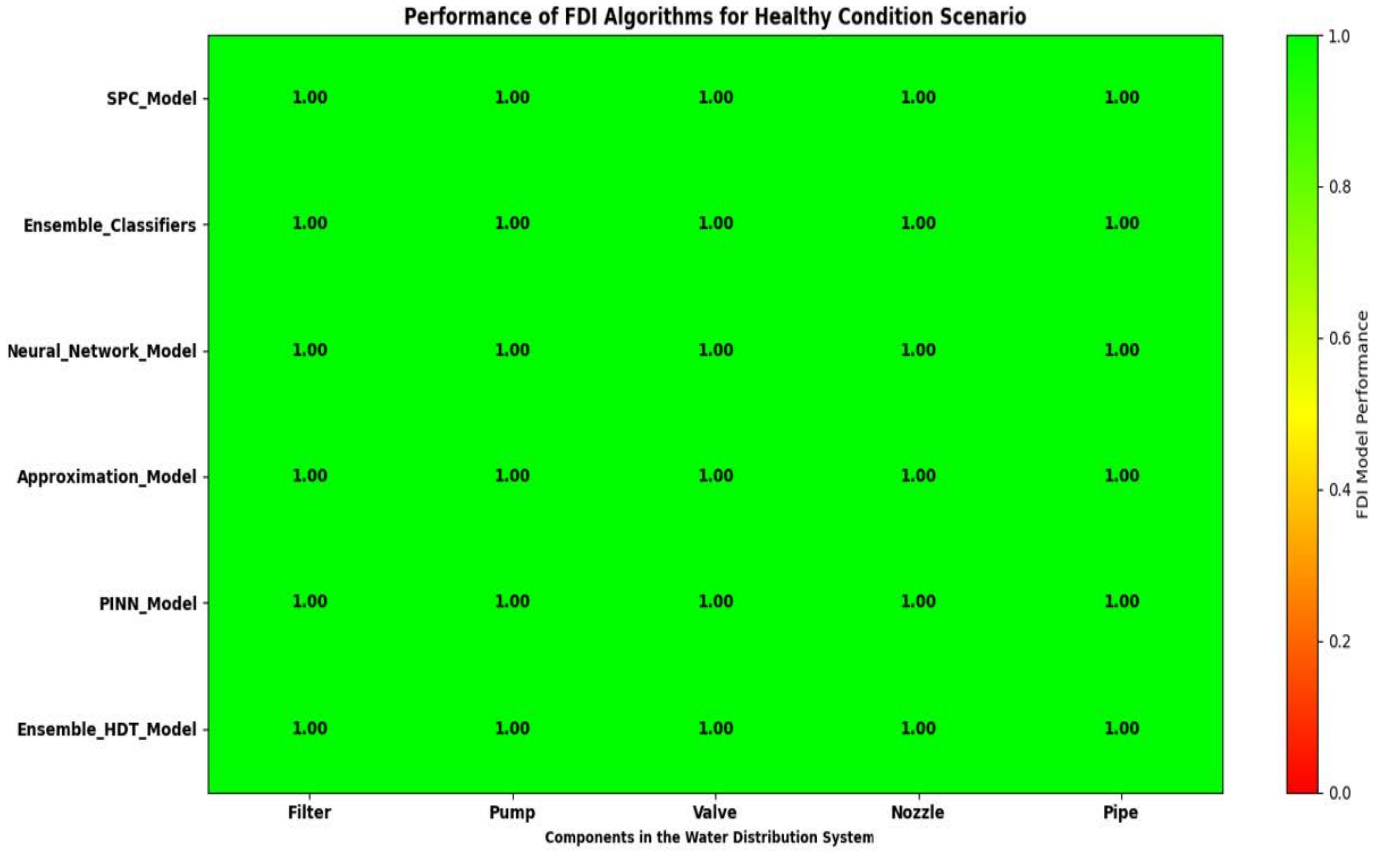

Figure 9. Performance of FDI algorithms for a Healthy Condition scenario at a pump speed of 700rpm.

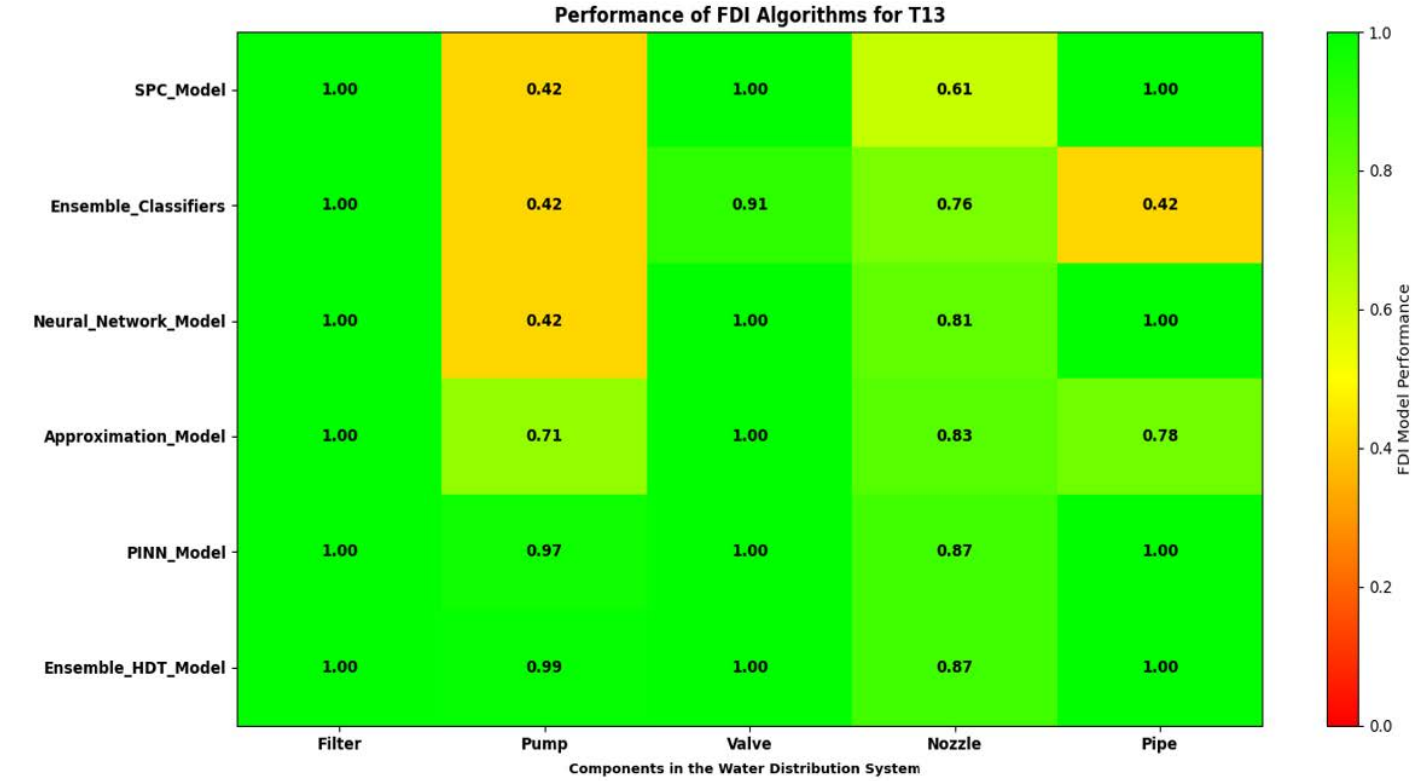

Figure 10. Performance of FDI algorithms on Test Degradation Scenario T13

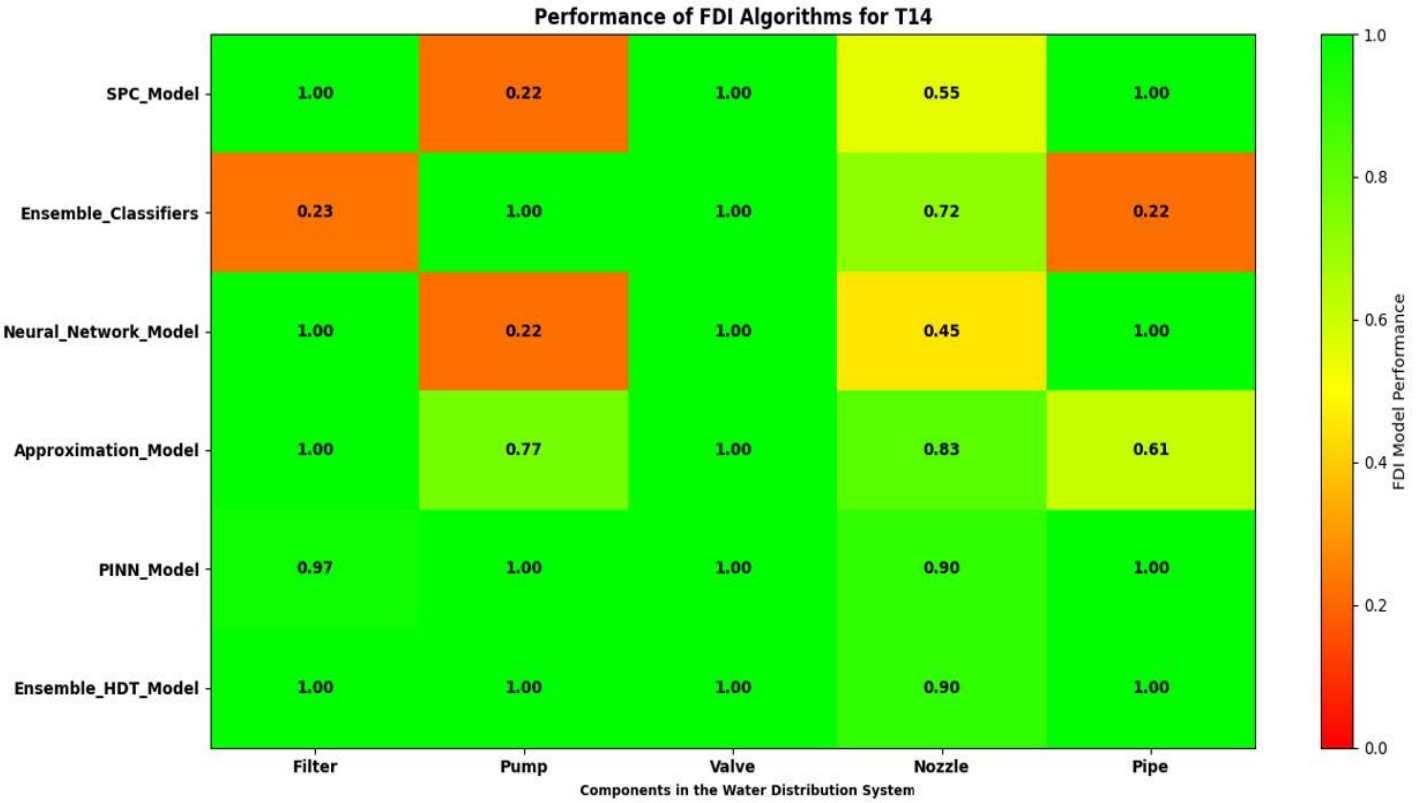

Figure 11. Performance of FDI algorithms on Test Degradation Scenario T14

5. DISCUSSION

For stakeholders in industry, training Fault Detection and Isolation models for PHM applications is key to optimizing asset health and logistics management. The challenge in model development as alluded to above is the availability of degradation data. The limited data available for training the FDI models presents a challenge in detecting MCD scenarios as seen in the results section above. The performance of the deep learning model for the test degradation scenarios showed the limitation in developing data-driven models on limited training data. This is seen in prediction of the state of the pump and nozzle in T13 & T17 as compared to the approximation and PINN models. However, it performs well when the training distribution of the available limited degradation data fall within the test degradation data scenario. This presents a challenge for stakeholders who have training data outside the distribution of the real time data from their assets. The ensemble hybrid approach proposed in Figure 8 compensates for this shortfall by integrating a heuristic approximation and a PINN approach with a neural network model to improve the overall model diagnostic performance. The main contributing parameters to the ensemble performance are the weights which were assigned using domain knowledge on the performance of the individual models with limited degradation data. This presents an interesting research opportunity for dynamically optimizing the weights in the ensemble hybrid model. The hybrid model also reduces the computational requirements for training the FDI models which ultimately reduces the cost for FDI model development for PHM applications.

6. CONCLUSIONS AND FUTURE WORK

In conclusion, this study highlights the capabilities of physics enabled fault detection and isolation algorithms for PHM diagnostics, emphasizing the challenges associated with limited training data and generalization issues. The proposed PINN-enabled hybrid model demonstrates promising FDI predictive capability for MCD diagnostics despite limited training data, indicating its potential for addressing the identification of multiple degraded conditions occurring simultaneously in a complex system. The contributions of the paper are:

C1. This study contributes to the application of physics informed FDI models for PHM applications in MCD scenarios, ultimately reducing model training data requirements for asset health management.

C2. The paper also presents an ensemble FDI approach with the capability of addressing the limitations of integrating both data-driven and physics based FDI models in multi-component degradation scenarios which can also be used in the analytics that drive digital twin applications.

Future research would focus on dynamically optimizing ensemble hybrid model weights, leveraging prediction uncertainty to further enhance model performance.

BIOGRAPHIES

Atuahene Barimah is an Operations Assistant at Wellscope Energy Solutions and is currently a PhD researcher at Glasgow Caledonian University where he received his MSc. in Applied Instrumentation and Control at in 2020. He also received his BSc in Petroleum Engineering at the Kwame Nkrumah University of Science and Technology in 2017. His research interests include data-driven maintenance, system reliability, process control, project management, operations research, digital twin design, IIoT, and computational finance.

Octavian Niculita is a Senior Lecturer in Instrumentation with Glasgow Caledonian University. He has a PhD in Industrial Engineering from the Technical University of Iasi, Romania carried out under the EDSVS framework. His current research interests include industrial digitalization, predictive maintenance, PHM system design, integration of PHM and asset design for aerospace, maritime, and oil & gas (surface and subsea) applications. Octav has over ten years of experience in design and development of prognostics and health management applications, having worked on applied aerospace projects funded by The Boeing Company and BAE Systems as a Research Fellow and Technical Lead on his previous appointment with the IVHM Centre at Cranfield University, UK. He is a member of the Prognostics and Health Management Society, InstMC and the IET.

Don McGlinchey graduated from Strathclyde University with a BSc (Hons) Physics before working as a project engineer at Babcock Energy Ltd. He returned to academia and gained an MSc in Bulk Solids Handling Technology and his Doctorate on a study of the effect of vibration on powder beds. He is currently a Professor in the Department of Engineering at Glasgow Caledonian University where he is the academic leader in teaching, research, and consultancy in the area of multi-phase flow. He has edited two books, and authored over 100 papers, articles, and consultancy reports.

Andrew Cowell is the Chair of the Department of Engineering Industrial Advisory Group at Glasgow Caledonian University. In addition to his short-term contracts in research into coal handling for entrained flow gasifiers, and particulate solids handling education materials, Andrew has undertaken consultancy projects in the United Kingdom (UK), and delivered short courses in the USA, Sweden and the UK. He has also presented at international academic conferences in the UK, Australia, Norway and Spain. He is a Chartered Engineer, a Member of the IMechE and Fellow of the Institution of Engineers and Shipbuilders in Scotland.

Billy Milligan is the Director of Instrumentation and Control at Chart Industries. He has worked primarily on the design, testing and commissioning of screw compressor control systems within the oil and gas industry for the past 15 years. He is a member of the InstMC and the IET.

ABSTRACT

Transfer learning is a method that transfers knowledge learned from a source domain to a similar target domain to improve learning. In power plants, obtaining sufficient anomaly data is difficult due to the characteristics of the systems. Transfer learning enables learning with only a small amount of data from the target domain by using a model trained in a similar domain. By applying transfer learning, models developed for one power plant can be expanded and used in other power plants where available data are limited.

Using actual data from an operating combined-cycle power plant, an anomaly diagnosis model was developed and tested. Its applicability to different operating conditions and anomaly cases was evaluated through transfer learning. The fine-tuned pre-trained model was effectively adapted with limited target domain data. Transfer learning was applied despite the limitations of data and distribution differences. The expandability of anomaly diagnosis models to different power plant systems was demonstrated by applying transfer learning.

1. INTRODUCTION

The limited anomalous data and labels in power plants are challenges for training anomaly diagnosis models. Due to the requirements for safety and operational stability, inducing failures or obtaining sufficient anomalous data is difficult in power plants (Qian & Liu, 2023). Variations in operating conditions also complicate model training by changing the distribution of data. The operating conditions of power plants change with variations in power demand over time and external factors such as temperature and humidity (Bai, Yang, Liu, Liu, & Yu, 2021). In actual operating power plants, it is difficult to obtain data while operating under the same conditions consistently, as power demands and external factors vary. Differences in operating conditions disrupt the assumption of consistent data distribution between training and testing sets in anomaly diagnosis models (Li, Lin, Li, & Wang, 2022; Zhou, Lei, Zio, Wen, Liu, Su, & Chen, 2023).

Developing diagnosis models for a new power plant system incurs additional costs, even after significant investments have been made to overcome challenges and develop the models. This is because the distribution of data collected varies due to differences in the structure and sensors of the systems in each new power plant. Each new power plant requires a customized approach to model development, involving the redesign of diagnosis models to fit the specific data characteristics of that plant. To develop models for other new power plants, the process should start anew with data collection. Training and validating models with the collected data are essential steps in developing the new model. This process again incurs significant time and costs.

The fact that power plants of the same type share a common domain can be utilized. When applying models to new power plants, it is typically necessary to redesign them due to differences in data distribution. Since the power plants operate on similar principles within the common domain, this can enable the expansion of existing models without a complete redesign. This approach utilizes the commonalities from the same types of plants, reducing development time and costs.

By applying transfer learning, a developed model can be expanded and adaptively used for a new power plant within a similar domain. Transfer learning is a method that transfers knowledge learned from a source domain to a target domain with insufficient data for a similar task (Pan & Yang, 2009). The transfer learning method involves fine-tuning model parameters pre-learned from the source domain using limited data from the target domain. With transfer learning, a model developed in the source domain can be adapted to a new system in the target domain, instead of restarting the entire process. Additionally, it can be applied to the target domain using only a small amount of data, serving as an approach to overcome the challenges of limited data and labels. By

applying transfer learning and using the model adaptively, the expandability and practicality of the diagnosis model can be enhanced.

In this paper, an anomaly diagnosis model was developed using data collected from the actual gas turbine of an operating combined-cycle power plant. The developed diagnosis model was tested by applying transfer learning to data with different anomaly features and operating conditions than the training data. Collected data have an emergency shutdown called a "trip", that occurs in the case of anomalies to prevent serious accidents. Cases, where actual data are collected under different operating conditions, have similar situations with other power plants data that have different data distributions. By fine-tuning with limited data from the target domain, this study demonstrated the potential to expand a developed model to different power plant systems. Comparative analysis was conducted by applying transfer learning, even in situations of data imbalance where little anomaly data is available in the target domain.

Section 2 introduces the related works that developed a diagnosis model for the power plant and applied transfer learning to the model. Section 3 describes the data, model, and transfer learning methods used in this study. Section 4 presents the results, Section 5 discusses these results, and Section 6 presents the conclusions and future work.

2. RELATED WORKS

Related studies on anomaly diagnosis in power plants have been conducted across various subjects and domains. Diagnosis using the Gaussian Process (GP) algorithm and model ensemble techniques were conducted at an actual coal-fired thermal power plant (Zhang, Dong, Kong, & Meng, 2019). They identified relationships between variables to reflect temporal dependencies and cross-variable associations, using combinational data relationships to develop the diagnosis model. Lee et al. (2021) collected data from a full-scope simulator for abnormality diagnosis in a nuclear power plant and developed a Convolutional Neural Network (CNN) algorithm model. To manage the 1004 sensor variable data, they converted it into two-channel 2D images with a data size of 32*32.

As mentioned in the introduction, power plants have challenges due to the limited anomaly data and differences in operating conditions. To address these challenges, transfer learning methods have actively been researched for diagnosing power plants. Studies have been conducted to apply transfer learning for fault diagnosis at different power levels in nuclear power plants. Data were collected at several power levels using a simulator, and a CNN algorithm was developed to handle numerous sensor variables. Maximum Mean Discrepancy (MMD) was used to develop the model to adapt to differences in distributions when power levels vary. With these approaches, Li et al. (2022) divided domains based on power levels and applied transfer learning across different power levels. They also analyzed the effects of various kernel functions used to calculate MMD. Wang et al. (2022) utilized Transfer Local MMD (TLMMD) combined with the ResNet-18 algorithm to develop a diagnosis model. Li, Lin, Li, and Wang, (2022) applied transfer learning to construct models for each power level. They proposed a framework that determines the current power level during actual operation and matches data to the model trained at each power level.

The CNN algorithm and transfer learning were also applied for fault detection in the gas turbine combustion chambers of power plant systems (Bai et al., 2021). Exhaust Gas Temperature (EGT) data collected from two gas turbines were used. The turbine with more data was used as the source domain for training, and transfer learning was then applied to the other turbine, which had limited data. The performance of the transfer learning approach was evaluated and compared with various other diagnosis methods.

3. APPROACH

A diagnosis model was developed for the gas turbine of an operating combined-cycle power plant. Training and testing were conducted using data from collected anomaly cases, and transfer learning was applied. The model's performance was evaluated, observing changes in performance based on the data used for training and the application of transfer learning.

3.1. Data

The operating data were collected from sensors related to the gas turbine equipment of a combined-cycle power plant A, located in region B of Korea. The power plant data were provided by KEPRI (Korea Electric Power Corporation Research Institute). A total of eight anomaly cases related to trips were detected. Data for each case were collected on the dates when the anomaly occurred for four years. Each case has different operating conditions, resulting in different characteristics.

Table 1. Collection of Data.

Collection period	4 years	
Number of sensors	118	
Number of Cases	8	
Data instance per cases	Total	256
	Normal	128
	Anomaly	128

Data were collected from 118 sensors of the plant's gas turbine system. Sensors collected data on flow rate, pressure, and temperature, such as EGT. Each sensor was related to the control and flow of fuel gas in the gas turbine.

Within each of the eight anomaly cases, there are 128 instances of both normal and anomaly data, labeled by

domain experts based on the investigation reports conducted for each case. The data format consists of 60-minute windows for the 118 collected sensor data points.

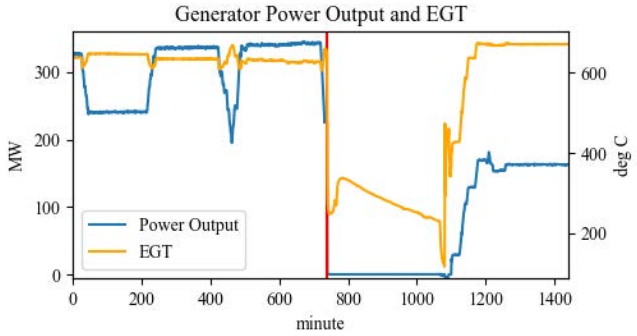

Figure 1. Example of collected data with a trip.

To utilize the overall 118 sensor data, the collected time series data can be concatenated in parallel to form a two-dimensional matrix. Each row is composed of a time series, and the patterns of the sensors contain information about anomalies. The data from 118 sensors have variations in units and ranges of values, depending on their measurement targets. To address this, min-max normalization was applied to each sensor. The matrix collected from 118 sensors over a 60-minute window is represented as an image as follows.

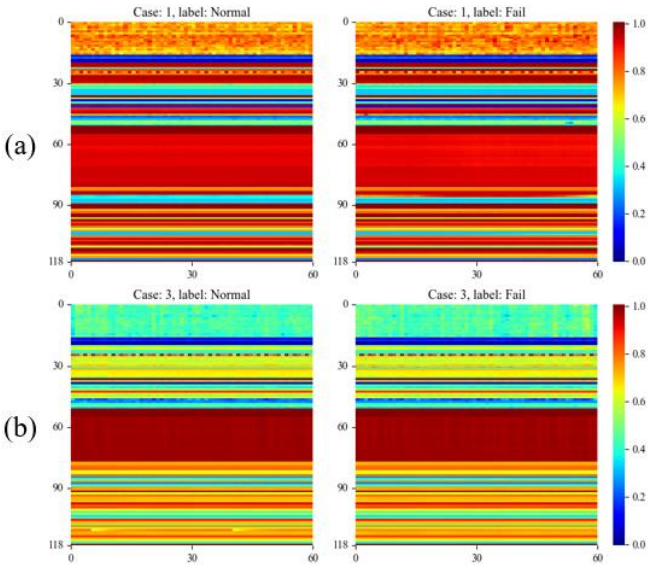

Figure 2. Example image of data. (a) Case 1, (b) Case 3.

3.2. Transfer Learning

Transfer learning was applied by taking a model trained in the source domain and fine-tuning it with a limited dataset from the target domain, with some weights of the convolutional layer fixed. The model was constructed using a Convolutional Neural Network (CNN) architecture, with 1D kernels utilized to detect patterns in the data from 118 sensors over a 60-minute window. The model's structure includes convolutional layers, max-pooling layers, batch-normalization layers, and fully connected layers. It is designed to learn features from the data and perform classification.

In the CNN model, the initial convolutional layers extract general features, while the fully connected layers extract specific features (Zhu, Peng, Chen, & Gao, 2019). This characteristic enables the use of general features validated in the source domain while adapting specific features for classification in the target domain when applying transfer learning. The model was trained using all available data in the source domain, and fine-tuning was conducted with only 60 data instances from the target domain.

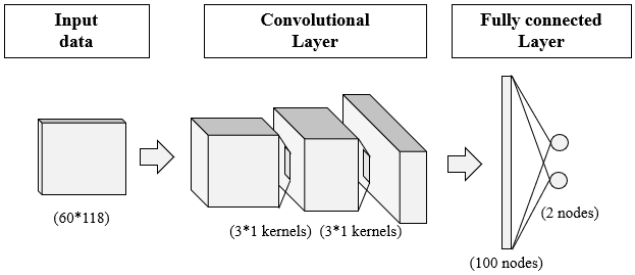

Figure 3. Outline for Structure of CNN model

3.3. Evaluation

Eight cases were used as different source domains, with each dataset being used to train a CNN model individually. Each trained source case model was evaluated using the validation data from that case and tested using the remaining seven cases as test data. Thus, there are eight evaluation results for one case model and a total of 64 results for all eight cases. The average of the calculated performance metrics was used to evaluate how each method applies. This average performance metric was compared based on the application of transfer learning and depending on the case used for training.

The performance metric used is the Matthews Correlation Coefficient (MCC), which represents performance through the correlation between actual and predicted labels, among metrics for binary classification (Chicco, Tötsch, & Jurman, 2021). MCC values range from [-1, 1], as it is a correlation coefficient. Accuracy, the commonly used performance metric, cannot represent cases of class imbalance and cases where predictions are made with only one label. The MCC metric can effectively show the relationship between actual and predicted labels. It is considered to perform well even in cases of class imbalance, indicating a value of 0 when predictions are made with only one label.

4. Result

The comparison of the average MCC for the three cases is shown in the figure below. CNN models were trained using data from eight different anomaly cases. The models for each

case were trained and validated in an 8:2 ratio, and data from different cases, which were not used in training, were utilized for testing.

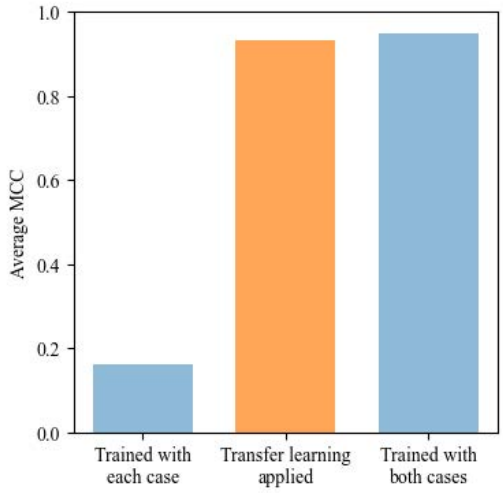

Figure 4. Comparison of the average MCC

The performance of the model significantly improved when transfer learning was applied, compared to using data from only one case. Additionally, although the best performance was in the case that used data from both domains, the performance with transfer learning exhibited similar levels of effectiveness.

Each anomaly case has different operating conditions and anomalies. While the models exhibit high performance in validation for each specific case, most exhibit low MCC scores when applied to other cases. Most test cases with low MCC scores are cases where predictions are made with only one label, either normal or anomaly. Figure 4 shows that the diagnosis models are well-trained for each specific case. Additionally, it indicates that the models cannot predict accurately in tests for other anomaly cases due to different operating conditions and anomalies.

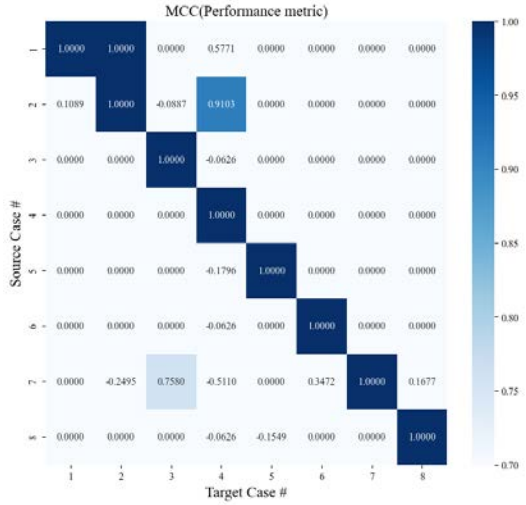

Figure 5. Performance of models trained with each case.

The performance of each case was evaluated by applying transfer learning. To evaluate the effectiveness of transfer learning, a comparison was made between models that applied transfer learning and those that used all the data from both the source and target domains without transfer learning. Initially, each case was fine-tuned with limited data from the target domain, based on the model trained in the source domain. The performance metrics were evaluated using test data that were not used in the fine-tuning of the target domain. Transfer learning was applied as described in Section 3.2.

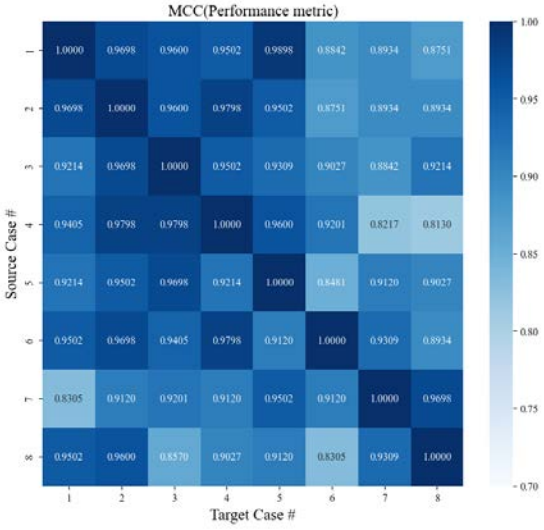

Figure 6. Performance of models applied transfer learning.

For comparison, a scenario was assumed in which data were collected and available from both domains. The model was trained using all the data from both the source and target domains without the use of transfer learning. The results are as follows.

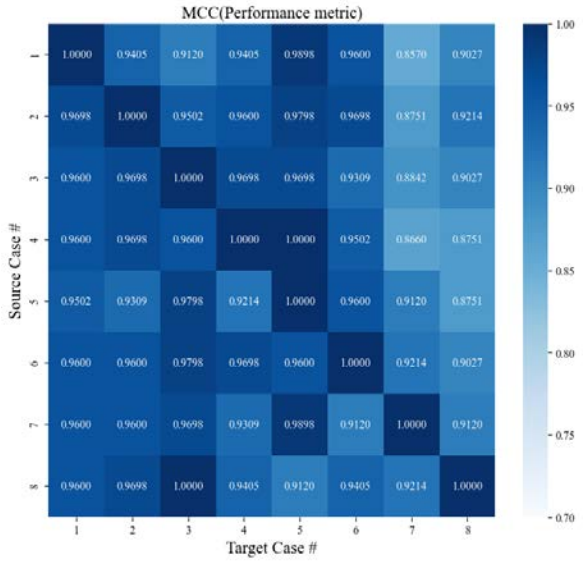

Figure 7. Performance of models trained with both domains.

When trained using data from both domains, the data for training and validation was the same as when only one domain was trained and validated, but the trained model was not completely accurate. This is because each domain has different operating conditions, making it challenging to treat and learn from them as a single domain.

It can be observed that diagnoses performed with transfer learning are effective. The difference in the effectiveness is due to the different distributions of data from each anomaly case under different operating conditions. When using models trained with a single case, the features identified during training differ from those in the test, leading to poor performance of the model. In contrast, the application of transfer learning has shown that fine-tuning the model with a limited amount of data can enhance performance. When compared to cases where data from both the source and target domains are available, similar performance metrics were observed. This indicates the effectiveness of transfer learning in cases with different data distributions. When expanding the model to different new power plant systems, data newly collected under different operating conditions or anomaly cases differ from the previously trained data. Previous results demonstrate the expandability of the diagnosis model through transfer learning, which has been effective despite these differences.

5. DISCUSSION

In real-world situations, collecting anomaly data is more challenging compared to normal data, resulting in a data imbalance. Additional analysis was conducted to monitor changes in the training models by applying transfer learning. A sensitivity analysis was performed on the ratio of normal to anomaly data used in fine-tuning the target domain. To address this, the performance of transfer learning was evaluated by gradually increasing the proportion of normal data. Figure 8 shows the results of the average MCC according to the ratio of normal to anomaly data used in fine-tuning. The results indicate a significant decrease in performance when no anomaly data were included.

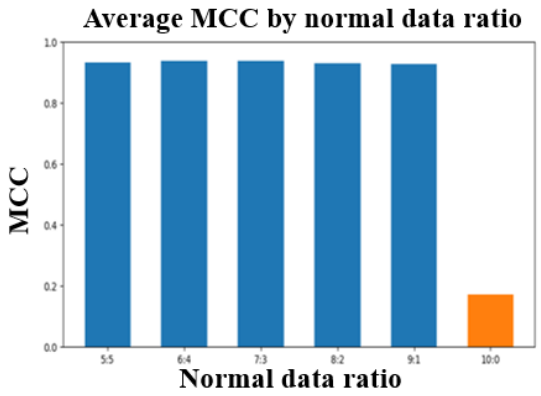

Figure 8. Average MCC according to the ratio of normal to anomaly data.

Using transfer learning, the ratio of normal to anomaly data used for fine-tuning was changed to analyze factors that influence its effectiveness. It was observed that even a small amount of anomaly data could yield good results when the overall proportion of anomaly data was reduced. In real-world application scenarios, normal data is generally more prevalent. The model could identify anomalies well even in imbalanced situations where the ratio of anomaly data was 9 to 1. However, the performance significantly decreased when there was no anomaly data at all. This decrease occurs because fine-tuning without any information about anomalies makes it difficult to adaptively use the identified anomaly features through transfer learning.

6. CONCLUSION AND FUTURE WORK

In this study, an anomaly diagnosis model was developed using data from an actual combined-cycle power plant. Diagnosis models were developed for each case, and it was observed that the operating conditions and anomaly features varied according to each case. To use the diagnosis models adaptively, transfer learning was applied to fine-tune the models and evaluate their performance. Using transfer learning, the ratio of normal to anomaly data used in the fine-tuning of the target domain was varied to analyze changes in performance. This process demonstrated that transfer learning could be effectively applied even in imbalanced situations with a predominance of normal data, and it also highlighted the importance of collecting anomaly data.

Next, Research could be conducted to validate the expandability of the model through transfer learning using data collected from different new power plants. Research could be conducted on applying the model in real-time

scenarios at actual power plants using transfer learning. In actual power plant operations, the occurrence of an anomaly is already critical. There is a need for an approach that allows for fine-tuning without information about anomalies and adaptively uses the model under different operating conditions. Additionally, considering that data are collected in a sequential time series, there is a need for a transfer learning framework that fine-tunes the model using only initial data and adaptively detects anomalies.

ABSTRACT

Machine learning-based condition monitoring of mechanical systems, such as bearings, employs two primary approaches: unsupervised and supervised methods. Unsupervised approaches aim to characterize the healthy state of the machine and monitor deviations from this state. The advantage lies in requiring only the health condition of the component without the need for historical data until breakdown. However, the disadvantage is the lack of information regarding the root cause of any potential malfunction. On the other hand, supervised methods consider both healthy and faulty cases, aiming to maximize the difference between them through post-processing, as well as among different fault types. The advantage is the ability to analyze the specific signature of a particular fault type. Nonetheless, the disadvantage is that available data usually do not cover all possible faults that may occur. Typically, obtaining a faulty bearing involves either a time-consuming run-to-failure test or the artificial induction of faults using drills, electro-discharge pens, etc. While artificial faults offer a quicker procedure, they often fail to replicate real faults faithfully. This paper suggests using picosecond laser technology to engrave the surface of the bearing and create artificial faults. Modern laser technology allows for precise control over the dimensions of injected faults, enhancing the understanding of fault progression at various stages in the life of bearings. These measurements are crucial parameters for evaluating the robustness of diagnostic algorithms. This paper focuses on artificially damaging a ball bearing used in an independent cart systems application, which comprises a fleet of linear motors moving on the same rail. These systems have recently been proposed by different manufacturers and adopted in the field of packaging machines for their flexibility. For such systems, no prior instances of faulted bearings are available, and the size of a real fault is also unknown. Hand-made faults with drills did not produce discernible faults appreciable in post-processing of the data. Therefore, a picosecond laser with a pulse duration of 10 ps and a maximum energy per pulse of approximately 100 μJ is utilized to create a set of test bearings with increasing fault sizes on the outer race. Post-processing of the data enables the qualification of the minimum fault severity detectable in this specific application.

1. INTRODUCTION

The emerging technology of independent cart systems comprises a fleet of linear motors that operate on a shared track and can be controlled individually and independently. Unlike conventional motors, where the stator and rotor are enclosed within the same frame, linear motors feature a completely detached rotor. In this design, the fixed frame of the motor serves as the stator, with coils evenly distributed along the track, while the single cart functions as the movable part, containing permanent magnets positioned above the coils, along with a set of bearings. The cart, while crucial, is a completely passive component of the system. It interact with the changing magnetic field of the motor coils, moving in synchronization with the magnetic field pattern.

Independent cart systems stand poised to revolutionize traditional conveyor belts. Offering a range of benefits such as increased flexibility and dynamic capabilities, independent cart systems are proving to be ideal solutions for a wide range of industrial and motion control applications. Comprising modular components such as linear motors, guide rails, and control circuitry, these systems offer adaptability and efficiency. Linear motors within independent cart systems are

available in both straight and curved modules, allowing for diverse path configurations tailored to specific industrial requirements. Across industries, various iterations of independent cart systems are being deployed, each with distinct features in guide rail and cart design. Depending on application needs, guide rails may either attach directly to linear motors (Jabbar, D'Elia, & Cocconcelli, 2023; Jabbar, Cocconcelli, D'Elia, & Strozzi, 2023) or form a separate bed parallel to them (see figure 2), a brief description of such a system with parallel guide rail can also be found in (Cavalaglio Camargo Molano, Capelli, Rubini, Borghi, & Cocconcelli, 1968). Similarly, cart and bearings can take on different configurations to suit specific application requirements. For example, in a previous study (Jabbar, D'Elia, & Cocconcelli, 2023; Jabbar, Cocconcelli, et al., 2023), the authors have described setups where guide rails are directly attached to linear motors, with options for 12 or 6 bearings featuring plastic outer races. One significant advantage of independent cart systems is their ability to define the entire track in stations, enabling the accommodation of distinct speed profiles for each cart along every station.

Despite the considerable benefits that these systems offer over conventional conveyors, economic concerns remain. To date, the high cost and substantial upfront investment required for independent cart systems present challenges to their widespread adoption. To ensure economic viability, it is imperative that these systems operate flawlessly. Thus, the implementation of robust condition monitoring measures is crucial for their sustained performance. Although independent cart systems are rapidly replacing conveyor belt systems, there has been a lack of studies focused condition monitoring of such systems. Due to the confidentiality surrounding these systems, often protected by non-disclosure agreements, there is no repository or public database where vibration, acoustic, or other data related to independent cart systems is available for conducting condition monitoring. Consequently, to the best of the authors' knowledge, there has been no research conducted on condition monitoring of the independent cart systems. This scarcity of research and data necessary for condition monitoring serves as a primary motivation for this study. Furthermore, another motivation for this research stems from the inherent challenges associated with monitoring the condition of such systems.

Condition monitoring of the independent cart systems presents a formidable challenge for several reasons. Firstly, it is a highly non-synchronous system, with speed variations ranging from a few millimeters per second to several meters per second. For instance, the system under study can achieve cart's speed of up to 4 meters per second. Additionally, the system supports speed reversal, allowing for changes in direction. Furthermore, with the addition of every cart to the fleet, the number of bearings increases by three. Given that each cart contains three bearings and there are hundreds of bearings in the fleet, monitoring the condition of the independent cart systems becomes complex. This monitoring process can be divided into several steps: firstly, identifying if there is a fault; secondly, determining the type of fault (such as inner race, outer race, ball fault, etc.); thirdly, distinguishing whether the top bearing is faulty or the bottom one; and fourthly, localizing the cart carrying the faulty bearing. Understanding the behavior of the vibration signal in the case of a top bearing fault is also intriguing. This is because there is a pair of bearings with exactly the same dimensions and dynamics supporting the same movement.

There are several bearing datasets available, including the Intelligent Maintenance Systems (IMS) dataset (Lee, Qiu, Yu, & Lin, 2007), the Case Western Reserve University (CWRU) dataset (*Bearing Data Center, Case Western Reserve University (CWRU)*, n.d.), and the IEEE Dataport bearing dataset (B. Hu, 2023). These datasets serve as benchmarks for testing and evaluating new condition monitoring algorithms. However, these datasets primarily focus on conventional configurations where the bearings are fixed around a shaft. In contrast, in independent cart systems, the bearings not only rotate but also translate along the path defined by a set of linear motors. This introduces a significant departure from conventional setups. Additionally, the linear motion of the cart is often highly non-synchronous, resulting in non-synchronous rotational speeds of the bearings. Furthermore, the possibility of instant speed reversal further complicates the dynamics of the system. Given these differences, there is a clear need for new datasets specifically tailored for the condition monitoring of such industrial systems. These datasets would need to capture the unique characteristics and challenges posed by the operation of bearings within independent cart systems.

Data-driven modeling has emerged as a valuable approach that can complement traditional signal processing techniques, offering a robust methodology for uncovering insights from complex datasets. This methodology involves leveraging machine learning algorithms to discern patterns and anomalies within the data. While implementation requires expertise in both data preprocessing and machine learning, the benefits of this approach can be significant. In light of these advantages, researchers have explored the integration of machine learning algorithms for bearing fault classification, alongside classical signal processing techniques. A diverse array of algorithms has been deployed for this purpose, encompassing Long Short Term Memory (LSTM)((Walther & Fuerst, 2022), (Y. Hu et al., 2022)), Autoencoders ((K. Cheng RC.and Chen, 2022), (R.-C. Cheng, Chen, Liu, Chang, & Tsai, 2021)), Support Vector Machines (SVM) ((Sun & Liu, 2023), (Y. Fan, Zhang, Xue, Wang, & Gu, 2020)), Artificial Neural Networks (ANN), Convolutional Neural Networks (CNN), Deep Learning (DL), Transfer Learning (Wan et al., 2022), Anomaly Detection (Z. Fan et al., 2023), and the K-means clustering algorithm (Yiakopoulos, Gryllias, & Antoniadis, 2011), among others.

Although this list is not exhaustive, it underscores the breadth of approaches available for analysis. By combining these various methodologies, researchers aim to construct more precise and reliable models for machine condition monitoring. Through this integration, the potential for accurately identifying and predicting faults in machinery is significantly enhanced.

Machine learning-based condition monitoring of mechanical systems relies heavily on data. To amass a large dataset, it's essential to gather a vast array of data encompassing various degrees of faults and experimental conditions. Achieving this requires the creation of artificial faults through specific methods. Artificially injecting faults poses challenges, particularly when it comes to ensuring repeatability and control over the size of the fault. Traditional methods such as cutting tools or drill mills may lack accuracy, and be limited by the high hardness of the materials employed for bearings, in particular, when attempting to damage different parts of the bearing with varying fault sizes. Consequently, manually employing these tools often results in irregular fault sizes and dimensions. In contrast, laser injection offers a solution that provides repeatability and precise control over fault dimensions. By utilizing laser technology, faults can be consistently created even in very high strength material with accurate control over their size and shape, ensuring greater consistency and reliability in experimental conditions.

The rest of the paper is structured as follows. Section 2 provides insights into the experimental setup of the independent cart system, including the cart and bearing configuration. Following this, Section 3 elaborates on the setup involving picosecond laser technology. In Section 4, the paper delves into the specifics of the experimental campaign. Moving forward, Section 5 presents preliminary results derived from the conducted experiments. Finally, conclusions drawn from the study are discussed in Section 6.

2. Independent Cart System and Experimental Setup

The experimental setup for the independent cart system utilized in this study comprises eight straight motor modules, two curved modules, and a total of 12 carts. Each straight motor module features a 250-millimeter (mm) long stator, while the stator of the curved module measures 500 mm in length. Consequently, the combined length of the track defined by the 10 motor modules totals 3000 mm (see figure 1). With the system's capability to program each cart independently for a desired travel path, provided there are no collisions between carts, experiments were conducted with varying numbers of carts. Each cart, measuring 50 mm in length, consists of five pairs of permanent magnets and is equipped with a set of three rolling-element bearings as shown in figures 3 and 4. The two top bearings share identical geometry, with an external diameter of 25 mm, while the bottom bearing is slightly larger, with an external diameter of 35 mm. These bearings ensure secure attachment of the cart to the guide rail, which runs parallel to the linear motor modules (see figure 2). The motor modules are outfitted with coils that generate magnetic field patterns, enabling the system to achieve the desired trajectory and motion profile for each cart.

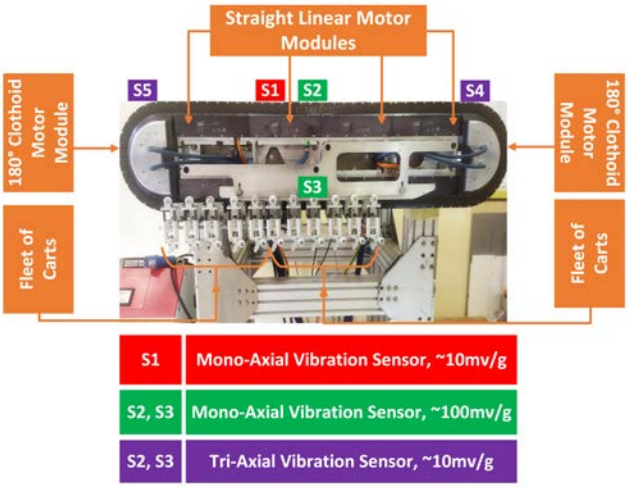

Figure 1. The independent cart system with Parallel guide rail.

To acquire vibration data, five vibration sensors were strategically installed at various locations throughout the system's geometry, as depicted in the figure 1. Among these sensors, three are monaxial, each with different sensitivities (e.g., 10mv/g and 100mv/g). The remaining two sensors are triaxial and are directly mounted onto the guide rail near the left and right sides of the system, with each axis exhibiting a sensitivity of approximately 10mv/g.

3. Picosecond Laser

An EKSPLA Atlantic 50 picosecond laser source was used to damage the bearings. It's a picosecond laser source which generates a Gaussian beam profile at the IR wavelength of 1064 nm. This kind of laser source produces ultrashort pulses in the picosecond regime thus allowing to ablate the inner (and the outer) race by creating a very precise in shape grooves without limitations in terms of hardness of the material to be harmed. The laser beam diameter in the focal position settled at $\phi \approx 10$ μm, evaluated at $1/e^2$ intensity. A dedicated optical path for the IR wavelength allowed the laser beam exiting from its source to be delivered to the scanning head. This is a Raylase Supercan IV galvanometric scanner copuled with an 80 mm F-theta lens thus allowing a square working area with a side of 39 mm. The remaining movements, outside the above scan area, were instead guaranteed by the translation, in X and in Y- direction, of a stage on which the bearings to be damaged were placed. The translation of Z axis

Figure 2. The parallel guide rail.

allowed to damage the bearings by working at the correct focal height. The entire system set up in BrightLab laboratory of the DISMI Department is shown in Figure 5. Preliminary tests were conducted to evaluate the response of the material to the infrared radiation. These tests allowed us to correctly identify, and define, all the process parameters to be able to carry out damage with specific geometry, dimension and prescribed depth. The adopted laser parameters are summarized in Table 1.

Table 1. Laser parameters used during experiments.

Parameter	Unit of Measure	Value
Wavelength, λ	nm	1064
Average Output Power, P	W	13.32
Pulse Frequency, f	kHz	300
Pulse energy, E	µJ	44.4
Pulse duration, τ	ps	10
Pulse fluence, F	J/cm^2	56.56
Line spacing, s	µm	5
Marking speed, v_s	m/s	1
Number of passes on each groove, p		150

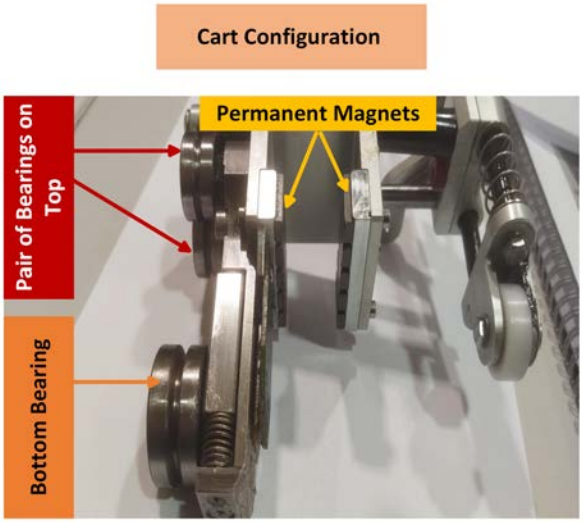

Figure 3. System's cart configuration.

4. Experimental Campaign

The experimental campaign can be divided into two main categories: fault injection and vibration data acquisition, with and without the presence of bearing faults. Fault injection campaigns, furthermore, can be categorized into two main types: those that do not involve dismantling the bearings and those that involve disassembled bearings. Initially, our approach aimed to create faults in bearings without the need for dismantling, utilizing Lab-available drill mill. However, due to the limited flexibility in maneuvering of the drill mill head caused by the close proximity of the bearing's inner and outer races, the faults injected were predominantly of an incipient nature. Consequently, these faults failed to fully encompass the entire grooves of the inner and outer races. Henceforth, these faults will be referred to as incipient fault types throught the remainder of this paper. Subsequently, we explored an alternative method using the EKSPLA Atlantic 50 picosecond laser to create faults in the bearings without disassembly. This approach allowed to reach controlled fault while entailing a challenging method to perform the damage of the bearing parts. The main difficulties were found in the creation of damage both in the inner race and in the outer race of the bearing and they referred to the following two aspects. The first is linked to the shielding effect of the laser radiation that some components of the non-disassembled bearing may have on the area that needs to be damaged. This inconvenience also occurred when specific supports were used to correctly orient (and strongly tilt) the bearing (e.g. the internal race didn't always allow the defect to be created in the external race in its entire axial extension due to the shielding effect performed). Instead, the second considered the need to create a groove with a predetermined depth on a strongly inclined component due to the considerations previously anticipated. To overcome these limitations, and also to be robust in ob-

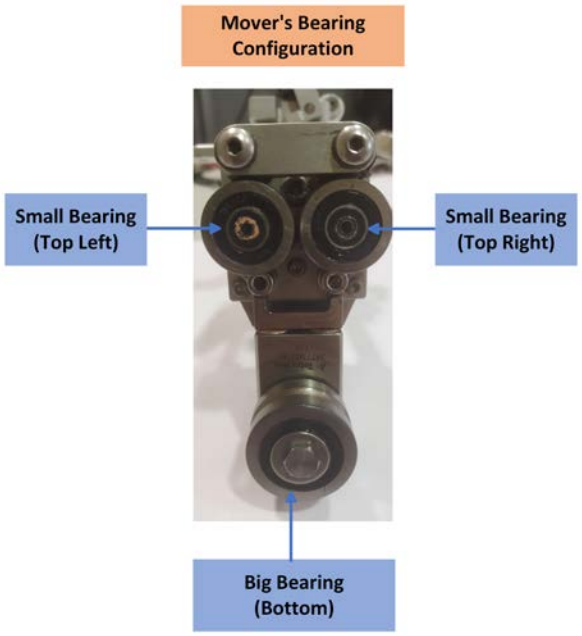

Figure 4. Cart's bearing configuration.

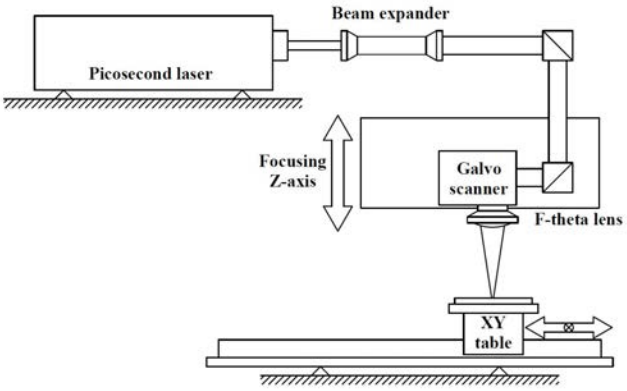

Figure 5. A schematic of the laser ablation system.

taining the damage on the various component of the bearings comparable to what was achieved on preliminary planar tests, an evaluation of the allowable depth of focus was required. In particular, by considering a beam quality factor M^2 of 1.5 and a laser beam diameter (evaluated at $1/e^2$ intensity) on the lens of $D_0 = 14$ mm, have been calculated:

- Rayleigh length z_f, as the distance from the beam waist where the beam radius is increased by a factor of the $\sqrt{2}$:

$$z_f = \frac{\pi \left(\frac{D_0}{2}\right)^2}{M^2 \lambda} \approx 100\ \mu m \tag{1}$$

- Depth of Field (D.O.F.), as the distance either side of the beam waist, D_0, over which the beam diameter grows by 5%

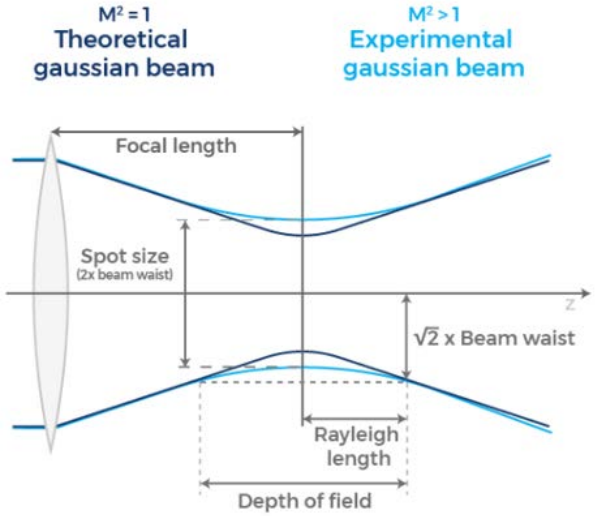

Figure 6. Pico-second laser beam profile

$$\text{D.O.F.} = \pm 0.08 \pi D_0^2 M^2 \lambda \approx 118\ \mu m \tag{2}$$

The modest value of the depth of Field (D.O.F.), which settles at 118 μm for our laser, did not allow for damaging the bearing components in a single laser pass. Therefore, a multi-pass approach was needed. This methodology involves focusing the laser beam on a target zone of the component that needs to be damaged. The process carried out is characterized by reaching the prescribed depth in the area where the laser was focused, and by unworked areas where the laser was unable to completely deposit its energy and properly ablate the material. The processing area can therefore be limited to a rectangle having as its height the depth of field previously calculated. The areas not included within this height will instead remain untreated due to the unfocused conditions. An incremental increase in depth is needed and allowed by varying the height of the galvanometric head (and correspondingly recovering the *X* position by advancing with the *XY* table). In this way, by focusing on a lower area, further ablation processing is possible. The process is performed continuously until the intended damage shape is achieved. The reached depth had a tolerance of ± 0.15 mm from the nominal shape. Finally, to fully overcome the limitations related to the first issue explained above, the bearings were completely dismantled. This way, individual parts of the bearing were fully exposed, facilitating controlled fault injection. The damage process was unaffected by the presence of, for instance, balls between the inner and outer races, which obscured the area to be damaged. Thus, better and more precise flat-bottom grooves were created using the multi-pass criteria mentioned above. An optical microscope (Mod. Nikon LV100ND), was used to characterize the final shape of the fault in terms of dimensions and, by changing the depth of focus.

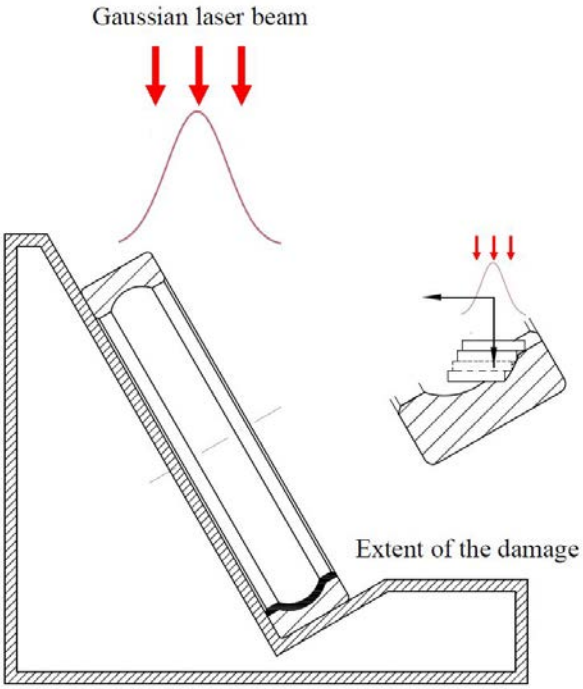

Figure 7. Positioning of bearings on an ad-hoc support. The operating principle of the multi-altitude approach for progressive focusing is explained in the enlarged image.

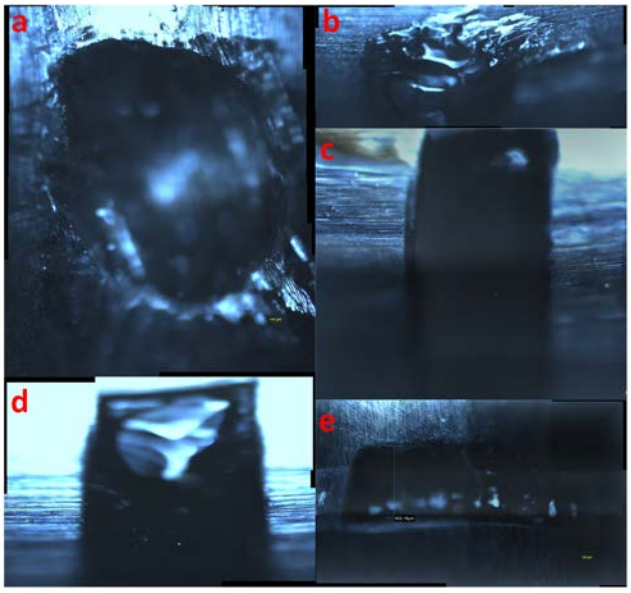

Figure 8. Microscopic view of bearing faults: a) Incipient version IR fault of bottom bearing, b) Incipient version OR fault of bottom bearing, c) Lase version 0.5 OR fault of top bearing, d) Lase version 1.0 OR fault of bottom bearing, e) Lase version 0.5 IR fault of bottom bearing.

Table 2. Bearing type, fault type, and fault version.

Bearing Type	Fault Type	Fault Version			
		Incipient Width	Laser 0.5 Width	Laser 1.0 Width	Laser 2.0 Width
Top Bearing	OR	NA	0.5	1.0	2.0
	IR	0.75	0.5	1.0	2.0
	BF	NA	0.5	1.0	2.0
	OROS	NA	0.5	NA	NA
Bottom Bearing	OR	1.3	0.5	1.0	2.0
	IR	1.4	0.5	1.0	2.0
	BF	NA	0.5	1.0	NA
	OROS	NA	0.5	NA	NA

The microscopic view of the some of the faults created without dismantling the bearings is illustrated in the figure 8. It is evident that the depth of the faults varies non-uniformly due to the challenges mentioned earlier. A tabular summary of the fault injection campaign without dismantling the bearings is presented in the table 2. In the table, ”IR” represents inner race faults, ”OR” denotes outer race faults, ”BF” signifies ball/roller faults, and ”OROS” indicates outer race outer surface faults. Whereas, laser versions 0.5, 1.0, and 2.0 represent the nominal width (in mm) of the injected faults.

5. Results

The experiments involved varying the number of movers and different experiment types, each focusing on different areas of the system, such as the straight path on the top or bottom side, or the curved side, with varying numbers of movers. However, the results presented are specifically for a particular experiment type involving a single mover traversing the straight path on the top side of the system, demonstrating back-and-forth motion. This experiment was conducted at different speeds: 1000 mm/s, 2000 mm/s, and 3000 mm/s. It is important to note that the results will not be discussed in terms of fault identification based on fault frequency. Instead, the focus will be on highlighting differences in the vibration data concerning fault injection types and fault sizes.

The figure 9 illustrates the Fast Fourier Transform (FFT) of the data obtained during the experiment conducted at a speed of 1000mm/s, showcasing different versions of IR faults in the top bearing. In the legend, ”F” indicates the presence of a fault, while ”H” denotes healthy conditions. Additionally, ”S1000” represents the linear speed of the cart. ”V” signifies the laser version of fault injection, while ”Incipient Fault” denotes manual fault injection. It is important to note that only one of the top couple of bearings is faulty at a time. Moreover, the width of the impulses in the data with faulty conditions appears to be directly correlated with the size of the faults; sharper faults result in narrower impulse widths. The same behavior is observed in the case of the outer race fault of the bottom bearing, as illustrated in the figure 12.

As evident from the table 2, the Incipient type IR fault in the top bearing measures 0.65mm, which closely aligns with the laser version 0.5 fault. This similarity is also reflected

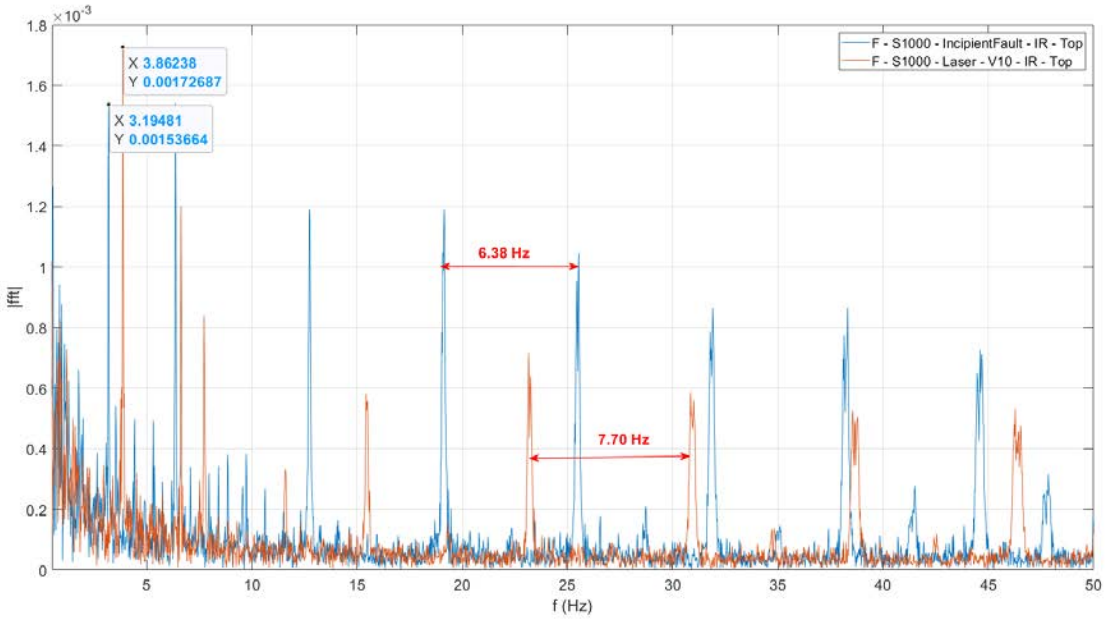

Figure 9. The FFT of the vibration data with an incipient and laser version 1.0 type inner race fault in the top bearing, at a linear speed of 1000 mm/s.

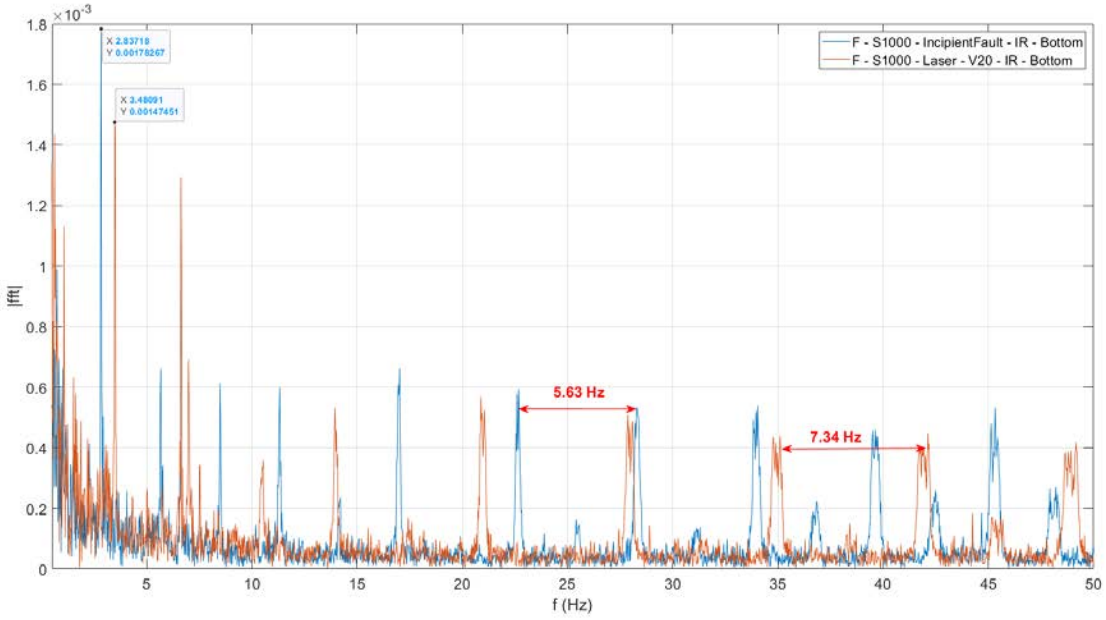

Figure 10. The FFT of the vibration data with an incipient and laser version 2.0 type inner race fault in the bottom bearing, at a linear speed of 1000 mm/s.

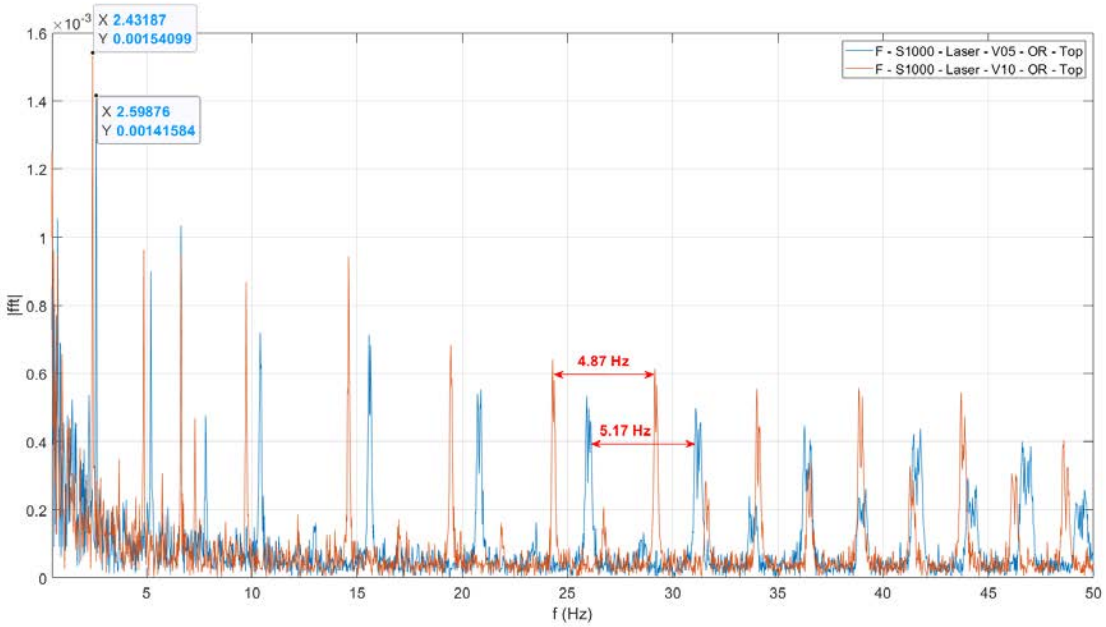

Figure 11. The FFT of the vibration data with laser version 0.5 and laser version 1.0 type outer race faults in the top bearing, at a linear speed of 1000 mm/s.

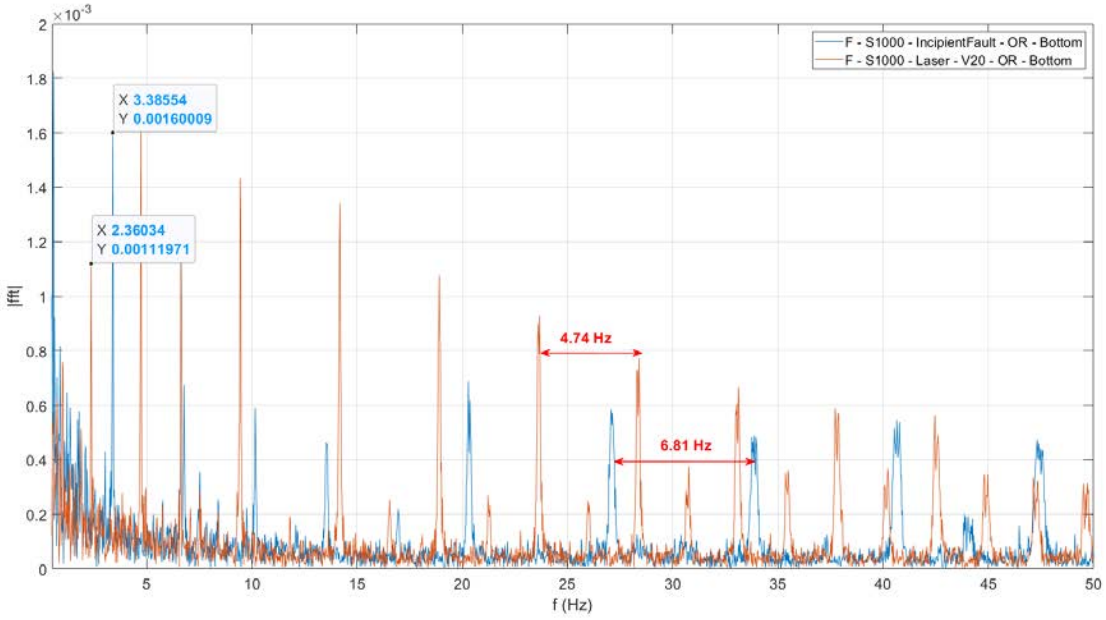

Figure 12. The FFT of the vibration data with an incipient and laser version 2.0 type outer race fault in the bottom bearing, at a linear speed of 1000 mm/s.

in the width of the impulses in the FFT of the vibration signal. However, it's noteworthy that the width of the incipient fault is not uniform throughout the fault area, nor does it completely cover the groove of the inner race where the rolling element glides. Therefore, a detailed explanation and analysis of these differences are yet to be conducted. Similarly, in the case of the IR bottom bearing fault, the incipient fault, approximately 1.4 mm wide at its widest, shows FFT characteristics more akin to the laser version 2.0 fault type as depicted in figure 10. Notably, for the incipient type IR fault of the bottom bearing, the modulating frequency appears to be 2.83 Hz, with even harmonics exhibiting higher energy than the odd harmonics. Conversely, for the laser version 2.0 fault in the bottom bearing, the modulating frequency seems to be 3.48 Hz, with even harmonics having more energy than the odd harmonics.

Likewise, for the IR top bearing fault in figure 9, the incipient type fault measuring approximately 0.75mm exhibits FFT characteristics more similar to the laser version 1.0 fault type. Interestingly, for the incipient type IR fault of the top bearing, the modulating frequency appears to be 3.19 Hz, with even harmonics having higher energy than the odd harmonics. Conversely, for the laser version 1.0 IR fault in the top bearing, the modulating frequency seems to be 3.86 Hz, with even harmonics exhibiting more energy than the odd harmonics.

Regarding the OR bottom bearing fault, the incipient fault, approximately 1.3 mm wide at its widest, exhibits FFT characteristics more aligned with the laser version 2.0 fault type as shown in figure 12. Notably, for the incipient type OR fault of the bottom bearing, the modulating frequency appears to be 3.38 Hz, with even harmonics demonstrating higher energy than the odd harmonics. Conversely, for the laser version 2.0 fault in the bottom bearing, the modulating frequency seems to be 2.36 Hz, with even harmonics having more energy than the odd harmonics.

Lastly, in the case of the OR top bearing fault in figure 11, the FFT of the laser version 0.5mm resembles more closely the laser version 1.0 fault type. Interestingly, for the version 0.5 OR fault of the top bearing, the modulating frequency appears to be 2.59 Hz, with even harmonics demonstrating higher energy than the odd harmonics. Conversely, for the laser version 1.0 fault in the top bearing, the modulating frequency seems to be 2.43 Hz, with even harmonics exhibiting more energy than the odd harmonics.

6. Conclusion

In order for the dataset to be utilized in developing new algorithms, it is imperative that at least a subset of the data exhibits clear fault signatures. The laser method of fault injection offers precise control over fault dimensions, ensuring repeatability. The data acquired from this experimental campaign could serve as a benchmark for the development and testing of condition monitoring algorithms, whether they are machine learning-based, statistically based, or employ classical signal processing techniques.

ABSTRACT

Prognostics and Health Management (PHM) plays a crucial role in maximizing operational efficiency, minimizing maintenance costs, and enhancing system reliability. Predicting Remaining Useful Life (RUL) is a key aspect of PHM, inherently incorporating uncertainty. This paper focuses on uncertainty quantification (UQ) within Data-Driven Models (DDMs), particularly Machine Learning (ML), such as Long Short-Term Memory (LSTMs), and stochastic models namely Hidden Markov Models (HMMs). While ML models emphasize accuracy, stochastic models offer a different paradigm for prognostics, directly addressing uncertainty. Traditional categorizations of uncertainty as aleatory and epistemic face challenges in practical implementation. This paper explores how, in prognostics, HMMs primarily tackle aleatory uncertainty, whereas LSTMs predominantly address epistemic uncertainty. It also discusses the complexities of uncertainty management in prognostics and analyzes further an already proposed alternative approach to categorize uncertainties. Despite theoretical advancements, practical implementation remains challenging, especially for DL models due to their limited interpretability. This study sheds light on UQ challenges and offers insights for future research directions in prognostics.

1. INTRODUCTION

Prognostics and Health Management (PHM) is a field that provides users with a thorough analysis of both the current and future health condition of a system. PHM has gained attention during the last years due to the potential that it has to maximize the operational availability, reduce maintenance costs, and improve the system reliability.

Prognostics, as part of the PHM field, aim at predicting the Remaining Useful Life (RUL) of a given engineering system while it is in operation. By definition, the prediction of RUL incorporates uncertainty. Therefore, it is imperative to model RUL as a random variable rather than a deterministic one to account for the inherent uncertainties in prognostics. The prediction of RUL is then used by a decision-making module, which will make health management decisions to fulfill PHM goals.

Nonetheless, uncertainty quantification (UQ) is a challenge within prognostics. In particular, when prognostics are performed with Data-Driven Models (DDMs), which only rely on historical sensor data, UQ can become a greater challenge depending on which type of prognostic DDM is used. Hence, this paper will solely focus on UQ for DDMs, given their extensive use in prognostics and their sensitivity to uncertainty sources related to the data.

As previously mentioned, DDMs use historical sensor data to predict the RUL of the engineering system, and there are different types of DDMs. For the purposes of this paper, we would consider Machine Learning (ML) and stochastic models as the two main categories of DDMs. ML models, which include decision trees, Support Vector Regressor (SVR), and Deep Learning (DL) models, among others, have gained attention in prognostics because of the high accuracy of the RUL predictions.

In contrast to ML, stochastic models offer a different paradigm for data-driven prognostics. Stochastic models, such as Hidden Markov Models (HMMs) and Wiener processes, model the degradation process of the engineering system based on the sensor data, i.e. unsupervised learning, unlike ML models that can find complex relationships between the sensor data and RUL, i.e. supervised learning. Thus, ML models find patterns in the data which allows them to have a good performance when trained with large and labeled datasets but struggle with outliers.

Another important difference between ML models and

stochastic models is UQ. In stochastic models, UQ is direct since the output of the model is a probability density function (pdf) of the RUL prediction. For ML models, UQ is a challenge given that ML models are deterministic by nature, i.e. they provide a single-point prediction for RUL. There are techniques to perform UQ, but these might not be suitable for a prognostic application, as will be discussed in Section 3.

It is important to know that UQ is not the ultimate goal, but it is a key step towards uncertainty management. Uncertainty management is defined as the identification of sources of uncertainty and the reduction of uncertainty by leveraging data to characterize better the inherent prognostic uncertainties. Hence, reducing their impact on RUL predictions, which is necessary for the decision-making process (Sankararaman, 2015).

The question is then, which are the sources of uncertainty? The classical categorization considers two sources of uncertainty, aleatory and epistemic. Aleatory refers to the uncertainties that are intrinsic randomness of a phenomenon. Epistemic uncertainty is caused by a lack of knowledge, thus, it is the uncertainty that comes from the model itself (Der Kiureghian & Ditlevsen, 2009). Another way to look at them is that aleatory uncertainty is irreducible, since there is no control over the randomness of the phenomenon, and epistemic uncertainty is reducible given that the model can be changed. Consequently, to perform uncertainty management epistemic uncertainty needs to be addressed.

Nevertheless, even if we manage to identify epistemic uncertainty effectively, how can this information be used to perform uncertainty management in prognostics? Aside from the variability of the data, i.e. aleatory uncertainty, there is uncertainty in the identification of the current state of the system's health or the future loading operation that the system will be subjected to. By considering all these different sources as part of "epistemic uncertainty", it is unclear what actions need to be taken to reduce the RUL uncertainty.

For that reason, it has been claimed that the aleatory and epistemic categorization is not suitable for prognostics (Sankararaman & Goebel, 2013) and a more suitable categorization has been proposed, which will be further explained in Section 5. Although this categorization has been presented in different publications, it has not been applied, to the best of the author's knowledge, to a real-life scenario. Until now, the few prognostics publications that identify sources of uncertainty continue to use the classical categorization.

This paper presents both an stochastic model and a DL model under the same case study. To understand the use of stochastic models, an HMM presented. With the HMM, a new expression for RUL prediction is introduced in this study and is compared with the state-of-the-art RUL expression in terms of UQ. For DL models, a Long-Short Term Memory (LSTM) is used, given that it has been argued as the one with the best performance in terms of accuracy for several engineering applications. The LSTM is analyzed by using different parameters for UQ.

Therefore, by the use of these models this paper aims to provide an understanding of uncertainty in prognostics, and how different types of DDMs deal with UQ. As well as to offer a discussion in terms of future perspectives to address the UQ challenge, ultimately aiming towards the goal of uncertainty management.

The paper is organized as follows, Section 2 offers the theoretical background of HMMs and the new prognostic expression and Section 3 details the UQ methods for DL models, as well as DL model approaches in prognostics. The case study, including the data prepossessing and results, is presented in Section 4. Section 5 offers a discussion about the future perspective on UQ for prognostics. Finally, the paper is concluded in Section 6.

2. HIDDEN MARKOV MODELS

HMMs are a widely used stochastic model for different engineering applications. In the context of prognosis, it has been used for composites (Eleftheroglou, 2020; Eleftheroglou et al., 2024), lithium-polymer batteries (Eleftheroglou et al., 2019), turbofan engines (Giantomassi et al., 2011), and simulated fatigue crack growth (Le et al., 2014). In each one of these publications, different variants of HMM are used. A multi-branch HMM is used in (Le et al., 2014) to take into account the multiple degradation modes that can occur. A more complex version of HMM is used in (Eleftheroglou, 2020; Eleftheroglou et al., 2019), called the Non-Homogeneous Hidden Semi Markov Model (NHHSMM). When applied to composites the author used an adaptive approach of the NHHSMM that allowed the model to predict the RUL for testing data that had gone through unexpected phenomena.

Thus, HMMs have demonstrated their applicability through the use of different variants of it. In this paper, the classical HMM will be used, and a new definition for prognostic is presented.

HMMs can model a sequence of observations, which in this case is the data coming from the sensors. It is used in processes in which the state of the engineering system cannot be directly observed, hence, they are hidden. The engineering system is modeled as a Markov process, meaning that the probability of transitioning from one state to another depends only on the current state. The sojourn time of each hidden state is defined by an exponential distribution (continuous case) or a geometrical distribution (discrete case). Each state emits an observation with a certain probability distribu-

tion. Below, the parameters that describe an HMM are detailed (Rabiner, 1989).

- N: number of states. Individual states are denoted as $S = \{S_1, S_2, ..., S_N\}$, and the state at time t as q_t.
- M: number of distinct observation symbols per state. Individual observations are denoted as $V = \{v_1, v_2, ..., v_M\}$.
- State transition: the state transition probability distribution is denoted as $A = \{a_{ij}\}$, where $a_{ij} = P[q_{t+1} = S_j | q_t = S_i]$. This expression is the probability that the state at time $t + 1$ is equal to the hidden state S_j given that the current state q_t is equal to the hidden state S_i.
- Observation distribution: the observation symbol probability distribution in state j, $B = b_j(k)$, where $b_j = P[v_k \text{ at t} | q_t = S_j]$, with $1 \leq j \leq N$ and $1 \leq k \leq M$.
- Initial state: the initial state distribution $\pi = \{\pi_i\}$ where $\pi_i = P[q_1 = S_i]$ with $1 \leq i \leq N$.

The complete parameter set of the model is denoted as $\lambda = (A, B, \pi)$. To train an HMM it is necessary then to adjust the model parameters λ to maximize $P(O|\lambda)$, meaning that the parameters are optimized to best describe the observation sequences, which in the case of prognostics are the degradation histories. Since there is no possible way of analytically calculating $P(O|\lambda)$, the iterative algorithm Baum-Welch can locally maximize it.

In the particular case of prognostics and this paper, some assumptions are made. First, the last state is not hidden but observable and it represents failure. Second, in the failure state, only one observation value is emitted. Third, only left-to-right transitions are allowed, meaning that while in hidden state i, it is only possible to remain in state i or to transit to state $i + 1$. This last assumption is valid only when modeling a degradation process independently from maintenance actions.

Once the model parameters λ are estimated and we have an observation sequence $O = O_1 O_2 ... O_T$, two questions arise. First, what is the probability of the observation sequence given the model $P(O|\lambda)$? The second question is, which is the most likely sequence of hidden states $Q = q_1 q_2 ... q_T$?

The answer to the first question, the Forward-Backward algorithm is used. The forward part calculates the likelihood of being in a hidden state at a certain time point given the available observations. The result of the forward part is then $P(O|\lambda)$, which answers the first question. The backward part is then used to answer the second question since calculates the likelihood of observing the remaining data, given the current hidden state. The result of the complete Forward-Backward algorithm is the posterior distribution which is the probability of being in each state at each time, given the entire sequence of observed data.

However, to answer fully to the second question it is necessary to find the single best state sequence that maximizes $P(Q|O, \lambda)$ that is equivalent to maximizing $P(Q, O|\lambda)$. The maximization is done via the Viterbi algorithm. After the Viterbi has estimated the most likely sequence of hidden states, it is possible to calculate the RUL. In the state-of-the-art, a time-invariant (TI) (Dong & He, 2007a) prognostic measure used is defined in (1). The variables $a_{i,i}$ and $a_{i,i+1}$ represent the probability of remaining in the current hidden state or transitioning to the next hidden state, respectively. The variable $D_i(d)$ represents the pdf (or pmf for the discrete case) evaluated in the probability of transition to the same state i, i.e. a_{ii}.

$$RUL_i^t = a_{i,i}(D_i(d) + RUL_{i+1}) + a_{i,i+1}(RUL_{i+1}) \quad (1)$$

In this paper, a new time-dependent (TD) prognostic measure is introduced in (2). This TD prognostic measure is expected to improve accuracy of the RUL prediction and to reduce the spread of the confidence intervals, which can be calculated by the weighted spread of uncertainty (WSU) presented in Appendix A.

$$RUL_i^t = d_{i,i}^T \left(D_i(d - \tau) + \sum_{i=k+1}^{N-1} D_k(d) + \mathcal{N}(1, \epsilon) \right) + d_{i,i+1}^T \left(\sum_{k=i+1}^{N-1} D_k(d) + \mathcal{N}(1, \epsilon) \right) \quad (2)$$

The notation for this expression is as follows. RUL_i^t, is the RUL in the state i and time step t. Once again, $D_i(d)$ represents the pdf (or pmf for the discrete case) evaluated in the probability of transition to the same state i, i.e. a_{ii}. The variable τ is the time spent in the current state i. Therefore, the term $D_i(d - \tau)$ represents a shift in the pdf making this RUL expression time-dependent. The variables $d_{i,i+1}^T$ and $d_{i,i}^T$ are derived from the transition matrix and are defined as shown in (3) and (4), respectively.

$$d_{i,i+1}^T = P(d \leq \tau | S_t = i) \quad (3)$$

$$d_{i,i}^T = 1 - d_{i,i+1}^T \quad (4)$$

The result of the expression 2 is the pdf of RUL per time step. Therefore, the confidence intervals can easily be obtained by calculating the cumulative density function (CDF) and, later, choosing the confidence level, usually 95%.

However, even if the HMM has a closed form for the posterior distribution, the distribution captures aleatory uncertainty, including uncertainty propagation and quantification via the prognostic measure. In state-of-the-art prognostics,

including the publications mentioned above, the HMMs presented usually address only aleatory uncertainty. Yet, epistemic uncertainty can be included in HMMs through a time-consuming sensitivity analysis, which traditionally has been used for accounting for epistemic uncertainty in stochastic models. In (Xie et al., 2016) a Generalized Hidden Markov Model (GHMM) is introduced that can identify both epistemic and aleatory uncertainties by using imprecise probabilities. The results show that the GHMM can make more robust decisions because the uncertainties can be differentiated. Yet, it is a computationally expensive model.

3. DEEP LEARNING MODELS

For DL models, as well as for any ML model, uncertainty quantification is a challenge since they are by nature deterministic, i.e. a single-point value for RUL prediction. Bayesian Neural Networks (BNNs), which are an extension of Neural Networks (NNs), overcome this by providing a pdf as a result. However, BNNs still have a problem when quantifying uncertainty since they offer an approximation of the posterior distribution (Abdar et al., 2021). The posterior distribution cannot be directly calculated because it is intractable to calculate the marginal distribution. Therefore, there is no close-form expression for the posterior distribution.

BNNs can provide a pdf as an output because they have distributions over the weights parameters and not deterministic values as in the case of NNs. These distributions in the weights parameters are learned over Bayesian inference, which uses the Bayes rules as shown in equation (5). In this expression, $P(w|X,Y)$ is the posterior distribution, $P(w)$ is the prior distribution, $P(X,Y|w)$ is the likelihood and $P(X,Y)$ is the marginal distribution.

$$P(w|X,Y) = \frac{P(X,Y|w)P(w)}{P(X,Y)} \tag{5}$$

Once again, it is computationally intractable to calculate $P(X,Y)$. Thus, these models offer an approximation of $P(w|X,Y)$ by using Variational Inference (VI). VI approximates the posterior distribution by using a variational parameter $q_\theta(w)$. The distribution q_θ is approximated by minimizing θ with the Kullback-Leibler (KL) divergence.

$$KL(q_\theta(w)||P(w|X,Y)) = \int q_\theta(w) \log \frac{q_\theta(w)}{P(w|X,Y)} dw \tag{6}$$

However, KL minimization is still intractable because it needs the posterior distribution that it was impossible to obtain in the first place. By rearranging KL into the evidence lower bound (ELBO), the need to have the posterior is avoided.

$$\mathcal{L}_{VI}(\theta) = \int q_\theta \log P(Y|X,w) dw - KL(q_\theta(w)||P(w)) \tag{7}$$

However, even though VI offers a good approximation of the posterior it is still challenging to implement given their computational cost (Nastos, Komninos, & Zarouchas, 2023). As a result, other techniques have arisen, such as Monte Carlo (MC) dropout, Deep Gaussian Processes, and Markov Chain Monte Carlo (Abdar et al., 2021).

MC Dropout has been introduced as a technique to quantify epistemic uncertainty and is the most used one due to its simple implementation (Gal & Ghahramani, 2016). This technique approximates the posterior by randomly switching off neurons, given a dropout probability. The same architecture is run multiple times and each dropout configuration corresponds to a different sample from the approximate posterior distribution.

However, MC dropout struggles to approximate complex posterior distributions, which may lead to good approximations only in certain regions of the posterior distribution but poor approximations in others (Fort, Hu, & Lakshminarayanan, 2019). Even more, it has even been questioned the fact that MC dropout is Bayesian since it fails sanity checks and is a design artifact since the posterior distribution converges to different values depending on the dropout probability assigned by a user (Folgoc et al., 2021). Hence, these techniques although easy to implement, do not always provide a good approximation of the desired distribution. The latter leads to uncertainty about the posterior distribution approximation that is already quantifying RUL uncertainty, adding up to uncertainty propagation of the entire prognostic model.

In the context of prognostics, these types of models have been applied with Bayesian LSTMs since LSTM, in general, provides the best results in terms of accuracy metrics. However, in (Peng, Ye, & Chen, 2019) and in (Xiahou, Wang, Liu, & Zhang, 2023) a point estimation of the final RUL value is made, instead of a prediction of RUL through the operation time. Nevertheless, (Xiahou et al., 2023) includes a RUL prediction during the operation time by including a credible interval. The results are promising, yet the main drawback of this approach is the complexity of the model and its optimization, as the authors have claimed to be "extremely intractable and time-consuming".

Other Bayesian approaches such as (Caceres, Gonzalez, Zhou, & Droguett, 2021) perform UQ including both aleatory and epistemic uncertainty. However, it is not reported in the results how much each source contributes to the confidence intervals, which are also quite volatile. Epistemic uncertainty is quantified with MC dropout with a probability dropout

value of 0.25, which is considered lower than the standard value of 0.5.

In (Pei et al., 2022) a Bayesian RNN is used with the dropout technique, however, they use a value of dropout between 0.05 to 0.2, which once again is considered low given that the standard dropout value. Low dropout values lead to narrow confidence intervals, meaning less estimated uncertainty in the RUL predictions. Thus, the choice of low dropout values can cause an underestimation of uncertainty that can be prejudicial for decision-making.

When it comes to aleatory uncertainty in DL models, it is split into two categories: homoscedastic and heteroscedastic. Homoscedastic uncertainty corresponds to the noise in the data and it remains constant through the whole data set, while heteroscedastic uncertainty corresponds to the noise that varies with the input (Nemani et al., 2023). The few DL models that include aleatory uncertainty, include only one part of it. For example in (Li, Yang, Lee, Wang, & Rong, 2020) a Bayesian DL framework is developed that takes into account heteroscedastic aleatory uncertainty. In the already mentioned work of (Caceres et al., 2021), only heteroscedastic aleatory uncertainty is address and it is also assumed to follow a Gaussian distribution.

4. Case Study

To perform a comparison between a stochastic and a DL model, the C-MAPSS (Commercial Modular Aero-Propulsion System Simulation) dataset is used (Frederick, DeCastro, & Litt, 2007). The C-MAPSS dataset is used as a benchmark within the prognostics community. This dataset is composed of four sub-datasets of simulated run-to-failure degradation histories from turbofan engines, with information from 21 sensors. Each sub-dataset considers a variety of operational conditions and injects different fault modes. For this paper only the sub-dataset FD001 is used, which consists of 100 training degradation histories. This dataset is divided into two in a random manner to have a training set of 80 degradation histories for training and 20 for testing. Additionally, sensors 1, 5, 6, 10, 16, 18, and 19 were eliminated from all the analyses since the values were fixed for every time measurement.

4.1. Pre-processing and training phase

For the HMM, only one feature can be used given the capabilities of the library used in Matlab. Therefore, sensor 11 is chosen since it is the sensor with the highest correlation to RUL. The sensor data is then discretized into 20 clusters using K-Means. The number of clusters was chosen based on the monotonicity index (MI), which allows to identification of the optimal number of clusters that can reasonably represent the degradation process. Once the data has been pre-processed, the optimal number of states is identified as 10, via the Bayesian Information Criterion (BIC). The expressions and results of both the MI and the BIC are shown in Appendix A, along with the estimated transition and emission matrices.

For the LSTM, first, an analysis of the importance of the sensors with respect to RUL was done. The sensors were selected based on their absolute Pearson Correlation Coefficient (PCC) with respect to RUL. Table 1 shows the results for all the sensors under analysis. The sensors selected were the ones with an absolute PCC higher than 0.6. Thus, sensors 2, 4, 7, 11, 12, 15, 17, 20, and 21 were used to train the LSTM. It is important to keep in mind that the LSTM is being trained with more data than the HMM, which only uses data coming from one sensor.

LSTMs need to receive sequences that have the same length, thus, the degradation histories were modified to fulfill this requirement. A sequence length of 362 was selected and values zeros were added in the RUL column, while for the sensors the last measurement was repeated. Thus, the shape of the training set tensor is (80, 362, 9).

The architecture of the LSTM is displayed in Figure 1. The last layer, which corresponds to a Dense layer, uses a linear function as activation. The model was trained using Adam as an optimizer, with a Mean Squared Error (MSE) loss function for 30 epochs.

Table 1. Sensor correlation to RUL values for dataset FD001 in C-MAPSS.

Sensor	PCC
2	-0.61
3	-0.58
4	-0.68
7	0.66
8	-0.56
9	-0.39
11	-0.7
12	0.67
13	-0.56
14	-0.31
15	-0.64
17	-0.61
20	0.63
21	0.64

4.2. Results and Discussion

The results are examined individually because the uncertainty captured by the HMM pertains to aleatory uncertainty, while that captured by the LSTM corresponds to epistemic uncertainty. While it is feasible to incorporate epistemic uncertainty for HMM, most publications employing this model overlook it. Therefore, this paper focuses on analyzing the impact of the prognostic measure on aleatory UQ.

Similarly, for LSTM, MC Dropout is often employed as a

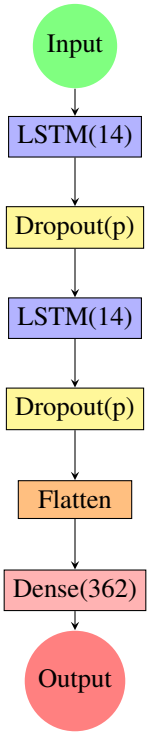

Figure 1. LSTM architecture for prognostics.

methodology to address uncertainty, hence, only epistemic uncertainty is considered. Though it is plausible to include aleatory uncertainty for LSTM, the few publications that do so, only address heteroscedastic aleatory uncertainty and disregard homoscedastic aleatory uncertainty. Consequently, this paper exclusively analyzes epistemic uncertainty via MC Dropout, a common methodology for UQ in LSTMs for prognostics.

4.3. HMM

The results for HMM both with the TI and TD prognostic measure are shown in Table 2. The results correspond to the average RMSE error and the average spread of uncertainty measured by the metric WSU, for the testing set.

Table 2. Average values of the test dataset for the prognostic performance metrics considering the TI and TD expressions of RUL for the HMM.

RUL Expression	RMSE	WSU
TI	45.00	3328839.60
TD	43.10	2978334.12

To visualize confidence intervals, engine #13 is utilized as an example. Figure 2 shows the RUL prediction alongside uncertainty quantification when employing an HMM with TI and TD prognostic measures. It is evident from the visualization that the TD approach provides results with reduced uncertainty and higher accuracy. Thus, the choice of prognostic measure significantly influences how aleatory uncertainty is quantified, as it propagates the aleatory uncertainty captured inherently by the HMM. Even with a simple model, as the HMM is, an improvement can be achieved merely by adopting a different prognostic measure. Therefore, for HMMs in prognostics, one course of action for managing uncertainty could be the development of new prognostic measures that mitigate the tendency to over-propagate inherent aleatory uncertainty captured by the HMM.

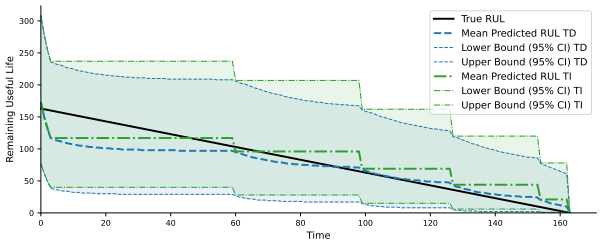

Figure 2. HMM RUL prediction for testing engine #13.

While higher performance is expected with more complex variants of HMMs, such as with a Hidden Semi Markov Model (HSMM) (Dong & He, 2007b) or the NHHSMM previously mentioned in Section 2. However, this paper offers a new time-dependent prognostic measure for the classical HMM that can be extended to other variants in future work. Furthermore, the goal of this paper is not to analyze RUL prediction accuracy but to discuss the challenges and potentials of different DDMs in terms of uncertainty.

4.4. LSTM

The results for LSTM with MC Dropout are summarized in Table 3 for dropout values 0.3, 0.6, and 0.9. The results show high accuracy in terms of RMSE for all three dropout values used, with a slightly better performance for lower dropout values. In terms of epistemic UQ, the value of WSU is higher for higher dropout values as expected.

Table 3. Average values of the test dataset for the prognostic performance metrics considering different dropout values for LSTM.

Dropout value	RMSE	WSU
0.3	1.19	150187.81
0.6	1.57	247935.42
0.9	1.63	645949.41

Figure 3 shows the RUL predictions and confidence intervals for engine #13 (the same engine used for visualization for the HMM). For clarity, only the RUL predictions with dropout values 0.3 and 0.9 are presented. The confidence intervals of the RUL predictions with the LSTM remain approximately the same throughout the degradation history since only the epistemic uncertainty is considered. Additionally, as explained in section 3, it has been claimed that MC Dropout

is not even Bayesian and the posterior distribution converges to different values depending on the dropout probability chosen by the user. In these results, it can be seen that according to the dropout values different model uncertainties are calculated. The question arises then on which is the best value to converge to the right posterior distribution of the model, meaning that there is an uncertainty on how to calculate the epistemic uncertainty.

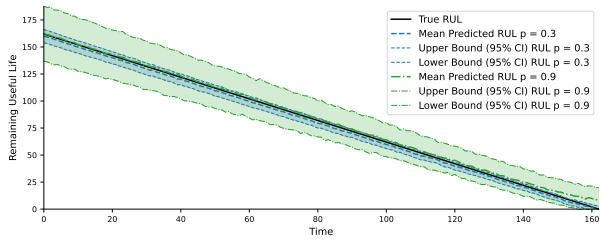

Figure 3. LSTM RUL prediction for testing engine #13 with dropout probability value of 0.3 and 0.9.

5. Future Directions in Uncertainty Quantification for Prognostics

The case study analyzed how UQ is commonly performed in prognostics for HMMs and LSTMs. While for HMMs in most cases only aleatory uncertainty is taken into account, in LSTMs only epistemic uncertainty is addressed via MC Dropout due to its simple implementation. However, even if both models could consider both aleatory and epistemic uncertainty, despite the concerns rising for both approaches, can uncertainty management be performed? Let us remember that epistemic uncertainty is reducible because it comes from the lack of knowledge. Nonetheless, it has been stated that aleatory and epistemic uncertainties often coexist, which makes it difficult to separate them (Nemani et al., 2023). By consequence, uncertainty management would not be feasible.

Hence, a different categorization of uncertainties is needed to allow differentiation. The categorization must be based on the variable of time, inherent in prognostics. This categorization should be subjective and focus on characterizing uncertainties specific to the studied system rather than uncertainties in the population. The need of a different categorization of the sources of uncertainty has been already mentioned in (Sankararaman, 2015), where the author identifies four sources of uncertainties: present, future, model and prognostic measure. The categorization was further extended in (Eleftheroglou, 2020) where a fifth source of uncertainty was included, past uncertainty.

To further explain, the five sources of uncertainty proposed are the following: first, past uncertainties are the ones that come from the manufacturing or assembly process and material quality. Second, present uncertainty refers to the lack of knowledge of the true state of health of an engineering system. Third, future uncertainty is the most difficult and important one to deal with. The future is unknown, and it is not possible to foresee the environmental conditions, loading profile, etc. Another source of uncertainty is the one from the model and it compromises several parts such as model parameters, biases, etc. The last source is the prediction method uncertainty, which is related to the uncertainty coming from the prognostic measure. In the case of supervised techniques, i.e. ML models, the model uncertainty and the prediction method uncertainty become one source.

A remark here is done for past uncertainties since they are not an uncertainty in the present, once uncertainty management is performed. For example, if sufficient data is gathered about the manufacturing process, it can be possible to manage past uncertainties and take them into account when predicting the RUL.

To the best of the author's knowledge, this categorization has not been applied to a real case study and it has only been introduced theoretically. However, an attempt to provide a better understanding on how this categorization can be implemented for HMMs is offered briefly in this section.

For HMMs, past uncertainties can be addressed by the initial parameters distributions π. Present uncertainty can be reflected by the hidden state with the highest probability at the current time step by using the forward probabilities. Future uncertainty, as already mentioned, is the most challenging one. Based on training data, loading profiles can be identified and the probability of changing from one loading profile to another one can be calculated. To account for unexpected phenomena a loading profile can be included that considers an extreme degradation rate, to give an example. Model uncertainty can be addressed by imprecise probabilities or by a sensitivity analysis, as mentioned in Section 2. Finally, the prediction method uncertainty is already considered by the prognostic measure.

DL models remain more challenging to implement under the alternative UQ categorization for prognostics due to the lack of interpretability that has already been mentioned in other publications such as (Fink et al., 2020). Given their black-box nature, the parameters of DL models do not hold a physical meaning making it intractable to connect them to each one of the five sources of uncertainties.

6. Conclusions

This paper explores uncertainty in prognostics, focusing on two main models: HMMs and LSTM networks. It finds that while HMMs primarily deal with aleatory uncertainty (inherent randomness), LSTMs predominantly address epistemic uncertainty (uncertainty from lack of knowledge).

For HMMs, results show the importance of understanding how different prognostic measures affect UQ by broaden-

ing the confidence intervals by introducing a new prognostic measurement that is time-dependant. Similarly, for LSTMs, when using the MC Dropout technique, the results show the importance of the parameter selection of the dropout probability value. Even more, from the theoretical background it has been claimed by other authors how a different dropout probability can lead to not converging to the posterior distribution needed to calculate epistemic uncertainty.

However, this paper also opens the discussion about how UQ can be used for uncertainty management in prognostics. Despite attempts to categorize uncertainty, such as distinguishing between epistemic and aleatory uncertainty, challenges persist, particularly in effectively reducing uncertainty. Future directions advocate for a different approach that considers five sources of uncertainty, such as past, present, and future uncertainties, model uncertainties, and prediction method uncertainties.

This alternative approach aims to offer a more comprehensive understanding. However, the prevalence of epistemic uncertainty poses challenges in disentangling from each one of the sources of uncertainty. Even when attempting to quantify past or model uncertainties, the presence of epistemic uncertainty persists due to data limitations and knowledge gaps. While theoretical discussions on implementing alternative categorizations for HMMs exist, practical implementation is constrained. Managing uncertainties in HMMs requires addressing multiple dimensions, encompassing past, present, and future uncertainties, as well as model and prediction method uncertainties. Conversely, implementing this alternative approach on UQ in DL models remains challenging due to their limited interpretability, raising questions about their efficacy in real-world prognostic applications.

APPENDIX A

Weighted Spread of Uncertainty (WSU)

The weighted spread of uncertainty (WSU) metric is shown in 8. It calculates the area between the confidence intervals while penalizing wider confidence intervals at the end of the lifetime. The penalization is considered because the longer time that has passed, the more information is available. Variable t_i is the time unit, RUL^{upper} is the RUL value of the upper confidence interval and RUL^{lower} is the value of the lower confidence interval.

$$WSU = \sum_{i=1}^{T-1}(t_{i+1} - t_1)\left(\left(\frac{RUL_{i+1}^{upper} + RUL_i^{upper}}{2}\right) - \left(\frac{RUL_{i+1}^{lower} + RUL_i^{lower}}{2}\right)\right) \quad (8)$$

Monotonicity

The equation for the MI is provided in 9 with $y(t_i)$ as the feature value at time measurement t_i and D as the number of measurements. The results in Figure 4 show that after 20 clusters the monotonicity index converges and remains stable.

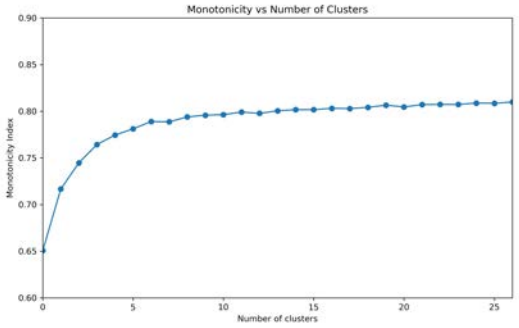

Figure 4. Monotonicity index versus the number of clusters for the sensor 11.

$$\text{MI} = \frac{\sum_i^D \sum_{j=1,j>i}^D (t_j - t_i) sgn(y(t_j) - y(t_i))}{\sum_i^D \sum_{j=1,j>i}^D (t_j - t_i)} \quad (9)$$

Bayesian Inference Criterion

In equation 10 M_i is the candidate model, $y^{(k)}$ is the sensor data from K degradation histories, $Q^{(k)}$ the state sequence for the kth degradation history, H is the number of estimated parameters of model M_i, and n the number of all the samples from the K training sessions. Figure 5 shows the results of the BIC, from which 10 states are proven to be the optimal number.

$$BIC(M_i) = \sum_{k=1}^{K} \log(P(y^{(k)}, Q^{(k)}|M_i)) - w\frac{H_i}{2}\log(n) \quad (10)$$

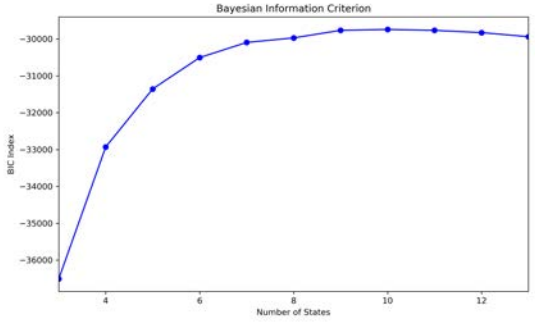

Figure 5. BIC to select the number of optimal states.

After training the HMM, the transition matrix A and the emission matrix B are estimated. The values of the elements of the matrices have been approximated

$$A = \begin{bmatrix} 0.9646 & 0.0354 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0.9648 & 0.0352 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0.9709 & 0.0291 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0.9735 & 0.0265 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0.9591 & 0.0409 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0.9417 & 0.0583 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0.9323 & 0.0677 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0.9281 & 0.0719 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0.8941 & 0.1059 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 \end{bmatrix}$$

ABSTRACT

Machine learning methods are increasingly used for rotating machinery monitoring. Usually at system set up, only data of the machinery in healthy conditions, the so-called nominal data, are available for the machine learning phase. This type of training data enables fault detection capabilities and several methods such as Gaussian Mixture Model, One Class Support Vector Machines and Auto Associative Neural Networks (Autoencoders) have been already proved successful for this task.
However, in some predictive maintenance applications, information on the type of defect may represent a key element for producing actionable information, e.g. to reduce diagnostic burden and optimize spare procurement. This requires to define classification strategies based on machine learning even in absence of data representing the behaviour of the system with defects.
In this study we present an approach that uses only nominal vibration data to train an autoencoder which will enable at same time fault identification and fault classification tasks.
As faulty data are expected to possess information content which is structured differently from the healthy ones their reconstruction at output will result inaccurate. In conventional anomaly detection approaches, the module of the reconstruction error, defined as the difference between output and input, is uses to determine an unusual input such as faults.
The proposed approach represents a step forward as here a single autoencoder is used both for detection and classification.
The underlying idea is that the components of the reconstruction error vector whose module is used to trigger fault identification in classical autoencoder approaches contain the information of the fault type. This way the analysis of the different components of the reconstruction error allows to differentiate the different types of faults.
Two methods to analyse the components of the reconstruction error vector will be discussed and their respective test results will be presented
Test data have been generated with a machine fault simulator to produce 3 different types of bearing defects with different load, speed and noise conditions. A dataset of about 10000 vibration signals has been used to evaluate the classification algorithms and to benchmark them with a supervised approach.
The results obtained using the autoencoder method do not achieve the same performances as the conventional supervised learning algorithms. However, they proved to be 88% accurate in classification when SNR is above 0dB with the ranking based method overperforming the barycentre one.

1. INTRODUCTION

Diagnostics is a crucial aspect for rotating machinery maintenance. Data processing methodologies range from traditional techniques such as frequency analysis to more innovative approaches like machine learning. In diagnostics process two main steps are often distinguished: detection and identification/classification. Detection aims to recognize the presence or absence of a defect. This can be sufficient in some situations where it is simply necessary to know if a machine is functioning correctly or if it requires intervention. Nevertheless, to optimize maintenance and repair processes, it is often essential to precisely target determining which component is failing: this requires fault identification.

Data-driven approaches are progressively more employed for anomaly detection and fault classification for machine condition monitoring purposes. However, high integrity systems could not always use the supervised learning/classification process needed for fault classification.

This depends on the fact that, at machine installation time, only healthy (nominal) data are available for training. Unsupervised learning offers a solution to fault detection by modeling nominal data and using a distance measure and a threshold for determining abnormality (Samanta, Al-Balushi, & Al-Araimi, 2003; Jack & Nandi, 2002; Booth & McDonald, 1998; Sanz, Perera, & Huerta, 2007; Guttormsson, Marks, El-Sharkawi, & Kerszenbaum, 1999; Rojas & Nandi, 2006; Prego, et al., 2013; Alguindigue & Uhrig, 1991; Fulufhelo, Tshilidzi, & Unathi, 2005; Rubio & Jáuregui, 2011). However unsupervised novelty detection approaches cannot be used for fault classification.
In (Nicchiotti et al.,2016) it has been proposed a strategy to extend machine learning capabilities from fault detection to fault classification with the constraint that only nominal data are available for training. The logic is to use a priori knowledge about the effects of each fault to be classified in order to produce input training data which are somehow fault tuned. These training data are generated by computing, on nominal data, features which are known to be the most responsive to each kind of fault which has to be classified.
The approach presented in this paper represents a step forward compared to the work presented in (Nicchiotti et al.,2016), where multiple unsupervised models were trained and classification was performed by comparing the models. In this case, classification is based on the analysis of the results of a single unsupervised model.

The case study used to validate this new approach is the classification of faults in ball bearings with a machine learning approach where only healthy data are used for training. The study required taking measurements on defective bearings under various operating and noise conditions. The collected signals were preprocessed to extract training features both in time (RMS, Kurtosis, Crest Factor, etc.) and frequency domains. The frequency domain proved to be particularly effective in discriminating between different types of failures, due to the characteristic frequencies associated with the defects.

The paper is organized as follows. Next section will briefly illustrate the test rig and the data set characteristics.
A description of data-driven method used in this study will be presented in section 2. The focus will be on Auto Associative Neural Networks (AANN) .
The novel strategy to extend the data-driven capabilities from detection to classification will be described in section 4
Two methods for classifying defects will be explored: the first based on the ranking of reconstruction errors components, the second on the analysis of the barycenter of the reconstruction error when represented in a polar plot.
The results obtained with the 2 data-driven methodologies will be then compared and discussed and their robustness against noise characterized.
The classification results will be finally benchmarked against supervised approaches.

2. Acquisition Setup And Dataset

The signals were acquired using acquisition systems developed by MC-Monitoring. Measurements were conducted on a fault simulator, allowing for measurements under different operating conditions. The fault simulator enables the rotation of bearings under various load, unbalance, and speed conditions. Bearings can be affected by defects in the inner race, outer race, balls, and a case presenting a combination of defects. The defective bearings were placed at location 5 (see figure 1), and the measurement via the accelerometer is carried out along the x and y axes. The sampling rate was 50 kHz

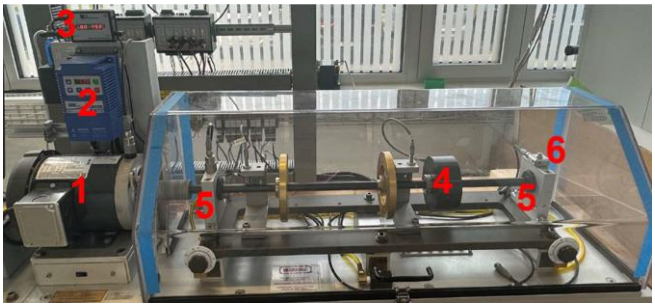

Figure 1. Machine Fault Simulator and acquisition setup. 1 AC Motor, 2 Frequency Converter ,3 Tachometer, 4 Additional mass load, 5 Right and left bearing 6Acceleration sensor x-y, 100mV/g.

For each type of bearing fault and under different loads and speed conditions, a 6-minute acquisition of the vibration signal has been performed.

After digital conversion, the raw signal undergoes filtering to remove the DC component. We then calculate the Root Mean Square (RMS) value of the filtered signal, which becomes the reference point for adding white noise. To assess the process's robustness, seven levels of white noise were added to each original signal. This resulted in a total of 140 sequences, each containing 6 minutes of healthy and faulty signal data under different load, speed, and signal-to-noise ratio (SNR) conditions.

3. Machine Learning Methods

Machine learning offers diverse tools for monitoring machine health, including density methods (KNN), boundary methods (SVM), and reconstruction methods (AANN) (Johannes, 2001). These techniques have been successfully applied to fault detection (Samanta et al., 2003; Jack & Nandi, 2002; Booth & McDonald, 1998). When used for classification, these approaches all require pre-existing fault data for training (Alguindigue & Uhrig, 1991; Fulufhelo et al., 2005; Wang et al., 2020; Prego et al., 2013).

However, acquiring such data poses a challenge when dealing with new equipment. In such scenarios, data-driven anomaly detection emerges as the only possible alternative which is

exemplified in studies by Rubio & Jáuregui (2011), Guttormsson et al. (1999), and Sanz et al. (2007) . Methods like Auto-Associative Neural Networks (Sanz et al., 2007) and one class SVM (Guttormsson et al., 1999) are among the most widely used methodologies that rely on "one-class classification", when only healthy data is available for training.

Despite their success in fault detection, one-class classification methods haven't been explored for fault identification. This research aims to bridge that gap by incorporating expert knowledge ("a priori") into these data-driven ("a posteriori") techniques, implementing fault classification within the AANN framework.

3.1. AANN

Auto-Associative Neural Networks (AANNs), also known as Replicator Neural Networks or Autoencoders, are like smart copycats in the world of artificial intelligence. These networks are trained to mimic whatever data they're given, but with a twist: they have a hidden layer with fewer neurons than the input and output. This "bottleneck", shown in Figure 1, forces them to compress the information, essentially learning the key features of the data they're trained on.

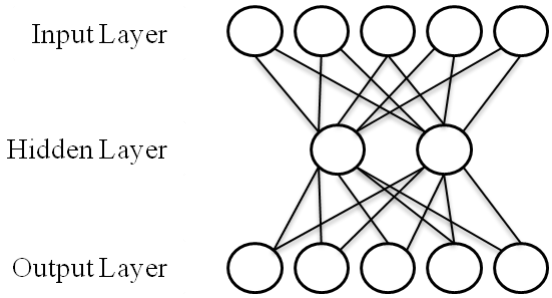

Figure 2. AANN Architecture.

Imagine training an AANN with healthy equipment data. Once trained, it can accurately reproduce similar healthy data. However, faulty data will contain different patterns that the AANN struggles to compress in the bottleneck. This results in a larger reconstruction error, which is the difference between the original data and the AANN's attempt to recreate it.

The reconstruction error can be considered as a measure of strangeness. The higher the error, the more different the data is from what the AANN knows as "healthy." By setting a threshold for this error, we can create a simple fault detection system: anything with an error above the threshold is likely faulty.

In practice once a new sample is processed by the AANN, the measure of the difference between output and input vectors, the Reconstruction Error (RE) of an input vector X, is computed as

$$RE = \|X - O_X\| \quad (1)$$

where O_X is the output of the AANN and || symbol stands for any p-norm. Once computed the R_E, a fault or anomaly detection logic can be easily implemented for instance by thresholding.

4. FAULT IDENTIFICATION STRATEGY

This section aims to examine the usage the reconstruction error of an autoencoder to classify different types of defects.

To compensate for the lack signals associated with the defects, the idea is to leverage the "a priori" knowledge of the phenomena linked to the type of fault and encode it within the autoencoder process. As shown in figure 3, this process requires an initial step consisting of extracting features from the signal through appropriate signal processing techniques.

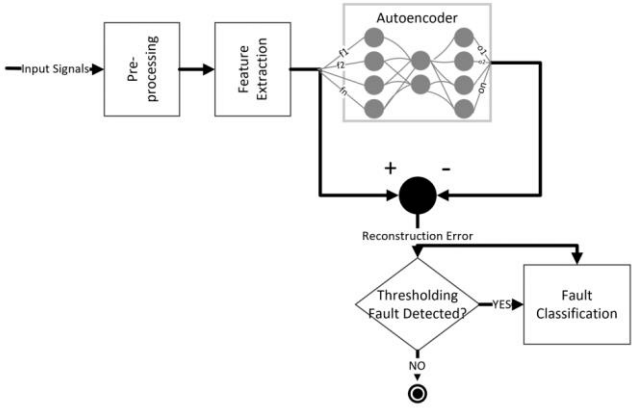

Figure 3. Main Processing Steps.

4.1. Pre-processing

In the subsequent discussion, the term "feature" refers to an individual measurable attribute of the observed phenomenon. In this research, the features represent various characteristics of the signals extractable from the signals. Features represent unique clues about a machine's condition, like symptoms for a doctor. Think of these features as different dials on a dashboard, each showing a different aspect of the machine's health.

Raw sensor data from ball bearings needs preparation before computing features and feeding it into machine learning algorithms. This involves filtering, windowing, and extracting the signal's "envelope".

- Filtering - Since the information we care about lies above 2 kHz, lower frequencies are irrelevant and clutter the analysis. We utilize a Butterworth bandpass filter [2-22kHz]to selectively remove them. In this proof of concept, we decided to use such a large bandwidth to represent the worst case. Practically, it is more efficient to filter around the frequency resonance of the entire system (motor, bearing, sensors, etc..) which is between generally somewhere between 2kHz and 20kHz to minimize the noise. However, as we wanted a "generic" system, we decided to use the overall bandwidth of our acquisition system. This also presents a practical benefit of not requiring to configure the filter during the installation procedure.

- Envelope Extraction - Ball bearing vibrations, like the one shown in Figure 3, contain information in their "envelope". This envelope reflects the modulation of the bearing's natural resonance frequency caused by impacts between rolling elements and defects. To uncover the characteristic frequencies of these defects, we calculate the Fast Fourier Transform (FFT) on the extracted envelope, not the raw signal. As most of the rotating machines we monitor in our applications run between 25Hz and 60Hz, we know that the characteristic frequency of the faults (BPFO, BPFI, etc) are between, let say, 5Hz an 500Hz, so the envelope size was chosen according to these values.

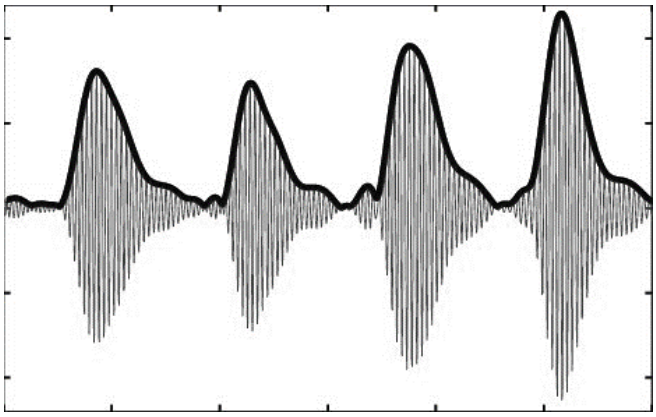

Figure 4. Bearing signal: Raw (slim lines) Envelope (bold lines)

- Windowing - To enhance the accuracy of frequency analysis, we apply a Hann window to the filtered data. This window smooths the signal edges, reducing artifacts in the resulting spectrum. The measured signal (240 s) will be divided into 1-second samples with a 1/2-second overlap. The choice of 1 second allows balancing the need for enough signals for machine learning model training and retaining sufficient characteristic information of the vibrational signal generated by the bearing. A too small window would make the model unreliable if the pseudo-periodic nature of the signal is not preserved in the sample. A too large window would also not allow good model generalization due to the more limited training dataset.

4.2. Feature extraction

Features have been extracted with time domain and frequency domain analysis.

In the time domain, signals from defective bearings exhibit periodic impulses corresponding to impacts between the balls and the cage defect or between the defective ball and the metallic components. The impulses excite the resonance frequencies of the system. Each impact can be compared to the impulse response of the system due to the short duration of contact between a ball and the defect The presence of defects in a machine can be detected by analysing the vibration signal. Defects increase the energy of the vibration signal and modify its statistical distribution. These changes can be used to identify the presence and severity of the defects. Time domain features used in this study are (Hornavar & Martin, 1995): RMS,Crest Factor, Kurtosis, Skewness, Impulse Factor and Form Factor.

Each bearing has a unique "fingerprint", its characteristic frequencies, determined by its geometry and rotation speed. (Kamaras et al. ,1995, Andhare, 2010)

- FTF - Fundamental Train Frequency: This is the rotation frequency of the bearing cage.

- BPFI - Ball Pass Frequency of the Inner Race: This frequency is generated by the passage of balls over the inner ring.

- BPFO - Ball Pass Frequency of the Outer Race: This frequency is generated by the passage of balls over the outer ring.

- BSF - Ball Spin Frequency: This frequency is related to the rotation of the balls.

When a fault develops, these specific frequencies become amplified, acting like warning lights. These frequencies not only reveal the presence of a problem but also pinpoint the exact type of fault, allowing for targeted repairs and preventing unnecessary downtime. Hence to identify faults in bearings, features were extracted from the vibration signal's envelope spectrum. These features included the peak ratio amplitudes of characteristic frequencies related to bearing health: the Ball Pass Frequency Outer Race (BPFO), Ball Pass Frequency Inner Race (BPFI), and Ball Spin Frequency (BSF). Additionally, the spectral centroid and the energy in the band 10-20 kHz were included. These features formed the frequency "fingerprint" of the bearing's health and were fed into an Auto Associative Neural Network (AANN) for fault classification.

To extract the features, we first chopped the time signal into half second intervals, making sure to overlap them by 0.25s to capture any important transitions. From each chunk, we

then extracted 14 specific features which we fed into the autoencoder for further analysis.

4.3. Classification

The fault detection by autoencoder is based on the premise that the reconstruction error for data similar to those used for training will be lower than the error for data from faulty bearings.

Since different features do not all have the same range of values, the data has to be standardized (Equation 2). Each new set of tested data will be standardized using the mean and standard deviation of the training data.

$$F_i = \frac{f_i - \mu_i}{\sigma_i} \qquad (2)$$

Where f_i is the value to be standardized, μ_i , σ_i are the mean and the standard deviation of the training set for feature i and F_i is the standardized feature value.

The parameters of the autoencoder have been determined according to the average reconstruction error on healthy data. The autoencoder has a single hidden layer which contain 10 neurons This value represents a good compromise between low reconstruction error and moderate training time. The maximum number of iterations (Epochs) for training is set to 500 beyond this, the improvement in performance is not significant.

For each feature F_i at the input, the autoencoder calculates a corresponding output O_i . The difference $E_i = \|F_i - O_i\|$ represents the components of the reconstruction error along the various axes represented by the features used, as shown in Figure 5.

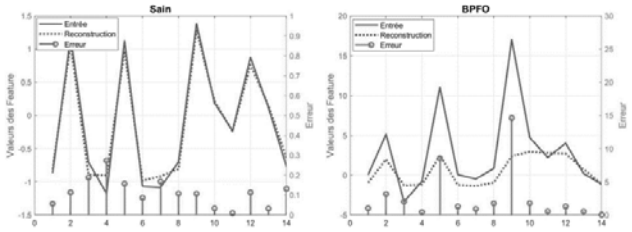

Figure 5: Reconstruction error for a healthy signal (left) and outer race fault (right). X-axis represent the feature index Errors E_i in stems (vertical lines), continuous lines input features dotted features as reconstructed by autoencoder

The two classification strategies here presented assume that the relative values of components E_i of the reconstruction error depend on the type of defect.

The first approach maps E_i on a polar plot (Figure 6), and uses the angle of the reconstruction error to discriminate the different types of faults.

To differentiate between fault types, each feature i is assigned a specific angle (θ_i). Using a priori knowledge about fault behavior, these angles are carefully chosen to maximize the angular separation between features clearly associated with different faults (e.g., Inner Race, Outer Race, Ball). For example, BPFO, BPFI, and BSF might be assigned 0°, 120°, and 240° directions, respectively.

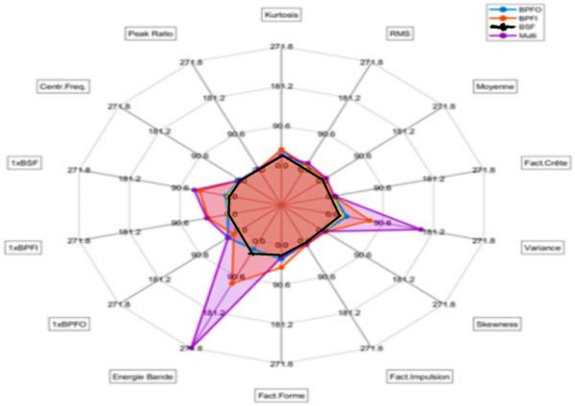

Figure 6: Polar Plot of the reconstruction error. Blue contour represents the shape of outer race fault, Red of inner race, Black ball fault, Violet Multiple faults. Different faults types correspond to different contours.

Next, each feature's reconstruction error component E_i is represented as a 2D vector $\overrightarrow{E_i}$ where the magnitude reflects the error value of the component itself and the angle corresponds to the pre-assigned θ_i based on fault type a priori knowledge. By summing these vectors, a resulting reconstruction vector $\vec{V}$ is created

$$\vec{V} = \sum_{i=1}^{N} \overrightarrow{E_i} \qquad (3)$$

Based on the vector direction Θ of $\vec{V}$ *with* Θ=arg($\vec{V}$) the fault type can be classified.

For instance, if Θ is falling within -60° to 60° we can classify the fault as inner race between 60° and 180° as outer race, else as ball error. The underlying idea is that reconstruction errors not strictly dependent on the type of defect interfere destructively, highlighting the direction of the defect in the polar plot.

The second method assumes different fault types make it harder for the autoencoder to reconstruct certain feature components. By leveraging a priori knowledge, we anticipate the ranking of reconstruction errors magnitude for the features across different fault scenarios as shown in Table 1.

Table 1. Ranking fault signatures

Fault type	Reconstruction error $E_i = \|F_i - O_i\|$													
	←Bigger													Smaller →
Inner	1	8	10	5	9	12	7	2	11	6	3	4	13	14
Outer	9	5	12	8	11	1	10	2	7	6	3	4	13	14
Ball	12	8	1	5	9	7	6	10	11	2	3	4	13	14

This expected ranking serves as a signature to identify the actual fault based on the observed ranking of reconstruction errors. Comparing the actual observed order to the expected ranking enables the classification task.

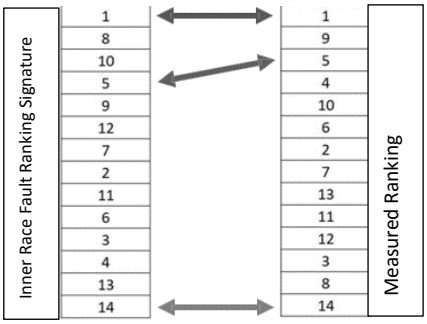

Figure 7: Example of ranking signature for Outer Race Fault and RBO algorithm

To effectively compare ranking list and classify the fault type, the algorithm needs to consider the varying importance of features in their ranked order (see Figure 7). The correspondence between two top-ranked features (top arrow) is more important than two lower-ranked features (bottom arrow). Additionally, two identical features that are not at the same rank (center arrow) must be taken into account. To accomplish this, the Rank Biased Overlap (RBO) algorithm (Joshi 2021), which meets these requirements, was used to compare the rankings. This algorithm allows assigning a weight (p) more or less significant to elements at the top of the ranking. The result of the comparison between the two lists is a number between 0 and 1 (the value '1' is obtained for two identical lists).

5. TEST RESULTS

An autoencoder with 14 input features and a single hidden layer with 8 nodes to distinguish healthy and faulty system states has been trained with 3000 healthy samples, each represented by a vector of 14 features extracted from a 0.25-second signal window. The model's performance was evaluated on 3000 healthy and 9000 faulty samples. While confusion matrices provided insights into classification errors, this document focuses on precision, defined as the ratio of the total number of correct predictions to the total number of predictions made by the model.

Figure 8 demonstrates the model's ability to accurately detect healthy states with excellent precision even when dealing with high levels of noise in the signal.

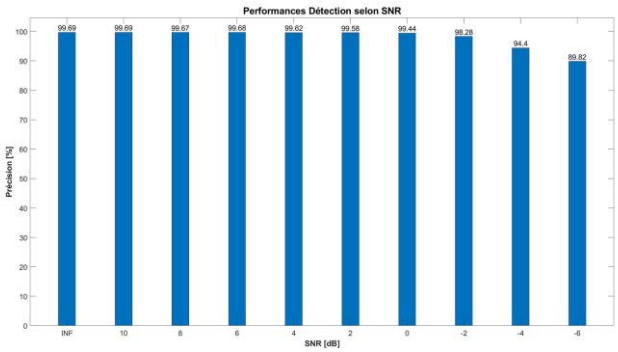

Figure 8: Precision of the anomaly detection as a function of SNR(dB)

To detecting faults, we set a threshold (Th_D) based on the reconstruction error (RE). If RE exceeds Th_D, a fault is likely present. This threshold is calculated as the mean (μ_{TS}) plus three times the standard deviation (σ_{TS}) of the reconstruction error computed on the training data (Equation 4).

$$Th_D = \mu_{TS} + 3 \cdot \sigma_{TS} \quad (4)$$

The autoencoder demonstrates exceptional anomaly detection capabilities even under low noise conditions, achieving precision levels exceeding 99.4% for signal-to-noise ratios (SNR) up to 0 dB. However, as noise levels increase, performance drops and false alarms become a concern, at SNR 6 dB, precision falls below 90%.

5.1. Vector Direction classification

Initially, with 14 features, the method based on the direction of the reconstruction vector (Θ=arg($\vec{V}$)) only achieved a 76.8% precision. The unsatisfactory percentage is likely due to the correlation between some features which produced the same interference pattern. Therefore, we applied Principal Component Analysis (PCA) (Shlens, 2014) to identify redundancies and reduce the number of features to 8 This process ends up with the selection of the most informative features, in statistical sense, like RMS, Kurtosis, Peak Factor, Impulse Factor, and key frequency components). This dimensionality reduction significantly improved classification performance, boosting the precision to 87.94%.

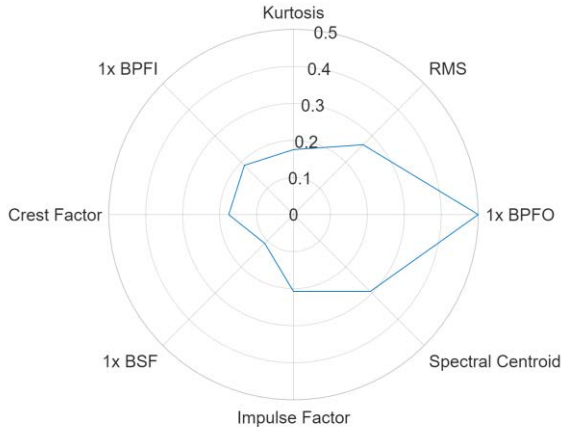

Figure 9: Polar Plot with 8 features pour outer race fault

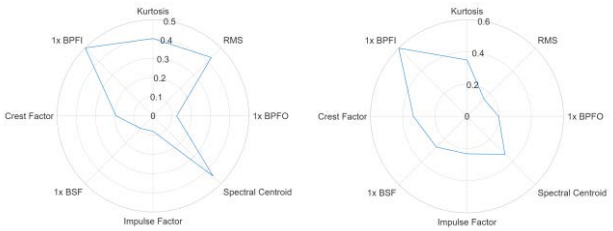

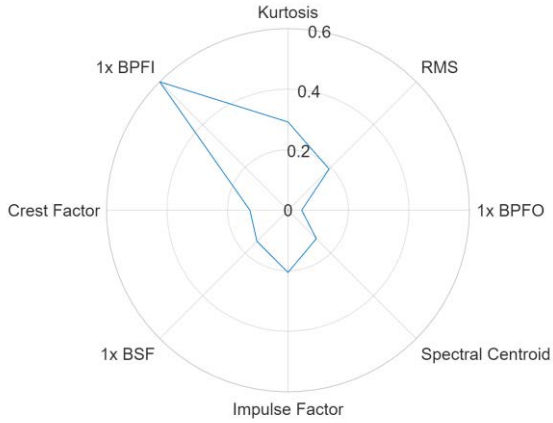

Figure 10: Polar Plots with 8 features for an inner race fault

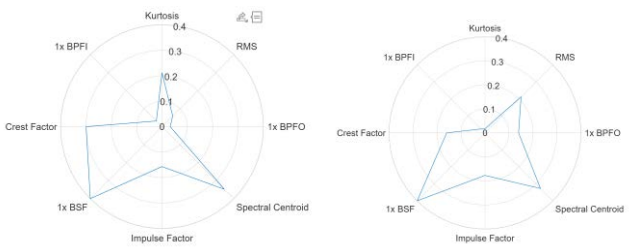

Figure 11: Polar Plots with 8 features for a ball fault

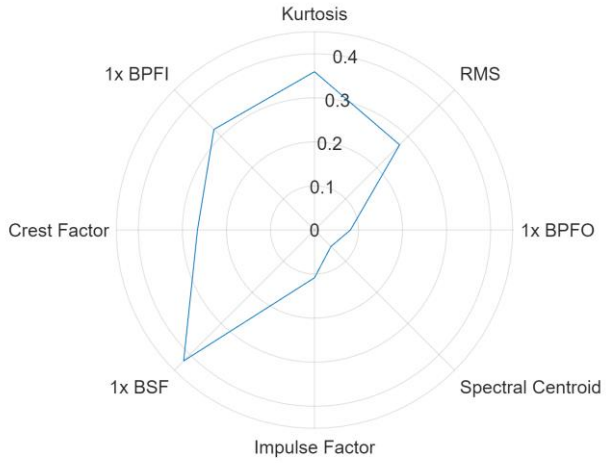

Figure 12: Polar Plots with 8 features for a ball fault, with misclassification

In addition to automated fault classification, our method provides a visual tool for identifying different fault types. Figures 9-11 showcase polar diagrams where each plot displays examples correctly classified. Figure 12, however, depicts a scenario where misclassification occurred.

In some maintenance situations, where misidentifying a failure could have serious consequences, operators can leverage these visualizations to perform a semi-automated diagnosis, especially if the automated results lack sufficient confidence. This allows them to combine the model's insights with their own expertise for a more informed decision.

5.2. Rank Order classification

When using the rank order RBO method for classification, the initial precision with 14 features was only 41.46%. Similar to the previous approach, we reduced the number of features to decrease redundancy and eliminate less relevant information. Using the same features as the "vector direction" classifier, the RBO method improved, and achieved a maximum precision of 76.8% when the parameter p (Joshi 2021) is set to p =0.9. The parameter p determines the weighting of the first positions in the similarity measurement between two ranked lists. By adjusting the value of p, it is possible to control the importance given to the first positions compared to the subsequent positions, thus providing flexibility to evaluate the similarity between ranked lists according to different criteria. The value of p is chosen between 0 and 1. In this case, it has been decided to give more importance to the first positions in the ranking, which have a more significant impact on the classification performances.

Therefore, the « directional » classifier appears more effective in our tests.

While unsupervised methods like RBO offer an advantage in not requiring labelled data, their precision in this case

(76.8%) falls short compared to supervised learning (>99% precision). (Cherif, 2023) This is likely due to the inclusion of actual fault data in the training set for supervised methods, providing them with a more direct understanding of failure patterns.

6. CONCLUSIONS

The application of unsupervised machine learning techniques for detecting bearing faults and anomalies in rotating machinery offers a compelling array of advantages for practical business implementations. By eliminating the need for labeled faulty data, these approaches streamline the deployment process, making it more accessible and cost-effective for industrial settings.

The ability to operate without pre-existing fault data enables unsupervised algorithms to uncover previously unrecognized patterns and anomalies, providing early detection of faults and proactive maintenance opportunities. This early detection capability, coupled with scalability and adaptability to changing conditions, empowers businesses to enhance reliability, minimize downtime, and optimize maintenance strategies.

In essence, leveraging unsupervised machine learning in industrial contexts not only circumvents the challenges associated with acquiring labeled data but also delivers tangible benefits in terms of reliability, efficiency, and cost-effectiveness. This approach represents a transformative paradigm for bearing fault detection and anomaly monitoring, enabling businesses to proactively manage their assets and maximize operational performance without relying on historical fault data.

However, whilst supervised and unsupervised methods show similar performance in defect detection, our proposed approach using an autoencoder for classification falls short compared to supervised learning. However, our method offers the crucial advantage of not needing rare defect data for training. This combination of unsupervised anomaly detection and classification enables defect detection without labeled data.

The "directional error" method achieves a promising 87.94% accuracy through optimized feature selection.

To further improve our classification system, we are pursuing two complementary research directions:

1. Improving precision over time: We're exploring how to combine classification results over time to potentially boost precision.
2. Implementing a rejection logic (Bartlett & WegKamp, 2008; Chow ,1970): This framework aims to prevent critical misclassifications by allowing the model to avoid predictions when uncertain, at a predefined cost. This enables semi-automatic diagnostics where polar plots of ambiguous cases can be sent to operators for confirmation.

From the validation point of view, it has been planned to validate our methodology on HUST bearing dataset (https://data.mendeley.com/datasets/cbv7jyx4p9/3)

NOMENCLATURE

E_i	Reconstruction error component
Θ	Direction of Reconstruction Vector
p	Weight of RBO
RE	Reconstruction Error
Th_D	Detection Threshold
$\vec{V}$	Reconstruction vector

BIOGRAPHIES

Gianluca Nicchiotti received an MSc in Physics from Università di Genova, Italy in 1987 and an MSc in Applied Science from Cranfield University UK in 2013. Since 2022 he holds the chair of Signal Processing at Haute école d'ingénierie et d'architecture in Fribourg. From 2005 to 2022 worked in the aerospace domain as system engineer by Meggitt, Switzerland. Prior to Meggitt, he managed an image processing research team at Elba Research Center and developed algorithms for sport video special effects at Dartfish. His career started at Elsag Bailey R&D in underwater acoustic cameras field. He is author of more than 50 papers and 5 patents. His current research interests are quantum computing and machine learning.

Idris Cherif got a degree in Electronic Engineering from Haute école d'ingénierie et d'architecture in Fribourg now he is R&D engineer at Inergio.

Sebastian Kuenlin's received a degree in Electronic Engineering from Haute école d'ingénierie et d'architecture in Fribourg, Switzerland, where he earned a Bachelor of Science HES in Electrical Engineering with a specialization in Electronics in 2010. At the end of his studies, he conducted his diploma work at Lawrence Berkeley National Laboratory, focusing on testing stave/module systems for the ATLAS detector at CERN. During this time, he developed an electronic test bench based on FPGA. Transitioning to MC-monitoring SA in 2011, Sébastien worked in embedded system development before assuming leadership roles, ultimately becoming Chief Technology Officer and of MC-monitoring SA in 2018. His current areas of expertise are acquisition system and signal processing.

Virtual Sensor for Real-Time Bearing Load Prediction Using Heterogeneous Temporal Graph Neural Networks

ABSTRACT

Accurate bearing load monitoring is essential for their Prognostics and Health Management (PHM), enabling damage assessment, wear prediction, and proactive maintenance. While bearing sensors are typically placed on the bearing housing, direct load monitoring requires sensors inside the bearing itself. Recently introduced sensor rollers enable direct bearing load monitoring but are constrained by their battery life. Data-driven virtual sensors can learn from sensor roller data collected during a battery's lifetime to map operating conditions to bearing loads. Although spatially distributed bearing sensors offer insights into load distribution (e.g., correlating temperature with load), traditional machine learning algorithms struggle to fully exploit these spatial-temporal dependencies. To address this gap, we introduce a graph-based virtual sensor that leverages Graph Neural Networks (GNNs) to analyze spatial-temporal dependencies among sensor signals, mapping existing measurements (temperature, vibration) to bearing loads. Since temperature and vibration signals exhibit vastly different dynamics, we propose Heterogeneous Temporal Graph Neural Networks (HTGNN), which explicitly models these signal types and their interactions for effective load prediction. Our results demonstrate that HTGNN outperforms Convolutional Neural Networks (CNNs), which struggle to capture both spatial and heterogeneous signal characteristics. These findings highlight the importance of capturing the complex spatial interactions between temperature, vibration, and load.

1. INTRODUCTION

Bearings are essential components in mechanical systems, ensuring the efficient and reliable operation of machinery and equipment across diverse industries, including wind energy, aerospace, and automotive sectors. Real-time monitoring of bearing conditions is crucial for optimal performance and proactive maintenance (Hou & Wang, 2021). Knowing the actual load experienced by bearings offers several key benefits. Firstly, deviations from the original design loads signal the need for adjustments to operational parameters and maintenance schedules. This allows for proactive prescription of health-aware load profiles, potentially extending the bearing's service life. Moreover, load monitoring aids in early detection of misalignments, enabling timely proactive adjustments to prevent further damage (Widner & Littmann, 1976). Additionally, knowledge of bearing load facilitates more accurate diagnosis of potential bearing faults (Peng et al., 2020). Finally, bearing loads are a key factor influencing bearing lifespan and failure (Harris & Kotzalas, 2006), and their understanding enables predicting damage propagation (Morales et al., 2019). An in-depth understanding of the load is essential for accurate Remaining Useful Life (RUL) prediction and effective Prognostic and Health Management (PHM).

Directly measuring bearing loads during operation presents complex challenges. Traditional approaches, typically using strain gauges, require direct contact or close proximity to the bearing's rolling elements. This introduces significant logistical and technical hurdles (Konopka et al., 2023), including accessing power and establishing sensor communication, making installation more expensive than conventional condition monitoring sensors, such as for vibration and temperature.

Recently, wireless sensor roller technology has been introduced, wherein sensors are embedded inside a rolling element to allow in-operation measurement of bearing loads (Baggerohr,

2023). However, their utility is still constrained by battery life. A virtual sensor could overcome this limitation by providing continuous, long-term load predictions, even when the sensor roller's battery is depleted. Specifically, our goal is to develop a virtual sensor that maps the measurements of conventional bearing condition monitoring sensors to loads. Since the relationships between these sensors and load are influenced by factors such as stiffness, damping, and thermal behavior, and are often unknown in real-world applications, we adopt a data-driven approach. Sensor roller provides crucial ground-truth load data, which is significant for enabling the development of this virtual sensor. Estimating the load without such direct data is extremely difficult without extensive modeling. Our approach not only extends the value of the physical sensor roller but also supports advanced PHM.

Virtual sensors have been applied in many different applications ranging from environmental sensing to complex industrial systems. They leverage readily available measurements and computational models to infer quantities that are challenging or costly to measure directly (Martin et al., 2021). They also play a crucial role in digital twins, providing insights beyond what physical sensors can capture (Song et al., 2023). Two primary directions exist for virtual sensors: *model-based* and *data-driven*. Model-based approaches rely on well-defined physical laws and principles to develop models describing the system of interest. In contrast, *data-driven* approaches use machine learning and data mining algorithms to find patterns and relationships within sensor data. Model-based virtual sensors require using existing sensor data to accurately infer and update model parameters to ensure accurate estimations. Methods such as Kalman filtering, which dynamically updates model states in real-time based on noisy sensor measurements, are well-established for calibrating physics-based virtual sensors for load estimation models (Kerst et al., 2019). Alternatively, Gaussian processes can be applied to latent force models to infer unknown load dynamics from a sensor network (Bilbao et al., 2022). While powerful, these methods rely on prior knowledge of the system's physics, which can be challenging or infeasible to obtain in many real-world cases. In contrast, data-driven virtual sensing offers flexibility by directly learning complex relationships from data. For example, (Dimitrov & Göçmen, 2022) demonstrated the potential of Long Short-Term Memory (LSTM) networks for predicting wind turbine blade root bending moment using SCADA data. (Wang et al., 2021) developed a Deep Belief Network (DBN) with event-triggered learning (DBN-EL) to improve the efficiency and accuracy of a water quality soft-sensing model for the wastewater treatment processes from the sensor data.

Model-based methods often depend on prior knowledge of the system's physics. In contrast, data-driven approaches can overcome this limitation but may require other forms of ground truth to learn the functional relationships, such as simulation data (Dimitrov & Göçmen, 2022) or periodic lab-based measurements (Wang et al., 2021), making them difficult to apply in real-world scenarios. Fortunately, bearing sensor rollers allow direct measurement of bearing load in operation, offering a direct ground truth that enables us to learn the complex relationships between load and conventional bearing condition monitoring sensors through supervised learning.

For large-size bearings, such as main shaft bearings in wind turbines, a common approach for bearing condition monitoring involves positioning multiple sensors around the bearing to measure rotational speed, vibration, and temperature. Although a correlation exists between load and these sensor readings, the relationships are complex and difficult to model accurately due to the lack of exact physical models. However, there exists an additional inductive bias in the form of spatial information, such as the correlation between higher temperatures and areas of increased load. Leveraging this spatial information can offer valuable insights into load distribution. While traditional machine learning algorithms struggle to effectively utilize this spatial information, Graph Neural Networks (GNNs) are well-suited for handling spatial-temporal dependencies (Jin et al., 2023). By modeling sensors and their connections as a graph, GNNs can directly capture the spatial dependencies and relationships between different sensor readings. They utilize message-passing techniques, where information from neighboring sensors is iteratively processed and aggregated, building a global understanding from local information (Gilmer et al., 2017). GNNs have been successfully applied in areas such as bearing remaining useful life prediction (Yang et al., 2022), cyber-physical attack detection for water distribution systems (Deng & Hooi, 2021), sensor calibration for air pollution (Niresi et al., 2023) and fault detection for chemical process plants (Zhao & Fink, 2023).

Nevertheless, existing GNN methods often assume relatively similar feature characteristics across nodes. Although GNNs have been applied to heterogeneous sensor networks, the focus has typically been on handling different sensor types (e.g., temperature, humidity, pressure). In these cases, while the data originates from diverse sources, the signal characteristics often exhibit some similarities. In our scenario, the heterogeneity is in signal characteristics. Vibration and temperature signals exhibit very different dynamics and frequencies. This poses a novel and significant challenge for GNNs, which often struggle to effectively integrate and learn from such highly diverse signal characteristics.

To address the challenge of heterogeneous sensor characteristics, we propose a novel virtual load sensor based on Heterogeneous Temporal Graph Neural Networks (HTGNNs). By explicitly modeling high and low-frequency signals as distinct node types and differentiating their interaction types, our HTGNN effectively fuses the information from diverse sensors. This enables more accurate load prediction, overcoming

the limitations of traditional GNNs. To the best of our knowledge, this represents the first design of such an architecture to analyze diverse sensor types for bearing load estimation.

The remainder of this paper is organized as follows: Sec. 2 describes the task of a bearing virtual sensor. Sec. 3 elaborates on HTGNN's core components to model the heterogeneous dynamic relationships within the bearing system. Sec. 4 describes the case study, experimental setup, and the baseline method Sec. 5 presents the results of and offers a thorough discussion. Finally, Sec. 6 summarizes key findings and proposes directions for further research.

2. Virtual Sensor for Load Prediction

In this paper, we establish the notation where bold uppercase letters (e.g., $\mathbf{X}$), bold lowercase letters (e.g., $\mathbf{x}$), and calligraphic letters (e.g., $\mathcal{V}$) to denote matrices, vectors, and sets, respectively. Time steps are indicated by Superscripts (e.g., $\mathbf{X}^t$ is the matrix $\mathbf{X}$ at time t), while subscripts identify specific nodes (e.g., $\mathbf{x}_i$ is the vector for node i).

2.1. Problem Statement

In our case study, we focus on monitoring a bearing with a heterogeneous network of sensors. The data are collected from a test rig and comprise N sensor signals captured at discrete time instances. We particularly examine temperature and vibration data, which are represented as vectors:

$$\mathbf{x_T}^t = [x_{T_1}^t, x_{T_2}^t, ..., x_{T_{N_T}}^t]^T \in \mathbb{R}^{N_T}, \quad (1)$$

$$\mathbf{x_V}^t = [x_{V_1}^t, x_{V_2}^t, ..., x_{V_{N_V}}^t]^T \in \mathbb{R}^{N_V}, \quad (2)$$

where N_T and N_V are the number of each sensor type, while $x_{T_i}^t$ and $x_{V_i}^t$ denote the measurements at time t from the i^{th} sensor for temperature and vibration. Additionally, the rotational speed is recorded as $w^t \in \mathbb{R}$ at time t. Importantly, this characterizes the system's operational state and acts as a control parameter, rather than being a direct sensor measurement. To construct time-series samples for each sensor type, we employ a sliding window of length L, resulting in the following representations:

$$\mathbf{X_T}^{t_l:t} = [\mathbf{x_T}^{t_l}, \cdots, \mathbf{x_T}^{t-1}, \mathbf{x_T}^t] \in \mathbb{R}^{N_T \times L}, \quad (3)$$

$$\mathbf{X_V}^{t_l:t} = [\mathbf{x_V}^{t_l}, \cdots, \mathbf{x_V}^{t-1}, \mathbf{x_V}^t] \in \mathbb{R}^{N_V \times L}, \quad (4)$$

$$\mathbf{w}^{t_l:t} = [w^{t_l}, \cdots, w^{t-1}, w^t] \in \mathbb{R}^L, \quad (5)$$

where $t_l = t - L + 1 > 0$ marks the beginning of the observation window.

Our goal is to develop a function f, referred to as a virtual sensor, to accurately estimate the bearing load $\mathbf{y}^t \in \mathbb{R}^d$ at time t, targeting both axial and radial loads ($d = 2$). This function learns from heterogeneous sensor data $\mathbf{X_T}^{t_l:t}$, $\mathbf{X_V}^{t_l:t}$, and $\mathbf{W}^{t_l:t}$. Several challenges arise in developing such a function. Firstly, temperature and vibration signals exhibit inherently distinct characteristics. Temperature signals, typically monitored at lower frequencies, reflect gradual changes in the system's thermal state. In contrast, vibration signals are captured at high frequencies, offering insights into the immediate mechanical interactions and anomalies within the system. These differences in frequency not only affect the data processing strategy but also the interpretation of these signals in real-time monitoring. Additionally, the dynamic operating conditions introduce further complexity. Variations in load, speed, and environmental factors can significantly alter the base characteristics of both temperature and vibration data.

3. Graph-based Load Prediction Model

3.1. Framework Overview

We propose a novel Heterogeneous Temporal Graph Neural Network (HTGNN) for real-time bearing load prediction. Our framework learns a virtual sensor function, $f(\mathbf{X_T}^{t_l:t}, \mathbf{X_V}^{t_l:t}, \mathbf{W_T}^{t_l:t}) = \mathbf{Y}^t$, to accurately estimate the bearing load $\mathbf{Y}_t$ at a given time t. The HTGNN's main novelty lies in its ability to effectively capture the heterogeneity of sensor data and model the interactions between different sensor types. We achieve this by representing different sensor types as distinct node types in an aggregated temporal graph. This allows us to extract unique dynamics of each sensor type using tailored models and then model their interactions with specialized GNNs, This offers a significant advantage over traditional homogeneous temporal GNN methods that consider only a single type of relation. Fig. 1 illustrates the HTGNN architecture. The model's key components are:

1. **Heterogeneous temporal graph construction**, which constructs the bearing graph. (Sec. 3.2).
2. **Context-aware heterogeneous dynamics extraction**, which captures dynamics of different sensor types (Sec. 3.3).
3. **Heterogeneous interaction modelling**, which models complex interactions between diverse sensors (Sec. 3.4).
4. **Load prediction**, which predicts the bearing loads using the learned node representations (Sec. 3.5).

In the following, we detail each component of HTGNN.

3.2. Heterogeneous Temporal Graph Construction

Heterogeneous Static Graph. Following (Shi, 2022), a Heterogeneous Static Graph (HSG), denoted as $\mathcal{G} = (\mathcal{V}, \mathcal{E})$, consists of a node set $\mathcal{V}$ and an edge set $\mathcal{E}$, where nodes and edges can be of different types. The graph is associated with a node-type mapping function $\phi : \mathcal{V} \to \mathcal{A}$ and an edge-type mapping function $\psi : \mathcal{E} \to \mathcal{R}$, with $\mathcal{A}$ and $\mathcal{R}$ representing the sets of node and edge types, respectively, satisfying $|\mathcal{A}| + |\mathcal{R}| > 2$.

Heterogeneous Temporal Graph. Extending the concept of a Heterogeneous Static Graph (HSG), a Heterogeneous Temporal Graph (HTG) is defined as a sequence of HSGs over T time steps, $\mathcal{G}^T = \{\mathcal{G}^{t_1}, \ldots, \mathcal{G}^{t_T}\}$. Each graph $\mathcal{G}^t = (\mathcal{V}^t, \mathcal{E}^t)$

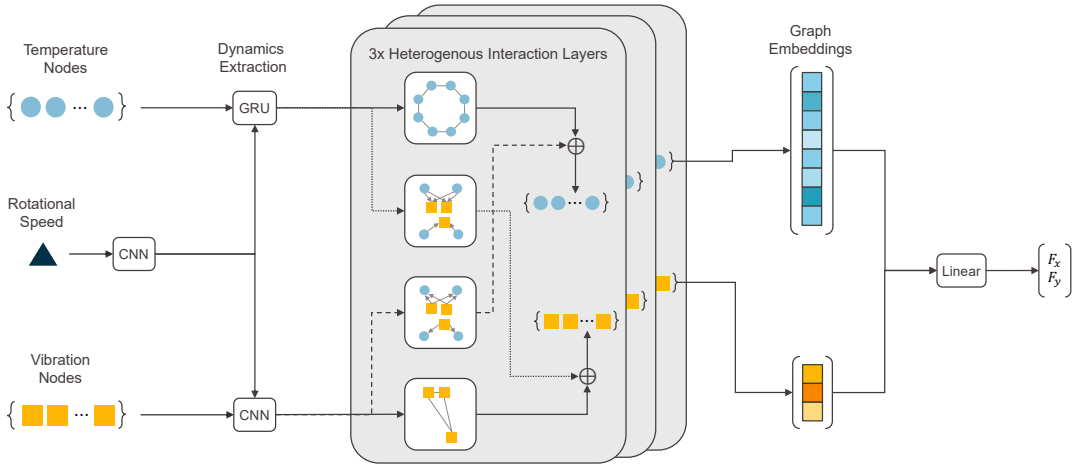

Figure 1. Architecture of the proposed Heterogeneous Temporal Graph Neural Network (HTGNN) for Load Prediction.

within this sequence represents the state of the graph at time t. The node and edge type mapping functions, ϕ and ψ remain consistent across time steps. The HTG can then be presented in an aggregated form as:

$$\mathcal{G}^T = \left(\bigcup_{t=t_1}^{t_T} \mathcal{V}^t, \bigcup_{t=t_1}^{t_T} \mathcal{E}^t \right), \tag{6}$$

combining nodes $\mathcal{V}^t$ and edges $\mathcal{E}^t$ across all time steps while preserving heterogeneity defined by ϕ and ψ.

Bearing graph construction. To model the heterogeneous sensor signals from a sensor network of the bearing system, we construct an HTG. This graph consists of two types of nodes: temperature (T) with attributes $\mathbf{X_T}^{t_l:t}$ and vibration (V) with attributes $\mathbf{X_V}^{t_l:t}$. Edge types represent relationships between node types: T-T, V-V, T-V, and V-T. We assume that these relationships are invariant over time. The HTG allows capturing the interactions and evolution of temperature and vibration signals within the bearing system. A visualization of the HTG is provided in Fig. 1.

3.3. Context-aware Node Dynamics Extraction

In complex systems, the behavior of individual nodes (sensors) is often influenced by the global operating context. In our bearing system, rotational speed can be considered a control variable, where increases in rotational speed lead to higher vibration intensity and faster temperature rises. To capture these important influences, our HTGNN model leverages context-aware dynamics extraction for node, following the strategy proposed in (Zhao & Fink, 2023). We extract contextual information from rotational speed and integrate it into the dynamics modeling of other sensor types using tailored techniques.

Rotational speed. To extract meaningful representations of operational state context from the rotational speed signal, which contains noise, we employ a 1D Convolutional Neural Network (1DCNN). We choose a 1DCNN due to its effectiveness in capturing patterns within time-series data. This process generates a hidden representation of dimensionality $\mathbf{h}_w \in \mathbb{R}^{d_w}$, which is used to augment the dynamics extraction from other sensor types. Our 1DCNN configuration adopts channel sizes [2, 2, 1], kernel sizes [3, 5, 5], and employs the SiLU activation function:

$$\mathbf{h}_w = \text{SiLU}\left(\text{1DCNN}(\mathbf{w}^{t_l:t})\right), \tag{7}$$

Temperature. We model the temperature dynamics using a Gated Recurrent Unit (GRU) network. For each temperature node j, the GRU updates its cell state at each time step τ to capture the temporal dynamics within the sequence $\mathbf{x_T}_j^{t_l:t}$. Importantly, we initialize the GRU's hidden state with $\mathbf{h}_w$ (rotational speed encoding from Eq. 7), allowing the operational state context to influence temperature dynamics:

$$\mathbf{h_T}_i^{\tau} = \text{SiLU}\left(\text{GRU-Cell}(\mathbf{x_T}_i^{\tau}, \mathbf{h_T}_i^{\tau-1})\right), \forall \tau \in [t_l, t]. \tag{8}$$

We use the final state $\mathbf{h_T}_i^{t} \in \mathbb{R}^{d_T}$, representing the encoded dynamics of node i up to time t and incorporating the operational state context, as the temperature node representation $\mathbf{h_T}_i \in \mathbb{R}^{d_T}$.

Vibration. Similar to the rotational speed encoding, we use a 1DCNN to model the dynamics of vibration signals. This process learns the hidden representation $\mathbf{h_V}_i^{t}$ from the vibration sequence $\mathbf{x_V}_i^{t_w:t}$ of a vibration signal i:

$$\mathbf{h_V}_i^{t} = \text{SiLU}\left(\text{1DCNN}(\mathbf{x_V}_i^{t_l:t})\right). \tag{9}$$

Finally, we concatenate $\mathbf{h_V}_i^{t} \in \mathbb{R}^{d_V}$ with $\mathbf{h_w} \in \mathbb{R}^{d_w}$ to form the complete node representation $\mathbf{h_V}_i = \left[\mathbf{h_V}_i^{t} \parallel \mathbf{h_w}\right] \in \mathbb{R}^{d_V+d_w}$. This incorporates both vibration dynamics and operational state.

3.4. Heterogeneous Interaction Modelling

We model heterogeneous interactions between different sensor types to capture the influence of operating context-aware dynamics. The proposed HTGNN model addresses two types of interactions within the graph: interactions among the same type of nodes and interactions across different types. This interaction modeling applies to node dynamics previously extracted in the node dynamics extraction section (temperature node from Eq. 8, vibration node from Eq. 9).

Same-type interactions. For interactions among nodes of the same sensor type, we employ Graph Convolutional Networks (GCNs) (Kipf & Welling, 2017). This allows us to refine node representations by aggregating information from neighboring nodes that share similar characteristics. Messages passed from node j to node i of the same type with relation $r_s \in \mathcal{R}_\text{s}$ are computed as follows:

$$m_{j\to i}^{(l,r_s)} = \frac{1}{\sqrt{\hat{d}_i}\sqrt{\hat{d}_j}} \mathbf{W}_{\phi(j),r_s}^{(l)} \mathbf{h}_j^{(l)}, \forall r_s \in \mathcal{R}_\text{s}, \phi(j) = \phi(k), \tag{10}$$

where $\hat{d}_i$ and $\hat{d}_j$ denote normalized node degrees, and $\mathcal{R}_\text{s}$ is the set of edge types connecting nodes of the same type.

Different-type interactions. To model the influence of one sensor type on another (e.g., the impact of temperature on vibration), we utilize Graph Attention Networks v2 (GATv2) (Brody et al., 2022). This mechanism dynamically computes attention-weighted messages, allowing the model to discern the varying importance of different neighbors. The attention coefficients $\alpha_{jk}^{(l,r_d)}$ for a target node i receiving a message from node j with relation $r_d \in \mathcal{R}_d$ are defined as:

$$\alpha_{jk}^{(l,r_d)} = \text{softmax}_j \left(\mathbf{a}_{r_d}^{(l)T} \text{LeakyReLU}(\mathbf{W}_{r_d}^{(l)} \cdot [\mathbf{h}_i^{(l)} \parallel \mathbf{h}_j^{(l)}]) \right), \tag{11}$$

where $r_d \in \mathcal{R}_d$ represents the set of edge types connecting nodes of different types. Messages are then computed as:

$$m_{j\to i}^{(l,r_d)} = \alpha_{jk}^{(l,r_d)} \mathbf{W}_{\phi(j),r_d}^{(l)} \mathbf{h}_j^{(l)}, \forall r_d \in \mathcal{R}_\text{d}, \phi(j) \neq \phi(k), \tag{12}$$

Aggregation and update: After aggregating messages of both same-type and different-types, the node representations are updated as follows:

$$\mathbf{h}_{\phi(i)}^{(l+1)} = \text{SiLU} \left(\sum_{r \in \mathcal{R}_s \cup \mathcal{R}_d} \sum_{j \in \mathcal{N}_r(i)} m_{j\to i}^{(l,r)} \right). \tag{13}$$

3.5. Load Prediction

Having extracted the context-aware dynamics of each node, we now combine the heterogeneous node representations to learn the virtual sensor function $f(\mathbf{X_T}^{t_l:t}, \mathbf{X_V}^{t_l:t}, \mathbf{W_T}^{t_l:t}) = \mathbf{Y}^t$. We achieve this by flattening the final node representations into a unified input vector for a Multilayer Perceptron (MLP). The MLP processes this aggregated information and outputs two values: the predicted axial and radial loads.

To ensure the model's accuracy under real-world conditions, the training objective is to minimize the L1 loss between the predicted bearing load $\hat{\mathbf{y}}^i$ and the actual load $\mathbf{y}^i$. We choose L1 loss for its robustness to outliers. This is particularly important in bearing systems, occasional measurement noise or transitional operating conditions might generate extreme data points. The loss is defined as $\mathcal{L} = \frac{1}{M} \sum_{i=1}^{M} \left| \hat{\mathbf{y}}^i - \mathbf{y}^i \right|$, where M is the number of training samples.

4. Case Study

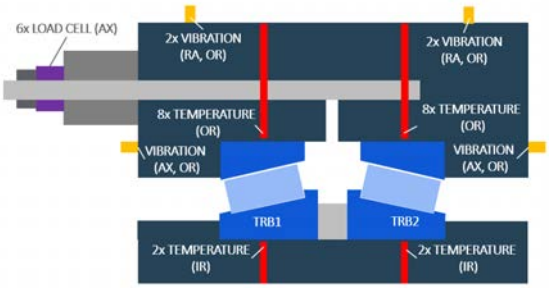

Figure 2. Cross-sectional view of the bearing test rig indicating sensor types and installation locations.

The data used in this study was collected at the SKF Sven Wingquist Test Centre (SWTC) using a face-to-face test rig with two identical single-row tapered roller bearings (TRBs). The TRBs feature a rotating inner ring, an outer diameter of 2,000 mm, an inner diameter of 1,500 mm, and a width of 220 mm, each incorporating 50 rollers. This setup aims to assess load conditions under various operational scenarios. Fig. 2 illustrates the sensor positioning on both identical TRBs. Ten temperature sensors are positioned on each bearing (eight uniformly distributed on the outer ring (OR), two on the inner ring (IR)). Additionally, six vibration sensors on the outer ring measure both axial (AX) and radial (RA) vibrations, with sensors placed at the top and bottom of the bearing housing for the radial direction.

Temperature is recorded at a 1 Hz sampling rate with a precision of 0.05°C. Vibration data is resampled to 1 Hz through RMS aggregations. Axial and radial forces are measured and controlled by several load cells, with an aggregated load value in both directions used as a ground truth for this study (note that the radial load cells are not shown in the figure).

4.1. Data Preprocessing

To reduce noise and transient fluctuations in the temperature data, we apply a moving average filter with a 1-minute window. We focus on the rate of temperature change because the bearing temperature responds gradually to changes in load and speed. We calculate this rate over 5-minute periods to

align with typical operational changes. This approach allows our model to identify the immediate impact of load changes on temperature, rather than the cumulative effects of historical variations. After preprocessing, we split both temperature and vibration signals using a sliding window, with a length of 30 seconds and a stride of 1 second.

4.2. Train-Test Split

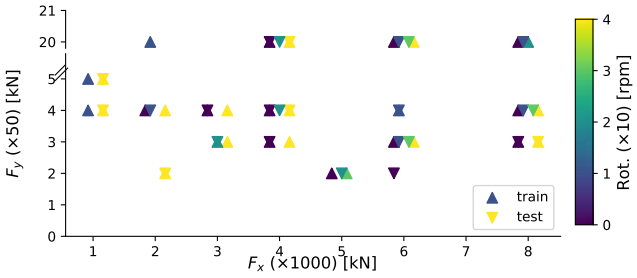

Figure 3. Train-test split of bearing load conditions for vibration data analysis (55% training, 45% testing)

We divided the dataset into training, validation, and testing sets. Approximately 55% of the data (924,230 samples across 31 unique operating conditions) was used for training and validation, with a random 80/20 split. The remaining 45% (699,340 samples across 25 unique operating conditions) was reserved for testing. We included only cases that maintained stationary operation for at least 10 minutes and up to 2 hours. We ensure that each case (a unique combination of axial load F_x, radial load F_y, and rotational speed) maintained stationary operation for at least 10 minutes and up to 2 hours. In total, the dataset comprised 56 unique operating conditions. To assess generalization, 12 conditions in the test set were unseen from the training and validation data. Fig. 3 provides a detailed breakdown of the specific conditions included in the training and test sets.

4.3. Heterogeneous Bearing Graph Construction

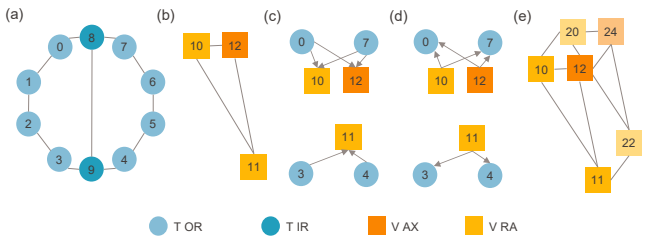

Figure 4. Heterogeneous graphs for bearing sensor network relationship modeling. (a) T-T (b) V-V (c) T-V (d) V-T (e) connectivity across two test rig bearings.

We construct a heterogeneous graph with nodes representing sensors (temperature (T) and vibration (V)). Temperature nodes are further classified into inner ring (T IR) or outer ring (T OR) nodes. V nodes, which are installed on the outer ring, are distinguished by their load direction: radial (V RA) or axial (V AX). We model four types of relationships: T-T, V-V, T-V, and V-T. Here, T-T and V-V represent homogeneous relationships, while V-T and T-V represent heterogeneous relationships. Node positions reflect physical sensor placement. Fig. 4(a) and (b) illustrate the connectivity within a single bearing based on physical proximity. Additionally, IR nodes are connected due to relatively uniform temperatures across the inner ring. Given that the test rig consists of two bearings, we connect them based on proximity, as illustrated in Fig. 4(e) for V nodes. We assume symmetrical (undirected) relationships within the same sensor type and model heterogeneous T-V and V-T relationships with directed edges, as demonstrated in Fig. 4(c) and (d).

4.4. Experimental Setup

Baseline. We employ a 1DCNN model as our baseline due to its established success in handling multivariate time series data. 1DCNNs are particularly well-suited for signal prediction tasks, making them a strong baseline. We adapt the design from (Chao et al., 2022), tailoring the architecture to our specific dataset through a grid search to minimize the mean absolute error (MAE) on the validation set. The explored parameter spaces included hidden channel dimension (20, 50, or 100), kernel size (3, 5, or 9), number of channels (20, 50, or 100), and number of layers (3, 4, or 5). The optimized model consists of four layers, each with 100 channels with 100 hidden dimensions, a kernel size of 9, batch normalization, a dropout rate of 0.5 for regularization, and a SiLU activation function (consistent with our proposed method). This configuration has a total of 209,403 parameters.

HTGNN hyperparameter tuning. We similarly used grid search for HTGNN hyperparameter tuning. To reduce the search space, we maintained a consistent hidden size across all layers and the same graph embedding dimension for all GNN modules. The search space comprised: node embedding dimension (values of 10, 15, 20), number of GNN layers (2 or 3), GNN hidden dimension (40 or 80), graph head hidden dimension (40 or 80), and number of graph head layers (2 or 3). The optimal HTGNN configuration consists of a node embedding dimension of 10, 3 GNN layers with a hidden dimension of 80, and a graph head dimension of 40. The configuration has a total of 142,394 parameters.

Training. We optimized the HTGNN and 1DCNN models using the AdamW optimizer with a learning rate of 1e-3. Training was continued for up to 50 epochs with early stopping at 30 epochs with patience of 10 steps. We used a batch size of 512 and minimized L1 loss (defined in Sec. 3.5). To ensure the robustness of our results, experiments were repeated five times with different initializations, and the mean and standard deviation of the results were reported.

Table 1. Averaged model performance over cases and runs

		1DCNN	HTGNN
Seen	MAE_{F_x} (kN)	531.3	**203.1**
	MAE_{F_y} (kN)	33.2	**12.4**
	$MAPE_{F_x}$ (%)	12.8	**4.5**
	$MAPE_{F_y}$ (%)	12.0	**5.7**
Unseen	MAE_{F_x} (kN)	1765.5	**1649.7**
	MAE_{F_y} (kN)	58.7	**57.4**
	$MAPE_{F_x}$ (%)	33.2	**29.2**
	$MAPE_{F_y}$ (%)	17.8	**15.8**

5. Results

We evaluate the model performance on Mean Absolute Error (MAE) and Mean Absolute Percentage Error (MAPE).

Superior performance on seen conditions. Tab. 1 highlights the HTGNN model's superior performance advantage compared to traditional 1DCNN models in predicting seen conditions. Notably, this improvement is evident in both axial (Fx) and radial (Fy) load predictions, with the HTGNN achieving approximately one-third the MAPE for Fx and half the MAPE for Fy compared to the 1DCNN. Importantly, the scenario considered here reflects real-world conditions. It is feasible for the sensor roller to collect load data across all typical operating conditions before its battery depletes, allowing the HTGNN to serve as a reliable virtual sensor.

HTGNN's physical prior. The superiority of the HTGNN in unseen conditions highlights the advantages of explicitly modeling heterogeneous sensor relationships. The physical connectivity in the bearing system acts as an effective inductive bias for the model. We attribute the improved performance of the HTGNN to its ability to capture complex interactions between temperature and vibration measurements, which often exhibit interdependent behaviors in bearing systems. The proposed architecture of the HTGNN is ideally suited to represent these heterogeneous relationships. In contrast, 1DCNN's homogeneous approach to processing variables limits its ability to model such complex interdependencies, leading to higher prediction errors.

Better generalizability. Fig. 6 presents the mean MAPE in F_x and F_y for various bearing load conditions, with unseen conditions highlighted in gray. Although the HTGNN generally outperforms the CNN in handling unseen conditions, as detailed in Tab. 1, there are instances depicted in Fig. 6 where CNN shows competitive performance. This challenge in generalization can be partially attributed to the dynamics shown in Fig. 5, which illustrates the significant effects of rotational speed changes on both vibration intensity and the rate of temperature change. Additionally, the underrepresentation of certain rotational speeds in the training data may impede interpolation, impacting the generalization capabilities of both models. Interestingly, as depicted in Fig. 5, the

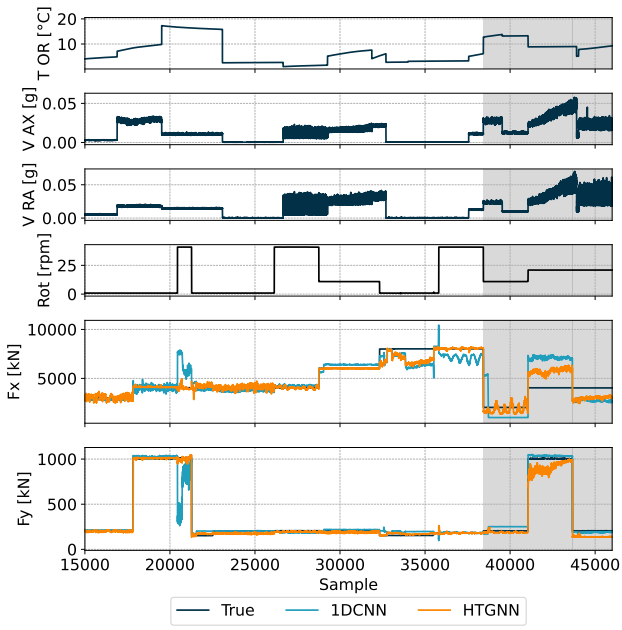

Figure 5. Examples of input signals and load prediction performance. Shaded areas indicate unseen conditions.

HTGNN tends to generalize better for the commonly encountered unseen rotational speed of 10 rpm than for the less frequently occurring speed of 20 rpm, across both axial and radial loads. For details on the distribution of conditions in the training and testing sets, see Fig. 3.

6. Conclusion

In this research, we propose HTGNN, a novel virtual sensor that accurately maps vibration and temperature signals under varying rotational speeds to axial and radial bearing load predictions. Our findings demonstrate that HTGNN outperforms 1DCNN models, particularly when trained on representative conditions. The success of HTGNN highlights the importance of incorporating physical priors and inductive biases: by modeling the connectivity of the bearing sensor network, HTGNN effectively captures the complex interactions between temperature and vibration. This superior performance suggests HTGNN's potential as a reliable virtual sensor in real-world applications, replacing battery-powered load sensors after their lifespan. This could facilitate proactive maintenance, reducing unexpected breakdowns and optimizing the lifespan of bearings. However, the models cannot generalize as effectively to unseen speed conditions. Future work should focus on investigating datasets that include a broader range of speed conditions in the training to determine if the model can improve its generalization capabilities. Additionally, measuring the model's performance using real load data measured from sensor rollers in real operations and not just from the test rig would be valuable.

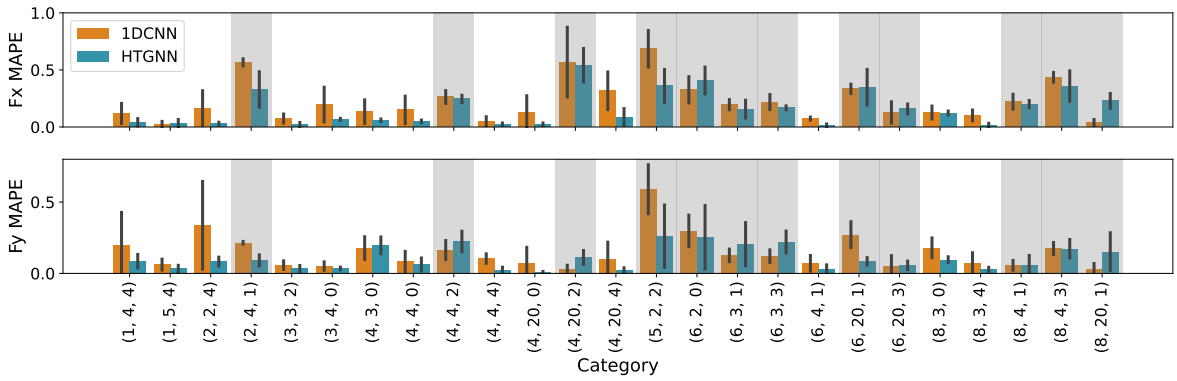

Figure 6. Mean test set performance averaged over 5 runs of CNN and HTGNN on bearing load conditions $F_x(\times 1000)$ [kN], $F_y(\times 50)$ [kN], and rotational speed $(\times 10)$ [r/min]. Shaded areas indicate unseen conditions.

ABSTRACT

The degradation of a system is a time bound phenomenon, which leads to the deterioration of turbomachinery, in terms of performance and reliability. If undetected and not acted upon in time, this could also lead to sudden system failure, resulting in unplanned unit downtime and maintenance. Unplanned downtime of a turbomachine leads to severe production loss for the end customer and consequent economic damages. Early detection of a degradation pattern would provide the customer with the opportunity to timely carry out corrective actions, preventing an unscheduled down time. The paper evaluates degradation identification methodology currently known from literature and finds them not accurate enough for general purpose application required by the solution. The paper discusses a novel methodology which can accurately detect degradation patterns of timeseries data. Critical features of this methodology are novel time-based correlation enabled regression model with variable observation window, autonomous training, and automatic adjusting capability to incorporate operating behavior change or physical system replacement. This leads to high accuracy, high generalization, and domain agnostic application capability. Moreover, particular focus is given to achieving high probability of detection and a low probability of false alarm. The paper demonstrates the performance achieved by the methodology when applied to the field of prognostics and diagnostics of IoT connected turbomachines through 50+ real application cases.

1. INTRODUCTION

Rotating Turbomachines play a critical role in Industrial domain in Oil & Gas / Energy Plants serving various applications, such as Liquified Natural Gas (LNG), pipeline, fertilizers, refineries and power generation units. One of the most important aspects for the operators of these turbomachines are continuous availability and reduced downtime covering the entire life cycle. Iannitelli et al. (2018) highlighted that unscheduled shutdown of the turbomachines can have impact on the whole plant downtime with associated significant loss of production.

Baker Hughes is a leading Original Equipment Manufacturer of Rotating Turbomachines with a wide Product Range of Gas Turbines, Centrifugal Compressors, Pumps, Steam Turbines, Electric Motors, Axial Compressors, etc. These products have been operating in various Oil & Gas and Power Generation facilities around the globe covering all the segments of the entire value chain of Oil & Gas industry and have an unparallel operating history.

Baker Hughes has developed monitoring capabilities which are offered as a service, applied to a broad installed fleet of rotating equipment including gas turbines. Baker Hughes' iCenter ecosystem continuously acquires different sensor parameters of its deployed assets at customer premises. These large number of operational data from the everyday operation of turbomachines is usually collected and analyzed by means

of analytics, component models and rules implemented by subject matter experts, as soon as new data is transferred to the monitoring center. Allegorico & Mantini (2014) indicated that anomaly detection rules and models are designed to scan through the data and notify the monitoring and diagnostic engineers, if any anomalies or emerging problems are detected. All alerts are analyzed by diagnostic engineers along with trouble shooting analysis and useful insights are sent to customers comprising set of recommendations.

With turbomachinery covering various applications and operating in different operational scenarios, Baker Hughes follows a hybrid approach consisting of physics and data driven methods, where strong OEM knowledge is further enhanced by state-of-the-art data science methodologies to create robust solutions. This approach can be applied to the entire fleet of operating machines, to bring economies of scale and help maximize the availability and uptime of the monitored units.

1.1. Degradation phenomena

In Turbomachines, degradation phenomena accumulate over a period of time. Zagorowska, et al. (2019) indicated that degradation in turbomachine is an unwarranted phenomenon which deviates from the expected behavior and that changes the behavior of the affected system. Few examples of degradation include clogging of filters, performance degradation of compressors, increase spread of exhaust temperature measurement of gas turbines, etc. If degradation is not detected early, this may lead to a gradual build up above the mechanical integrity of the system which can cause sudden failures, break down and consequent downtime of the turbomachine with production loss for the end customer. A typical example of degradation in turbomachinery systems concerns filters. A filter acts as a mechanical stop for contaminants, to make sure they do not pass through the downstream systems. Due to their nature, filters have a tendency to get clogged or choked after a period of operation with gradual buildup of contaminants, creating a higher resistance to the flow. To detect abnormal operating conditions, analytics could be built to observe the behavior of the component by monitoring physical quantities, such as the pressure drop on the filter. This can be analyzed to infer information on its actual defect state. The ability to promptly detect these deteriorating conditions could be useful for implementing corrective actions.

Generally, degradation phenomena cannot always be directly measured, however it is possible to make use of indirect information or calculated parameters to verify the level of degradation of a system (for example the level of fouling of an axial compressor can be determined indirectly through the analysis of its compression efficiency). In general, the presence of a degradation phenomenon is signaled by the fact that the timeseries of interest shows a drift over time. If the timeseries has an upward trend, it is considered a positive degradation, otherwise it is considered a negative degradation.

In the current study, authors have focused on univariate time series with a stationary behavior in the normal operating range of the system. In these cases, a monotonic signal trend is considered anomalous and possibly linked to an ongoing degradation phenomenon. In the event that this monotonic trend is accompanied by a similar behavior of other signals related to it, the event is considered non-independent and therefore not anomalous.

Figure 1 shows a typical behavior of a sensor going through a degradation trend. As the sensor value increases over a period, this is considered a positive degradation phenomena.

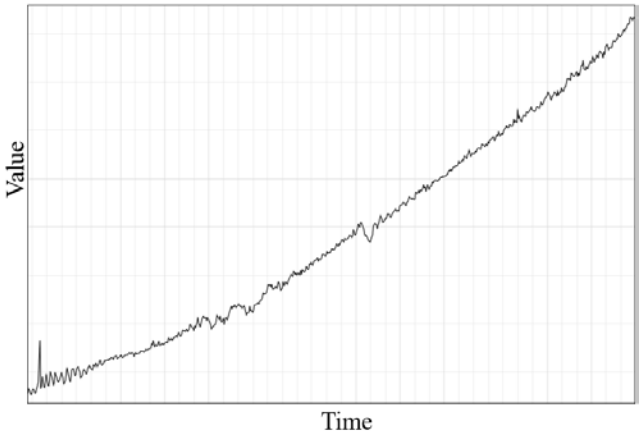

Figure 1. Example of a degradation pattern in a generic signal

In the analysis of degradation phenomena, another factor to consider is the observation time window. Figure 2 highlights the behavior of the same signal over a longer observation time.

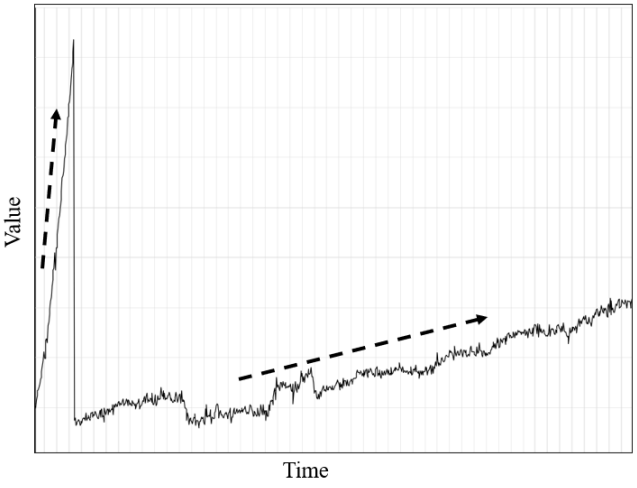

Figure 2. Example of multiple degradation patterns for the same signal

In this case, two different degradation profiles can be noted that evolve with two different time scales. The first degradation profile is quite sudden, while the subsequent one is rather slow and it build up over a longer period of time. The sudden drop down of the signal after the first degradation pattern is currently excluded from the current analysis.

2. EXISTING METHODS FOR TREND IDENTIFICATION

2.1. Monotonicity Trend – Mann-Kendall Test

The purpose of the Mann-Kendall (MK) test (Mann 1945, Kendall 1975, Gilbert 1987) is to statistically assess if there is a monotonic upward or downward trend of the variable of interest over time. A monotonic upward or downward trend means that the variable consistently increases or decreases through time.

The MK method calculates test statistics as the count of positive and negative deltas in the dataset.

$$\boldsymbol{S} = \sum_{\boldsymbol{j-1}}^{\boldsymbol{n-1}} \sum_{\boldsymbol{i-j+1}}^{\boldsymbol{n}} \boldsymbol{sgn}(\boldsymbol{x_i} - \boldsymbol{x_j}) \quad (1)$$

Where x is the observation value, i and j are time indices.

If number of observations, $n \geq 10$, Variance of S is calculated as follows.

$$VAR(S)_{MK} = \frac{1}{18}\left[n(n-1)(2n+5) - \sum_{p-1}^{g} t_p\,(t_p-1)(2t_p+5)\right] \quad (2)$$

where g is the number of clusters of data points having the same data value and t_p is the number of observations in the p th group.

For example, in the sequence of observation in time $\{28, 32, 34, 2, 29, 32, 2, 34, 32\}$ there are $g = 3$ tied groups. Tied group $t_1 = 2$ for tied value of 2, tied group $t_2 = 3$ for tied value of 32 and tied group $t_3 = 2$ for tied value of 34

MK Test statistics is calculated as follows:

$$\begin{aligned} Z_{MK} &= \frac{S-1}{\sqrt{VAR(S)_{MK}}} \; if\; S > 0 \\ Z_{MK} &= 0 \; if\; S = 0 \\ Z_{MK} &= \frac{S+1}{\sqrt{VAR(S)_{MK}}} \; if\; S < 0 \end{aligned} \quad (3)$$

A positive value of Z_{MK} indicates an increasing trend, while a negative value of Z_{MK} indicates a decreasing trend.

The MK test was applied on the generic signal in Figure 3, which shows a clear degradation trend in different periods of time. The points where the increasing trend is detected are highlighted in orange.

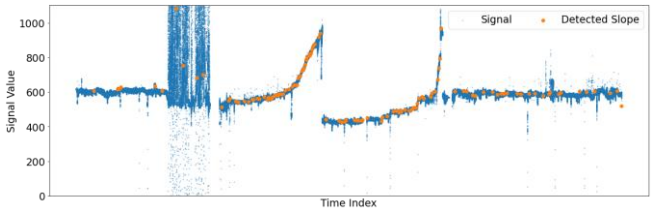

Figure 3. MK Test results

As observed from the Figure 3 for the given data set, the method was promising in terms of detecting the slope region, however it produced many false positives. To improve this manual threshold tuning is required, however this is not a practical and most effective solution for more general and scalable applicability of the methodology.

2.2. Theil Sen Slope Method

Theil (1950) proposed the median of pairwise slopes as an estimator of the slope parameters. Sen (1968) extended this estimator to handle ties. Sprent et al, (1993) indicated that Theil-Sen estimator is a regression method, robust to outliers.

Thiel-Sen estimator calculates the slope by taking the median of the slopes between each pair of points in the data. For a pair of points, $(x_i,\ y_i)$, *the slope is calculated as*

$$slope = \frac{(y_j - y_i)}{(x_j - x_i)} \quad (4)$$

An intercept between each pair of points, can be calculated as

$$b_i = y_i - m * x_i \quad (5)$$

where m is the Thiel-Sen slope. Following the similar methodology of finding the median of each slope between each pair of points, median of intercept is calculated.

Theil-Sen Slope method was applied on the same signal of Figure 3 after setting an appropriate threshold to detect the degradation pattern. Figure 4 shows the results of the Thiel Sen slope method.

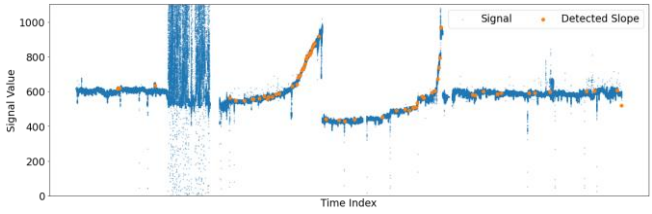

Figure 4. TS Test results

As observed from Figure 4 for given data set, Thiel-Sen method identifies trending patterns, however it still generates many false positives and is strongly dependent on the threshold value, which need to be manually adjusted based on the profile of the signal. This limits the general purpose and scalable applicability of the methodology.

3. NOVEL METHODOLOGY

Abernathy et al. (1973) indicated that sensor measurement are affected by noise and noise increase over a period of time as the sensor ages. Noise of the sensor measurement impacts the method development and it's ability to identify the degradation patterns. Furthermore, the degradation detection method must be easily scalable to other use cases and be able to work with different degradation patterns such as slow and fast degradations and presence of noise.

De Giorgi et al. (2023) have done an exhaustive literature review on detecting degradation phenomena as part of prognostic and diagnostics for jet engine health monitoring and have found that current literature degradation health monitoring techniques have certain gaps in terms of lack of standardization, lack of real world testing/comparative studies and limited consideration of multiple degradations.

Following the above analysis, it was concluded that current methods available in the literature may not effectively provide a generalized and robust solution. Furthermore, the existing methods are quite difficult to be fine-tuned in real application scenarios and are prone to generate a high rate of false positives.

As seen in Figure 3 & Figure 4, the degradation profile of a signal is a function of time. This could be caused by various factors, such as the intrinsic structure of the system, external interferences, natural aging and so on. In order to effectively capture degradation phenomena which evolves over a different time scale, authors had decided to distinguish 2 types of degradation profiles:

- Fast Degradation – These degradation profiles are quick with respect to typical behavior of the given signal/system.
- Slow Degradation – These degradation profiles slowly build over a period of time and may not show an obvious degradation behavior when the observation window is small.

Authors have then devised a novel methodology by filtering the signal into a High Frequency component and a Low Frequency component.

The High Frequency component of the signal is calculated as:

$$High\ Frequency_t = High\ Frequency_{t-1} * \alpha_t + Signal_t * (1 - \alpha_t) \quad (6)$$

Where α is the exponential smoothing average constant. As degradation phenomena are function of time and depends on past values, this constant has been selected to keep a balance between past observations and current values. After a careful analysis and various tests on real cases, this value was kept at 0.35.

The low frequency component of the signal is then calculated as

$$Low\ Frequency_t = Signal_t - High\ Frequency_{t-1} \quad (7)$$

Figure 5 shows the original signal and decomposition of the same into high & low frequency component of the given signal. Observing Low Filter, it is evident that, this features carries out the denoising of the signal.

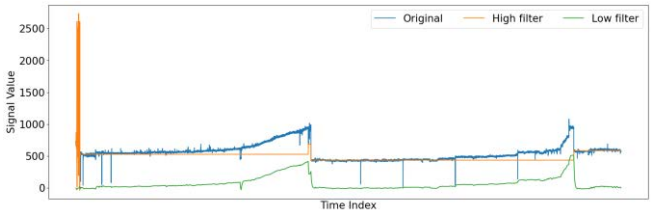

Figure 5. Signal decomposition in Low frequency

A novel time-based correlation approach was used to identify the degradation patterns of the low frequency component. The approach was based on the observation that if the signal is trending up or down over a period of time, it shall have a strong correlation with time, which will be positive or negative respectively.

The correlation coefficient was obtained by normalizing the covariance of the low frequency signal.

The covariance of the signal is calculated as

$$Covariance = E[XY] - (EX)(EY) \quad (8)$$

The variance is calculated as

$$Var_X = E[X^2] - E[X]^2$$
$$Var_Y = E[Y^2] - E[Y]^2 \quad (9)$$

Then the correlation coefficient is calculated as

$$Corelation\ Coefficient = \frac{Covariance}{\sqrt{Var_X * Var_Y}} \quad (10)$$

A threshold of 0.9 was then applied to this correlation coefficient to detect sections of the signal with high slope, as showed in Figure 6.

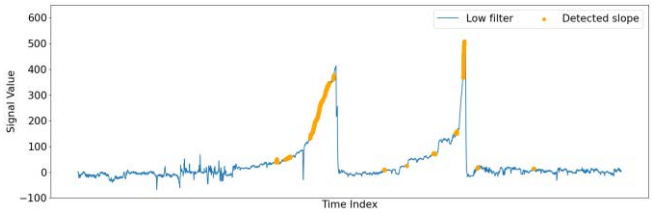

Figure 6. Time based correlation on Low frequency

As observed from Figure 6, the method is more robust and less sensitive if compared to previously discussed methods. It effectively captures the sections with high slopes; however, it is not capable of capturing the areas where degradation is slowest and it also generates some sporadic false alarms.

To overcome the limitation of the current method on the slow degradation patterns, the authors devised the dedicated approach described in the next paragraph.

3.1. Methodology for Slow Degradation

Verbai et al. (2024) applied linear regression method to identify and predict the degradation phenomena. Authors have further used the linear regression method to develop the methodology to capture slow degradation

The linear regression model is expressed as:

$$\hat{y}_i = b_0 + b_1 * x_i \quad (11)$$

Where $\hat{y}_i$ is the predicted value, b_0 is the intercept of the line, b_1 is the slope of the line, and x_i is the actual value.

The linear regression model is fit on 1 week of Low frequency data of the signal and further analysis is carried out on the line slope b_1, R^2 error and Root Mean Square Error.

R-squared (R^2) of the linear regression model is calculated as

$$R^2 = 1 - \left(\frac{SS_{residual}}{SS_{total}}\right) \quad (12)$$

Where $SS_{residual}$ is the sum of squares of the residual errors and SS_{total} is the total sum of the errors.

R^2 indicates the proportion of data points which lie within the line created by the regression model. A higher value of R^2 is desirable as it indicates a better fit.

To ensure a good regression model for subsequent analyses, a minimum value of R^2 score is required.

The Root Mean Square Error (RMSE) indicates the quality of predictions. It evaluates how far predictions are from the measured true values using Euclidean distance.

$$RMSE = \sqrt{\sum_{i=1}^{n} \frac{(\hat{y}_i - y_i)^2}{n}} \quad (13)$$

Where $\hat{y}_i$ is predicted value, y_i is actual true value and n is number of observations.

Above regression methodology was applied on low frequency of 7 days data. However in order to early detect the degradation phenomena, observation window considered was 1 day.

To further make sure that generated errors are within the typical operating range of the signal a threshold was applied on RMSE as a function of normal operating range of the signal.

To make sure, that only important degradation patterns are captured, a minimum threshold value was applied on the slope on top of already discussed threshold on R^2 and RMSE values. The proper value of the threshold was selected while doing an exhaustive testing to obtain a balance between False Positive and False Negative.

Results of Figure 7 shows the degradation pattern captured by the new methodology with high accuracy.

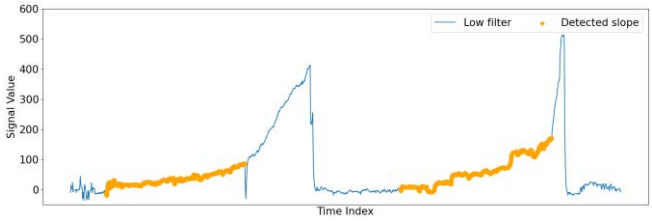

Figure 7. Detection by Slow Degradation Methodology

3.2. Time Window for Fast and Slow Degradation

Based on the extensive tests carried out and iteratively optimized, authors have specified 2 different observation periods, 24 hours and 7 days, which have proven to be effective on use cases that are common in our industry.

Table 1. Time Window duration

Degradation Type	Time Window
Fast Degradation	24 Hours
Slow Degradation	7 Days

3.3. Autonomous Training and Self Adjusting Capability

The developed methodology is intended to have a general-purpose application by covering various types of signals that are typically acquired on turbomachines. Moreover, it must

be able to function correctly for signals that span in a wide operating range.

To meet the above requirement, authors have developed a methodology to characterize the "Normal State" of operation of a signal, namely its typical operating range known from the past.

In order to define an operation range of the signal and detection of potential anomalous behavior of the signal, authors have then developed a typical operating range of signal called as confidence band.

Confidence Band is a function of the following signal statistical indicators and is calculated dynamically:

$$Confidence\ Band = f(Mean, Standard\ Deviation, Quantiles) \quad (13)$$

Any sustained operation outside of the normal state could be considered as a potential degradation pattern.

The method continuously updates the above statistics and redefines the system normal state when needed. Other factors that influence the signal behavior are the maintenance events such as major inspections, repairs, replacements, etc. and other external contributors like the process load and ambient conditions, which can lead to different operating behavior of a given signal. The algorithm is designed to self-adjust when this change in signal behavior occurs.

4. TECHNICAL CASES

Authors have extensively applied and tested this methodology on a variety of turbomachinery signals acquired by Baker Hughes' monitoring service. In the following section the authors reported some examples of real degradation events captured by applying this methodology on historical data. If not detected promptly, the progression of the degradation phenomenon could have caused the signal of interest to reach protection thresholds, causing alarms or even the trip of the unit. A trip leads to unavailability of the turbomachine and the loss of production for the end customer, with consequent economic damage.

The implemented methodology provides early detection of degradation of critical signals and provides the opportunity to perform corrective actions and increase the availability of turbomachinery.

This section captures few of the real technical cases captured from variety of signals acquired by Baker Hughes' monitoring service. Few of these signals are part of Centrifugal Compressors Auxiliary systems, Gas Turbines, etc. Some of the examples of these signals are Filter Differential Pressure, Vent Pressure, Compressor Efficiency etc,. As discussed before, these signals are expected to be stationary with in the normal operating range of the system. Any independent monotonic trend identification is considered to be anomalous behavior of the signal.

The grey are highlighted in the figures represents Confidence Band of the signal, which is the expected range of operation. As discussed before, methodology keeps on dynamically calculate this confidence band. Anomaly events are generated when the signal exceeds this confidence band.

4.1. Example of Fast Degradation

This section describes the example in which underlying degradation phenomena is Fast in nature and happens with in time window of 24 hours.

4.1.1. Fast Degradation Profile 1

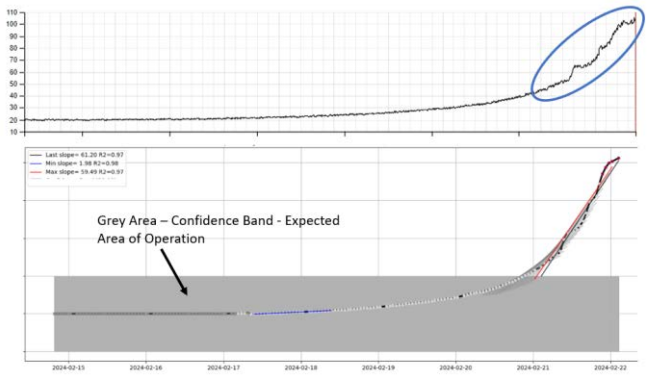

Figure 7. Detection of Fast Degradation event 1

4.1.2. Fast Degradation Profile 2

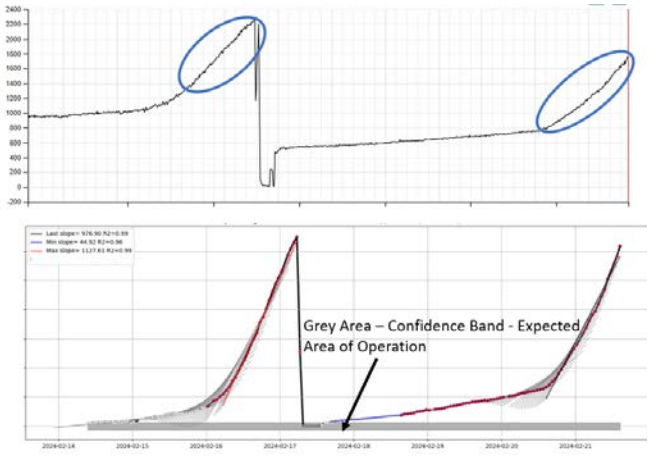

Figure 8. Detection of Fast Degradation event 2

As seen from Figure 7 & Figure 8, the methodology can effectively capture fast degradation of the signal, even when signal has high oscillation or a reset.

4.2. Example of Slow Degradation

This section describes the example in which underlying degradation phenomena is Slow in nature, accumulates over a longer period of time and happens with in time window of 7 days.

4.2.1. Slow Degradation Profile 1

Figure 9. Detection of Slow Degradation event 1

4.2.2. Slow Degradation Profile 2

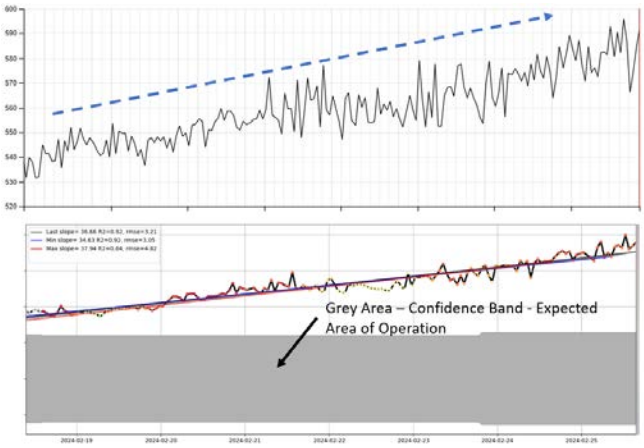

Figure 10. Detection of Slow Degradation event 2 – Noisy signal

In some cases, the monitored signal can be noisy and this may impact the detection capability of the algorithm. A such example is visible in Figure 10, where the raw signal is noisy, but at the same time shoes a slow degradation process. With the novel approach of the methodology, segregating low frequency of the signal, the methodology is effectively able to denoise the signal and accurately captures the degradation trend.

4.3. Timely Corrective Actions

The degradation patterns detected by this analytic could be associated to some specific failure modes of the system, thus mapping of this potential root cause with detected type of degradation phenomena is of high importance. Based on strong OEM knowledge, Baker Hughes has identified up to 8 root causes for degradation patterns. Some of these root causes are Instrument deviations, Clogging, Condensation, Process fluctuations, Fouling etc. With the given identified root cause, diagnostic engineers then propose a targeted corrective actions to the site service engineers. Implementation of this corrective actions eventually leads to improved uptime of the unit with no unscheduled shutdowns/repairs for the end customer.

5. Result Analysis

To summarize, the novel methodology proposed by the authors, separates High frequency and Low frequency component of the signal to effectively denoise the data and separate the rapid changes happening into the signal.

As the degradation profile is strongly dependent on the time interval, currently 2 observation windows have been considered. Results have shown that method is effectively able to capture the Fast and Slow degradation of the signal, whereas standard methods like Mann Kendall and Thiel Sen slope has not been very effective and accurate in either identifying the degradation trend or wrongly capturing the degradation. It is to be further noted that, analytic has quite good generalization capability as it is able to catch wide operating range of signal as observed from Figure 7, 8, 9 & 10.

In order to validate the methodology on a larger data set, the approach was applied on 600+ turbomachines being monitored by Baker Hughes's iCenter eco system. With extensive understanding of Turbomachines system, signals for validation were selected in such a way that signal show a degradation trend due to inherent malfunctioning of the system. Some of the examples of these signals are Filter Differential Pressure, Vent Pressure, etc. Methodology was tested in a Batch process where incoming data with a given sampling frequency of 1 minute was processed in a batch of 2 hours.

To calculate the key performance indicators of the methodology, a manual approach was used which required a great effort from the subject matter experts to analyze all the events generated by the algorithm. The methodology was also tested on a number of real cases of degradation that were already known to the monitoring service.

Table 2 shows the performance metrics of the method implemented.

Table 2. Performance of Method during Validation

Details	Value
Number of Assets on which methodology was applied	600+
Average processing time for 2 hours batch with 1 minute sampling	1.1 seconds / asset
Total Degradation events captured on multiple signals	50+
Probability of Detection	> 95%

False Positive Rate	< 5%
False Negative Rate	< 5%
Precision	> 95%
Recall	> 95%

6. CONCLUSION

In this paper, the authors discussed the problem of detecting degradation phenomena in the application field of turbomachinery and explained the importance of implementing early detection of such events in Baker Hughes continuous monitoring service.

Authors have also described degradation phenomena which accumulates with time scales of different duration, happening on different signals acquired on turbomachines. The existing methods for the identification of degradation patterns, already known in the literature, have not been deemed accurate enough for general purpose applicability required by the solution. A novel approach has been developed comprising strong features, like the extraction of low frequency component of the signal, the incorporation of time based correlation and linear regression model applied on multi time observation window. It was shown that these unique features empower the method with accurate detection rate, precision and recall. The proposed methodology also embeds autonomous learning and auto setting capability that enables generalized application covering multiple types of signals with wide operating ranges.

To validate the new methodology on a large data set, tests were performed on historical timeseries data from more than 600+ turbomachines being monitored by Baker Hughes's iCenter eco system. The signals were chosen on some families of mechanical systems which generally can present degradation phenomena during their life cycle. The paper then also discusses some real detection cases and explains the process through which the probable associated root causes are identified and the corrective actions are suggested to the final customers for field implementation. Finally, the performance matrix of the methodology is shown, which was found to comply with the stringent detection requirements followed by Baker Hughes.

BIOGRAPHIES

Unnat Mankad is a Staff engineer, Mathematics and Data Science, Service Engineering at Baker Hughes, Bengaluru, India. He received his master's degree in mechanical engineering from Birla Institute of Technology and Science (BITS), Pilani. In his current role, Unnat develops complex analytics for on-line prognostics, diagnostics, and predictive maintenance of Baker Hughes' iCenter covered turbo machines. As expert of time series sensor data analysis, he also supports data science and machine learning driven algorithm developments focusing on emissions, reliability, and availability improvements.

Gabriele Mordacci is the iCenter engineering Manager at Baker Hughes, Kuala Lumpur, Malaysia. He received his master's degree in Aerospace engineering from Universita degli studi (UNIPI), Pisa Italy, with a final thesis on the High speed gearbox diagnostic with microphone dynamic analysis. He worked in RMD developing the first analytics based on the fleet statistical for different type of technology and translating the field experience in digital application. As OEM expertise supports diagnostic and data scientist to prepare and validate the new analytics algorithm and output.

Aidil Fazlina Binti Hasbullah *is a Diagnostic Engineer at Baker Hughes, Kuala Lumpur, Malaysia. She received her former tertiary education from Universiti Teknologi PETRONAS (UTP) in Electrical & Electronic Engineering major in Instrumentation and Control. In her current role, Aidil Fazlina focuses on remote monitoring and diagnostics of turbo machines of global installed fleet. She also act as focal point for onshore LNG plants for Malaysia and India fleet. Prior joining Diagnostic team, she has experience of working with LNG plant as Instrument engineer, leading Factory Acceptance test for instrument control system. She also actively collaborates with Baker Hughes' Data Scientists to support advanced analytics development to improve the reliability and availability of the turbo machines*.

Fahzzira Jaafar is a Product Service Engineer at Baker Hughes, Kuala Lumpur, Malaysia. She received her bachelor's degree in mechanical engineering from Universiti Teknologi Malaysia (UTM). Fahzzira has expertise in Balance of plant and a strong experience in monitoring, analysis and troubleshooting of different type of turbomachines covered by Baker Hughes's RMD services. Prior joining Product Services team, she has been involved in number of EPCC (Engineering, Procurement, Construction and Commissioning) and DED (Detailed Engineering Design) projects for Offshore and Onshore applications. In her current role, she is responsible for all activities relating to enhancing services technology integrating customer data, or capturing engines/products reliability, availability, maintenance, safety and other performance parameters.

Carmine Allegorico is a Senior Principal engineer and experienced data scientist at Baker Hughes, Firenze, Italy. He received his master ' s degree in mechanical engineering from University of Napoli Federico II. In his current role, Carmine is a technical point of reference for the analytics discipline providing engineering guidance to other teams, helping to train new engineers and keeping abreast of industry trends and issues. He provides consulting during the development and implementation of advanced solutions for the on-line diagnostic and predictive maintenance, coordinates the creation of internal processes and support the adoption of new platforms and technologies

Gionata Ruggiero is currently covering the position of Asia Pacific Service technology leader and he is currently based in Kuala Lumpur where he lives with his family. In his 20+ year of international experience having worked in Florence, Nigeria, Angola and India and covered several positions in the engineering organization: Subject Matter of expert, Project engineering serving different NOC and IOC, and Monitor & Diagnostic bringing innovative idea with an inclusive approach. Leader of a multicultural and multidisciplinary team, Gionata is responsible of the engineering support since the Installation and commissioning until the end of the life cycle included the IET iCenter in Kuala Lumpur. He is known as Customer focus engineering able to identify solutions and pioneering new technology injection mixing SME and digital domains. Gionata hold the Bachelor of Industrial Engineering and he recently completed advanced studied in Digital transformation and Clime Change Toward Net Zero Emission.

Case Study of Product Development through Generative Design according to Anemometer Replacement Cycles

ABSTRACT

Product Lifecycle Management (PLM) systems are commonly used to manage various product data generated throughout the product lifecycle. This paper explains the results obtained by multiple participants using commercial software within the PLM environment to perform structural and vibration analyses of an Anemometer. Generative design techniques were employed for 3D CAD modeling of the Anemometer, and the commercial analysis software NASTRAN was used for simulation analyses. The open-source PLM system ARAS Innovator's project and workflow management modules were utilized to manage the generated design data, allocate tasks among participants, and control schedules. Through this approach, we propose a method to predict and manage the replacement cycle of Anemometer.

Key Words: Generative Design, PLM, Nastran, ARAS Innovator

1. INTRODUCTION

Currently, the technology for generative AI is very active and progressing at a very fast pace. [1] This direction is also being applied to industrial companies to reflect generative design [2], and this research is being conducted through a research project as described later.

This study is still a work in process, and the model applied in this study evaluated the structural stability of an anemometer, one of the products of the client company, and presented a case of applying it to ARAS Innovator, an OPEN PLM solution, as a management method for a large number of design plans generated through generative design. He is currently conducting research by expanding its application to assembly design in the aero/defense field.

2. DISCUSSION

2.1. Structural Analysis

Fig. 1 shows an anemometer that was damaged during operation. To analyze it, we performed a structural analysis as shown in Fig. 2, a structural analysis was performed.

Fig. 1 Breakage of the Anemometer cup

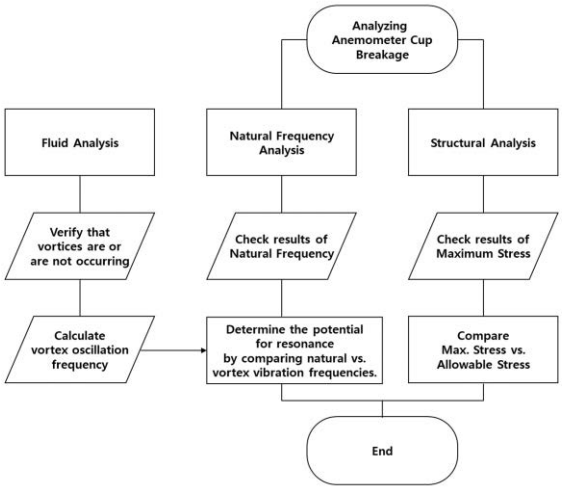

Fig. 2 Analysis process flow chart

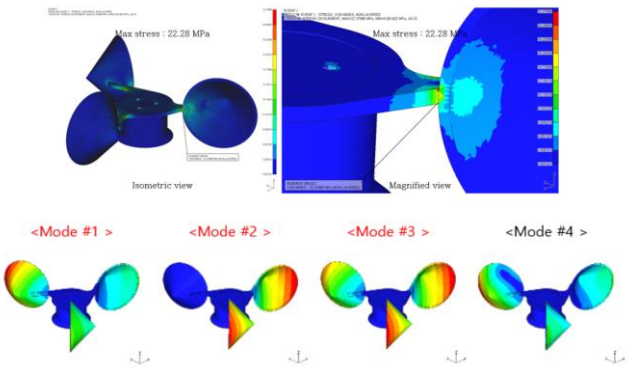

Fig. 3 Structural & Natural Frequency Analysis

The analysis showed that the natural frequency analysis of the structure should be designed to avoid the vortex-induced vibration frequencies around the anemometer cup, and a generative design was derived to satisfy these design criteria.

2.2. Generative Design Draft

Fig. 4 shows a schematic of the design generation process. It shows the process of generating a large number of designs using generative design methods and then optimizing them to find the optimal design. This detailed study is in progress through joint research [3].

Fig. 4 at the bottom, Generative Adversarial Networks with Boundary Constraints (GAN-BC), a deep learning-based model for reverse engineering, is shown. The samples generated from the model and their prediction performance were considered, and supervised learning was performed using the data extracted for prediction and used as a surrogate model. This improved the engineering performance and additive manufacturing suitability of the design created by learning in a direction that minimizes the predicted performance value.

1,000 samples were generated by learning GAN-BC, and compared to existing randomly generated samples, the average weight decreased by about 35.6% from 2.16 kg to 1.39 kg, the average amount of support also decreased by about 21.6%, and the defined It was noticed that the evaluation criteria had improved.

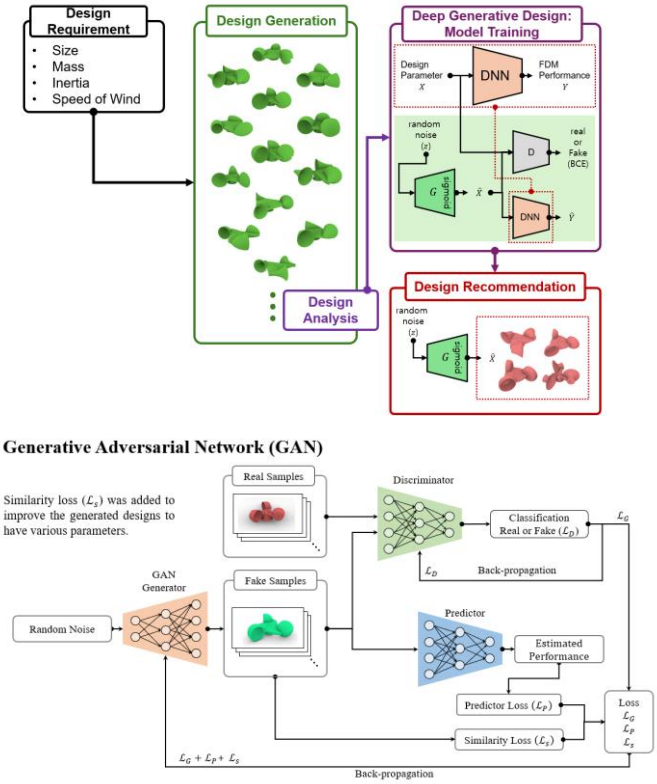

Fig. 4 Generative Design Framework

2.3. Adapting to an open PLM system

The massive number of design alternatives generated through generative design techniques necessitates the establishment and management of a database containing the characteristics of each design alternative. Additionally, procedures such as history management for items reviewed at each step of the workflow will be required.

To implement these elements, we applied the open-source PLM system ARAS INNOVATOR to our research. In Fig. 5, we created a Workflow Manager environment for the design process using the Workflow Map module. Fig. 6 demonstrates an example of establishing a database for the design alternatives.

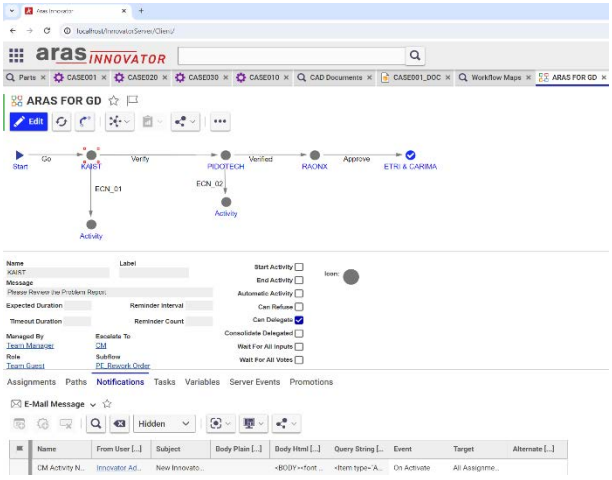

Fig. 5 Workflow Manager for Generative Design

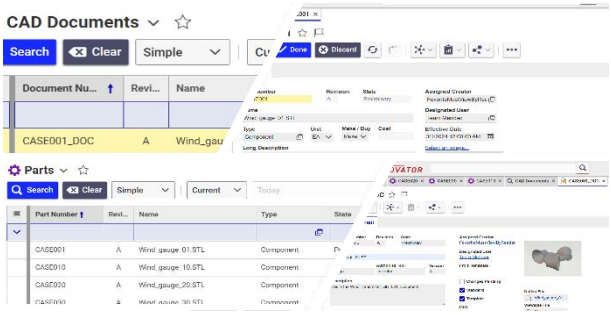

Fig. 6 Open PLM System Application Cases

In the case of workflow manager development, the first year was conducted in an environment where the outputs from each joint organization were integrated, and the second year was conducted to apply it to the PLM system. Currently, research on embedding it in the CAD system is in progress through the third year.

3. CONCLUSION

So far, we have introduced the analytical evaluation and generative design of anemometer, as well as the management plan for multiple design alternatives. Although there were limitations in terms of functionality due to its open-source nature, it is believed that systematic management data for the generated designs will play an important role. Subsequent research is ongoing to apply the final design selected through optimization to production via 3D printing [4]. Based on the technologies developed through such application cases, we are currently conducting generative design for wearable devices in the aerospace and defense industries. Additionally, we are actively promoting our work to secure demand from companies in the electrical and electronics sectors.

ABSTRACT

In the construction of health indicator for electromechanical equipment, selecting features that exhibit monotonicity, trend characteristics, and a strong correlation with equipment health is paramount to accurately reflect these indices. With the advent of numerous libraries and models for time-series data feature extraction, the range of potential features has expanded significantly. Despite this proliferation, there is a lack of extensive research on effective feature selection. This paper investigates the efficacy of the Maximum Information Coefficient (MIC) method in extracting features that align with the monotonicity and trend-related requirements of electromechanical equipment health indicator. Our experiments indicate that the MIC method adeptly identifies pertinent features for the construction of these indices, underlining its utility in the field of health monitoring for electromechanical systems.

1. INTRODUCTION

The construction of health indicator is essential for evaluating the current health status of engineering systems and their critical components, playing a pivotal role in inferring their Remaining Useful Life (RUL). The accuracy of RUL predictions hinges on the ability to develop health indicator that precisely reflect the condition of these components. Gears, for instance, are key elements in transmission systems. Damage to gears can lead to severe economic losses and potential personnel injuries. Therefore, accurately assessing their health status is crucial to prevent accidents caused by gear failures. This underlines the importance of reliable health indicator construction as a preventative measure against unforeseen mechanical breakdowns.

Currently, in the fault diagnosis and predictive analysis of gears, the application of vibration signals collected by accelerometers is the most widespread. Compared to other types of signals, such as temperature and pressure, vibration signals exhibit a higher sensitivity in detecting changes in gear health status [1]. The typical process for constructing health indicator, as illustrated in Figure 1, comprises four distinct stages: data acquisition, feature extraction, feature selection, and feature fusion, culminating in the construction of the health indicator. This structured approach ensures a comprehensive analysis, leveraging the sensitivity of vibration signals to accurately reflect the health status of the gears.

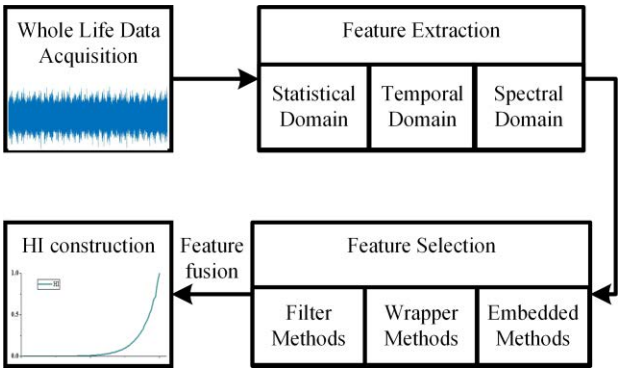

Figure 1. Typical Process for Health Indicator Construction.

In the construction of health indicator, feature extraction methods predominantly yield three types of features [2]-[3]. The first type, statistical domain features, are derived through statistical analysis to capture key characteristics of the data. They describe central tendencies, distribution ranges, and deviations in data shape. The second type, temporal domain features, focus on analyzing changes and dynamic properties in time series data. Finally, spectral domain features are identified through frequency analysis, uncovering periodic

components and spectral distributions within the data. Techniques like Fourier transform and other spectral analysis methods are employed to extract frequency components, which are crucial for understanding oscillatory patterns and frequency-related characteristics in the data. These three feature types compress information carried by the original signal from different perspectives. In health indicator construction, they play pivotal roles, complementing and interrelating with each other to provide a robust feature foundation for a comprehensive assessment of health conditions.

In the context of constructing health indicator, three principal methods are employed for feature selection: filter methods, wrapper methods, and embedded methods [4]. Filter methods involve selecting features based on specific metrics, with the selection process operating independently of the health indicator construction algorithm. This approach prioritizes features based on their statistical properties. In contrast, wrapper methods iteratively utilize the algorithm to assess the impact of different feature sets on the performance of the health indicator. This process iteratively evaluates and selects features based on their contribution to the model's effectiveness. Finally, embedded methods integrate feature selection directly into the algorithm's internal structure. This approach leverages the intrinsic properties of the algorithm to optimize feature selection concurrently with model training, leading to a more cohesive and efficient feature selection process.

Filter methods operate independently of any health indicator construction algorithms. In the context of health indicator construction, filter methods generally rely on a single metric for feature evaluation or employ an average of 2-3 metrics to determine the ranking. Medjaher et al. [5] introduced a novel hybrid feature significance ranking metric in their feature evaluation, incorporating monotonicity, correlation, and robustness for Health Indicator selection. Sun et al. [6] proposed the TWM-U2PL, consisting of a teacher model and a student model. The teacher model includes two independent classifiers that assist in extracting and categorizing wear features. Hu et al. [7] presented a method using minimum Redundancy Maximum Relevance (mRMR) to measure the similarity between features and the correlation between features and categories, facilitating the selection of dimensionless indices. Anil Kumar et al. [8] extracted statistical features from time-domain, frequency-domain, and time-frequency domain signals. They identified important features by calculating feature scores based on the differences in feature values between nearest neighbor pairs of instances.

In the process of constructing health indicator, information theory has been applied to enhance the effectiveness of fault feature extraction and health indicator formulation. Akhand Rai et al. [9] utilized multiscale fuzzy entropy extracted from vibration signals as fault features. These multiscale fuzzy entropy feature vectors form probability distributions. The Jensen-Rényi divergence technique is then applied to differentiate the probability distributions of degraded and healthy multiscale entropy feature vectors, thereby establishing the desired health indicator. Sui et al. [10] proposed a bearing RUL prediction method using Mutual Information (MI) and Support Vector Regression (SVR) models to accurately assess the degradation state of mechanical equipment and comprehend bearing RUL information. Ekhi Zugasti et al. [11] introduced feature selection methodologies using Principal Component Analysis (PCA), Uniform Minimum Redundancy Maximum Relevance (UmRMR), and a combination of both, aimed at resolving the damage detection problem. These approaches demonstrate the value of information-theoretic techniques in creating more accurate and reliable health indicator for mechanical systems.

Selecting features based on criteria such as monotonicity and correlation poses a challenge in effectively gauging the relative importance of each metric. This paper introduces a feature selection method for health indicator utilizing the MIC ranking, which is adept at identifying features that encapsulate a comparatively higher quantity of degradation information. The structure of the remainder of this paper is as follows: Section 2 details the proposed MIC-based health indicator feature selection method. Section 3 describes the experimental setup and data acquisition process. Experimental results are presented in Section 4. Conclusions are drawn in Section 5.

2. METHODOLOGY

In the construction of health indicator, feature selection constitutes a crucial aspect. Given the plethora of feature extraction methods available, it is imperative to selectively identify features that accurately represent the state of degradation. Such features typically necessitate possessing two key attributes: monotonicity and correlation. These attributes are quantifiable and can be effectively measured using specific formulas, designated as Eq. (1) for monotonicity and Eq. (2) for trendiness, as detailed in the referenced literature [12].

Monotonicity primarily measures the trend of a feature, whether it is consistently increasing or decreasing. A feature with the higher monotonicity indicates the better degradation with an increasing/decreasing trend. The calculation of monotonicity is conducted as follows:

$$Mon(f_i) = \left| \frac{\#(\Delta f_i \geq 0)}{L-1} - \frac{\#(\Delta f_i < 0)}{L-1} \right| \quad (1)$$

where $Mon(f_i)$ is the monotonicity value for the i^{th} feature f_i with length of L. $\Delta f_i = f_{i+1} - f_i$ is the difference between consecutive elements. $\#(\Delta f_i \geq 0)$ represents the number of non-negative differences in the f_i sequence. $\#(\Delta f_i < 0)$ represents the number of negative differences in the f_i sequence.

Correlation as a metric primarily reflects the degree of correlation between a feature and the time of degradation. The formula for calculating correlation is as follows:

$$Corr(f_i, T_i) = \left| \frac{cov(f_i, T_i)}{\sigma_{fi} \cdot \sigma_{Ti}} \right| \quad (2)$$

where cov is the covariance of i^{th} feature f_i with the time vector T,and σ is the standard deviation.

An effective understanding of the concepts of monotonicity and correlation in feature analysis can be easily achieved by referring to Figure 2. This figure is divided into two parts: the left side depicts the behaviors of four distinct features, labeled F1 through F4, across their entire lifecycle. The right side, in contrast, illustrates the corresponding Monotonicity Score and Correlation Score for each of these features. By examining these graphical representations, one can clearly discern how different features exhibit varying levels of monotonicity and correlation over time.

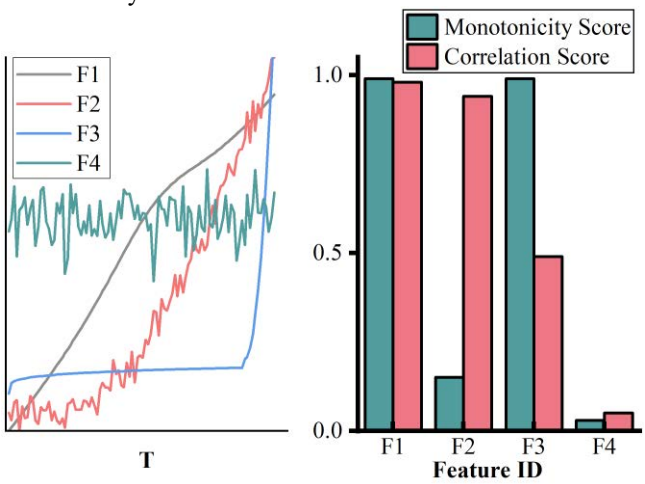

Figure 2. Four representative features. F1 represents high Monotonicity and high Correlation, F2 represents low Monotonicity and high Correlation, F3 represents high Monotonicity and low Correlation, and F4 represents Low Monotonicity and Low Correlation.

The feature selection method for gear health indicators with MIC proposed in this paper is able to complete the feature selection quickly and, at the same time, ensure the monotonicity and trend of the features to a certain extent.

2.1. Basic theory of The MIC

The calculation of the MIC [13] necessitates the computation of mutual information values between variables. Mutual information is a concept in information theory that quantifies the degree of mutual dependence between two random variables. It serves as a measure of the amount of information one variable contains about another. The greater the mutual information value, the stronger the interdependence between the two variables. When considering two random variables, X and Y, their mutual information, denoted as $I(X,Y)$, is defined as follows:

$$I(X,Y) = \sum_{x \in X, y \in Y} p(x,y) \log \left(\frac{p(x,y)}{p(x)p(y)} \right) \quad (3)$$

Where $p(x,y)$ represents the joint probability distribution of X and Y, $p(x)$ and $p(y)$ denote the marginal probability distributions of X and Y.

Unlike mutual information, the MIC demonstrates heightened sensitivity to a broader range of relationship types between variables. It is adept not only at identifying linear and non-linear functional relationships, such as exponential and periodic, but also at detecting non-functional relationships, including combinations or overlays of functional relationships. The aim of MIC is to provide a unified measure of similarity for various types of relationships. MIC builds upon the concept of mutual information. It operates by exploring all possible grid partitions of the data, seeking the partitioning that maximizes the mutual information. The value of MIC ranges between 0, indicating no relationship, and 1, signifying a perfect correlation. This range provides a clear and quantifiable indication of the strength and nature of the relationship between the variables. The MIC functions by calculating mutual information across a range of different grid partitions, with the objective of identifying the partition that maximizes this mutual information. Specifically, for a given dataset, the MIC algorithm evaluates various grid sizes and configurations. It systematically computes the mutual information for each of these configurations. The configuration that yields the highest mutual information is then selected, and its corresponding mutual information value is designated as the MIC value.

In a dataset comprising data points with two attributes, X and Y, these points are distributed within a two-dimensional space. To analyze these data, an $m \times n$ grid is utilized to partition this space. The frequency of data points falling within a specific row x of the grid is used to estimate the marginal probability $p(x)$. Similarly, the frequency of data points in a particular column y is used as an estimate for the marginal probability $p(y)$. Furthermore, the frequency of data points located within a specific cell (x,y) of the grid provides an estimate for the joint probability $p(x,y)$.

$$p(x,y) = \frac{N(x,y)}{\sum_{i=1}^{m} \sum_{j=1}^{n} N(i,j)} \quad (4)$$

By altering the method and arrangement of the grid partitioning, a range of mutual information values can be generated. This variation is crucial in the process of calculating the MIC.

$$MIC(X,Y) = \max_{m*n \leq n^a} \frac{I(X,Y)}{\log_2 \min(m,n)} \quad (5)$$

Where n represents the scale of the data. The value of the constant a can be set based on experience or scale. The condition $m * n \leq n^a$ is to limit the size of the grid for the purpose of dividing regions. Dividing by $\log_2 \min(m,n)$

completes the normalization of data in different dimensions, ensuring that their values fall within the interval [0,1].

2.2. Features Selection in Health indicator Utilizing MIC Ranking

This paper primarily investigates feature extraction and selection from vibration signals. The features extracted in this study are listed in the accompanying table. For detailed explanations of each feature's significance and technical definitions, readers are referred to literature [2], as this paper focuses on the application rather than the detailed descriptions of these features. It is important to note that some features yield multiple output values. In such cases, each distinct output is assigned a unique Feature ID to facilitate clear identification and analysis.

Table 1. Feature List.

ID	Statistical Domain Features	ID	Temporal Domain Features	ID	Spectral Domain Features
1	Absolute energy	2	Area under the curve	9	Fundamental frequency
4	Average power	3	Autocorrelation	23	Max power spectrum
6-7	ECDF Percentile	5	Centroid	33	Median frequency
8	Entropy	24	Maximum frequency	39	Power bandwidth
10-19	Histogram	27	Mean absolute diff	43	Spectral centroid
20	Interquartile range	28	Mean diff	44	Spectral decrease
21	Kurtosis	31	Median absolute diff	45	Spectral distance
22	Max	32	Median diff	46	Spectral entropy
25	Mean	35	Negative turning points	47	Spectral kurtosis
26	Mean absolute deviation	36	Neighbourhood peaks	48	Spectral positive turning points
29	Median	38	Positive turning points	49	Spectral skewness
30	Median absolute deviation	41	Signal distance	50	Spectral slope
34	Min	54	Sum absolute diff	51	Spectral spread
37	Peak to peak distance	56	Zero crossing rate	52	Spectral variation
40	Root mean square				
42	Skewness				
53	Standard deviation				
55	Variance				

In the context of feature selection for health indicators, it is necessary to first construct a progressively growing sample sequence $\boldsymbol{T} = [1, 2, \ldots, N]$ based on the sampling interval. The feature set composed of features in TABLE I is denoted as $\boldsymbol{F} = \{\boldsymbol{F_1}, \boldsymbol{F_2}, \ldots, \boldsymbol{F_L}\}$. The pseudocode for feature selection is as follows:

Table 2. Based on MIC Health Indicator Feature Selection.

Input: $\boldsymbol{T}, \boldsymbol{F}$
output: $\boldsymbol{F}$ *are sorted by MIC*

1: for each feature $\boldsymbol{F_i} \in \boldsymbol{F}$ do
2: MIC of $\boldsymbol{F_i} = \boldsymbol{0}$
2: for (m, n) such that $m * n \leq n^a$ do
3: Divide $\boldsymbol{T}, \boldsymbol{F_i}$ according to m, n to form a grid G
4: Calculate the mutual information $I(\boldsymbol{F_i}, \boldsymbol{T})$ of $\boldsymbol{F_i}$ and $\boldsymbol{T}$ on grid G
5: Normalized mutual information
6: if Normalized mutual information> MIC of $\boldsymbol{F_i}$
7: MIC of $\boldsymbol{F_i}$ = Normalized mutual information
7: Add MIC of $\boldsymbol{F_i}$ in MIC list
8: Sort $\boldsymbol{F_i}$ in $\boldsymbol{F}$ by MIC list

The two principal characteristics of the MIC offer significant advantages in the context of feature selection for health indicator.

Generality: The MIC demonstrates a high degree of applicability across a wide array of relationship types, encompassing linear, non-linear, monotonic, and non-monotonic associations. This Generality enables the selection of features that are representative of diverse functional relationships, thereby facilitating more effective feature fusion in reflecting health indicator.

Equitability: MIC exhibits a relatively consistent sensitivity across different types of relationships. This means that whether the relationship between variables is linear, curvilinear, or follows other complex patterns, MIC can identify it with similar efficacy, provided the relationship is sufficiently strong. Consequently, MIC is capable of selecting features that are most relevant and informative, enhancing the accuracy and reliability of the resulting health indicator.

3. EXPERIMENTAL PROCEDURE

In this study, the experimental data set was collected through accelerated degradation tests conducted on gears. The experimental platform consisted of a two-stage parallel-axis gearbox. The torque applied to the gearbox was generated by a load motor attached to the output end. An accelerometer was mounted at the output cover to capture vibration signals along the Z-axis of the gearbox. The data collection was conducted with a high sampling frequency of 12,800 Hz, ensuring detailed capture of the vibration characteristics. The input frequency to the gearbox was set at 40 Hz. The platform for accelerated degradation tests conducted on gears is shown in Figure 3. The position relationship of each transmission gear in the gearbox is shown in Figure 4.

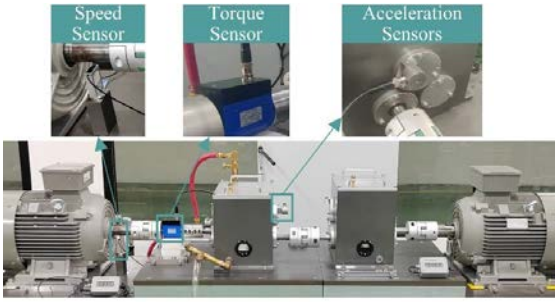

Figure 3. Experimental Platform.

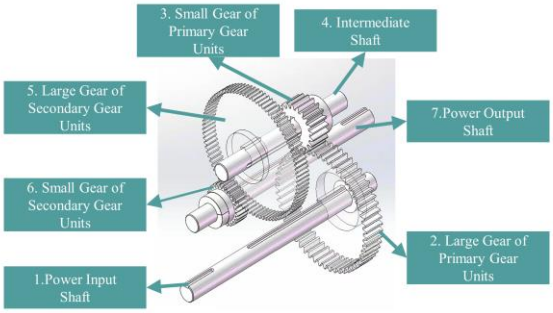

Figure 4. Position Relationship of Each Transmission Gear in the Gearbox

For detailed specifications of the basic gear parameters, readers are directed to Table 3. Additionally, the data set encompasses real-life operational data of gearboxes throughout their entire lifecycle, recorded under three different load conditions. For a more comprehensive understanding of these data sets, including the specific conditions and parameters, please refer to Table 4.

Table 3. Gearbox Parameters.

Parameters	Primary Gear Units	Secondary Gear Units
Number of small gear teeth	29	36
Number of large gear teeth	95	90
Pinion tooth width/mm	15	15
Large gear tooth width/mm	15	15
Modulus/mm	1.5	1.5
Pressure angle/°	20	20

Table 4. Experimental Data Set.

Gear ID	torque load	Total Working Hours (H)	Sample Size
G_1	50%	110	3303
G_2	60%	102	3079
G_3	70%	34	1022

Figure 5 provides a graphical representation of the vibration signals from the tested gearbox, labeled G_1, over its entire lifecycle. The temporal progression of these signals is distinctly illustrated, with noticeable variations becoming evident as time progresses. This variation in the vibration signals is indicative of changes in the gearbox's condition, suggesting a correlation with the performance degradation of the gear.

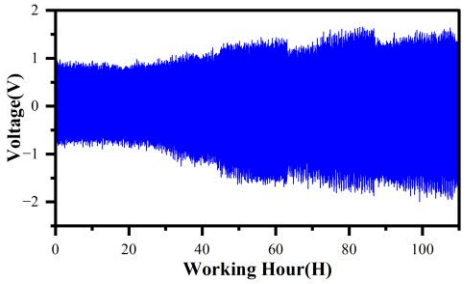

Figure 5. The Z-axis Vibration Signals Over Entire Lifecycle of G_1.

4. RESULT AND DISCUSSION

The study involved extracting a comprehensive set of 56 features from the full lifecycle experimental data of three distinct gear sets. Following the extraction, the feature selection process, as detailed in Section 2.2 of this document, utilized the MIC algorithm. This algorithm was applied to each feature to calculate its MIC value, assessing the strength of the relationship between the feature and the gear's health status. Subsequently, the features were sorted based on the average MIC values computed across the three gear sets, providing a comparative view of their significance. The results of this feature selection and sorting process are illustrated in the Figure 6, offering insights into the relative importance of the various features in the context of gear health monitoring.

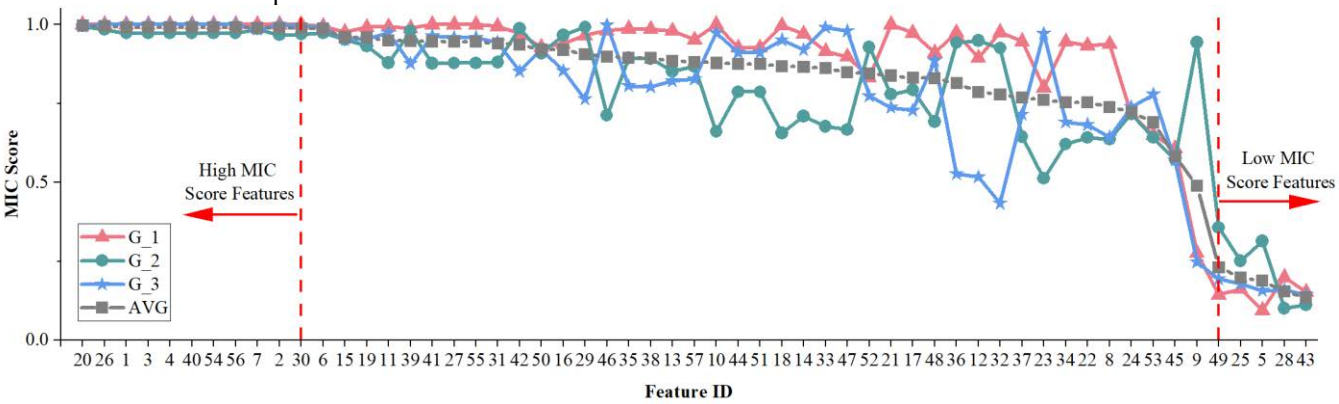

Figure 6. MIC Values for 56 Features of Three Gears.

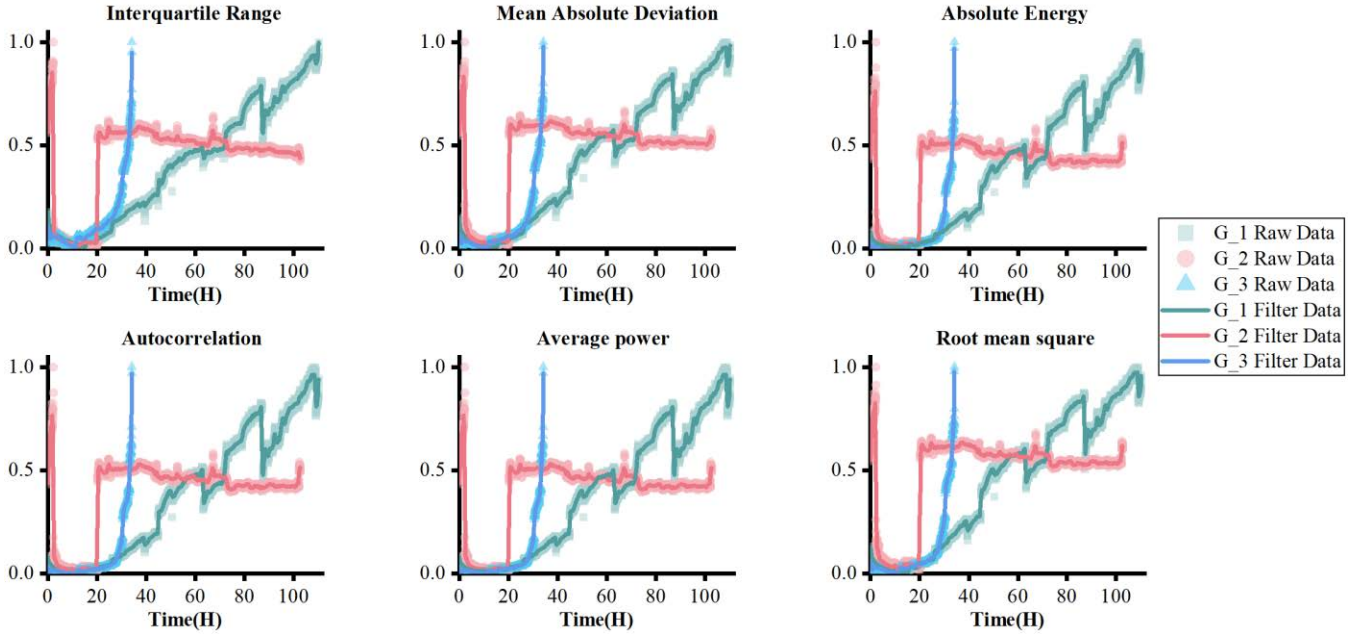

Figure 7. Lifecycle Curves of the Top Six Features Ranked by MIC Score.

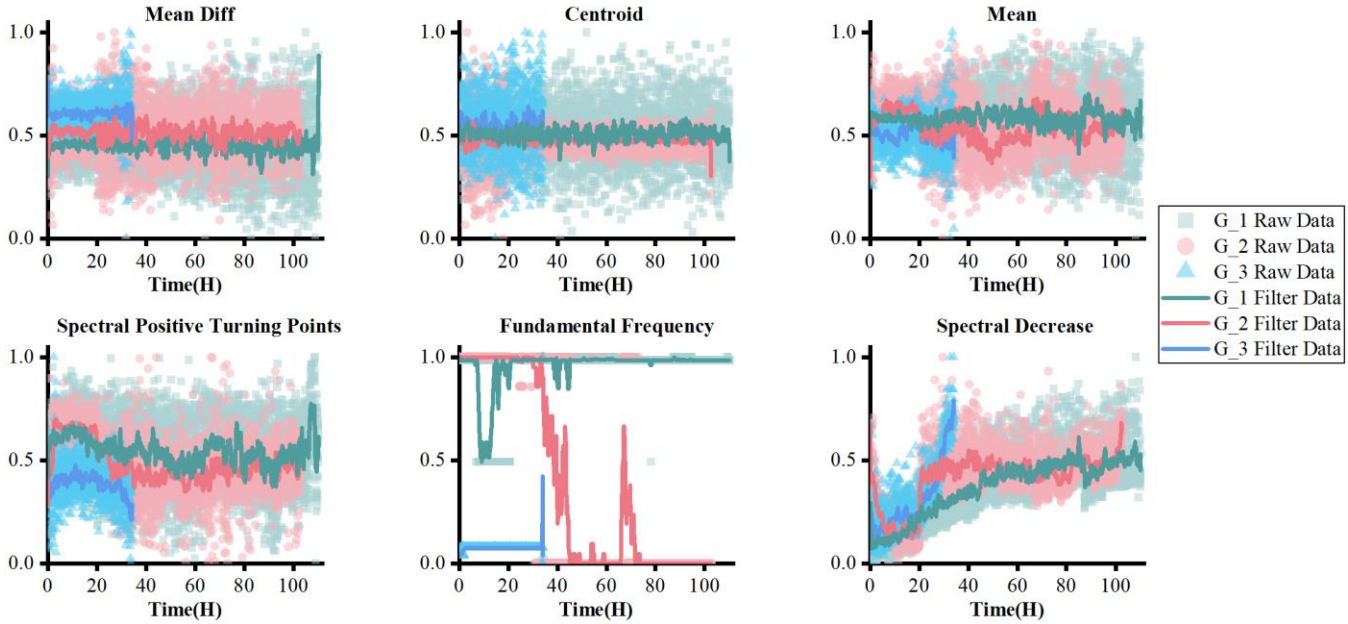

Figure 8. Lifecycle Curves of Features Ranked in the Bottom Six by MIC Score

It is observed that some features exhibit MIC Scores nearing 1 in Figure 6, indicating a significant non-linear relationship between these features and the equipment's degree of degradation. To analyze this further, the features with the top six and bottom six MIC Scores were normalized and their lifecycle variation curves were plotted in Figure 7 and Figure 8. The analysis reveals that the features ranked in the top six display pronounced trendiness and a certain degree of monotonicity, suggesting a strong correlation with the equipment's degradation process. Conversely, the features ranked in the bottom six show little to no discernible trend or pattern. This contrast underscores the efficacy of MIC Scores in distinguishing features that are strongly indicative of equipment health from those that are less informative.

Utilizing Eq. (1) and (2), the monotonicity and trendiness indices of the features were calculated. The analysis revealed a discernible positive correlation between the MIC values and these indices in Figure 9. Specifically, it was observed that features with higher MIC values tend to exhibit more pronounced monotonicity and trendiness. Conversely,

features with lower MIC values generally show weaker performance in these aspects. This correlation indicates that the MIC can be a reliable indicator of a feature's relevance, particularly in terms of its monotonic and trend-based behavior, which are critical attributes in assessing the health and degradation of equipment.

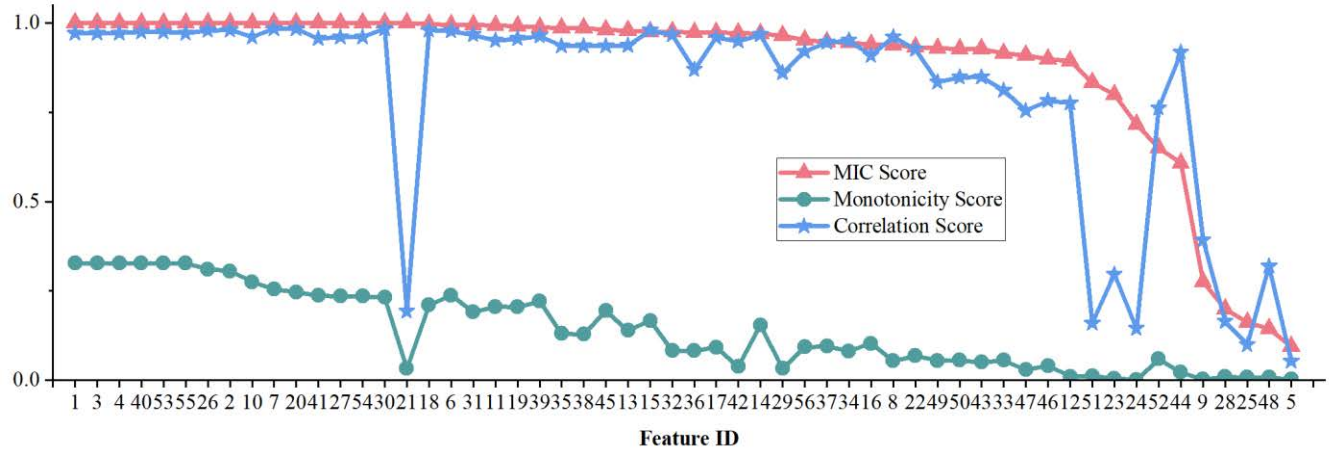

Figure 9. MIC Score, Monotonicity Score and Correlation Score.

5. CONCLUSION

The application of the MIC algorithm in this study has proven to be highly effective in selecting features that correlate closely with gear health. This approach ensures that the resultant health indicator exhibit enhanced monotonicity and trendiness, thereby providing a more accurate reflection of the gear's condition. Notably, MIC also effectively compensates for the shortcomings of mutual information by offering a more comprehensive quantification of the correlation between features and equipment health.

However, it is important to acknowledge a key limitation of the MIC algorithm: its reliance on large datasets for meaningful computation. The efficacy of MIC is significantly reduced when applied to smaller datasets. Recognizing this constraint, future research efforts will focus on modifying and improving the algorithm to better suit applications involving smaller data samples. Such advancements will broaden the applicability of this method, allowing for more versatile and reliable gear health assessments across a wider range of data scenarios.

ABSTRACT

Historical condition monitoring data from technical systems can be utilized to develop data-driven models for predicting the remaining useful life (RUL) of similar systems, whereas the Health Index (HI) often is a crucial component. The development of robust and accurate models requires meaningful features that reflect the system's degradation process, enabling an accurate prediction of the system's HI. Traditionally, the identification of those is supported by one of various feature ranking methods. In literature, feature interdependencies and their transferability across various similar systems are not sufficiently considered in feature selection, exacerbating the challenge of HI prediction posed by the scarcity of data and system diversity in real-world applications. This work addresses this gaps by demonstrating how filter-based feature selection, incorporating failure thresholds and cross correlations, enhances feature selection leading to improved HI prediction. The proposed methodology is applied to a novel dataset* obtained from run-to-failure experiments on geared motors conducted as part of this study, which presents the aforementioned challenges. It is revealed that classical feature selection, consisting of feature ranking only, leaves potential untapped, which is utilized by the proposed selection methodology. It is shown that the proposed feature selection methodology leads to the best result with a RMSE of 0.14 in predicting the HI of a constructive different gearbox, while the features, determined by classical feature selection, lead to a RMSE of 0.19 at best.

1. INTRODUCTION

Early fault detection of mechanical systems like gears and motors is an important topic for industrial production, helping companies to predict equipment failures, reduce downtime and to ensure the reliability and safety of industrial systems. The analysis of data from time series sensors like acoustic, vibration, position, or current is of great interest to monitor the health condition of machines and to predict failure in the mechanical systems life-cycle. The prognostics of the remaining useful lifetime (RUL) aims to predict operating time of a typical operational lifespan that a mechanical system has already passed and estimate the amount of the remaining useful life. In particular, vibration signals have been widely used for RUL-prognostics. However, the usage of signals acquired from inverts like the motor current reduces costs of installation and maintaining external sensors. Under the limitation of a drive system including an induction motor and an inverter with a sufficient data interface, the motor becomes the sensor.

A major challenge in developing accurate and robust RUL-prognostics is the limitation of data, especially in scenarios where abnormal observations are rare or difficult to obtain, referred to as data scarcity. In this study geared motors are focused, which are combinations of toothed-wheel-based gearboxes and of electric induction motors. To match the diverse requirements of customers, the geared motors can be configured and scaled individually. These customized geared motors can be used in a variety of different machine types, which also may be customized. In many real-world problems it is realistic that only a few or none run-to-failure data-collections are available and thus often only data from the healthy motor can be used for model training.

The work is structured as follows. Section 2 presents a comprehensive feature engineering methodology with focus on

feature selection to overcome data scarcity and address system differences. A multi-stage feature selection methodology is described followed by the machine learning (ML) models used and trained based on the selected features. ML algorithms employed are Gaussian Process Regression (GP), Linear Regression (LR), Multi-Layer-Perceptron (MLP), Random Forest (RF) and Support Vector Machine (SVM). Next, a novel dataset from run-to-failure experiments on geared motors including gear-mesh and bearing failures is introduced in section 3. The experimental setup and the recorded data, which are obtained from a frequency inverter, are described. In section 4, the proposed feature engineering methodology is applied on the new data. In section 5 the advantages over the classical feature selection, consisting of feature ranking only, is shown resulting in the best root mean squared error (RMSE) of 0.14, in contrast to the classical selection's best RMSE of 0.19 in predicting the health index (HI).

2. METHODOLOGY

In this paper, a broadly used workflow for diagnostics and prognostics of technical systems is utilized, which comprises the elements data preprocessing, feature extraction and diagnostics or prognostics algorithm (Goyal, Mongia, & Sehgal, 2021; Ly, Tom, Byington, Patrick, & Vachtsevanos, 2009). Depending on the application, these elements are generally adapted and optimized to suit the circumstances of any given application. The methodology employed prioritizes a more generalized process. To address this limitation, feature engineering is focused wherein a wide range of features are computed, adapted and a multi-stage feature selection process is adopted to select subsequently the most relevant features. Data-driven algorithms are then trained with the selected features within a cross-validation process that includes hyperparameter optimization to predict the HI of the system. These steps are parameterized by means of the systems used for training and then applied to the system used for testing. The whole process is shown in Fig. 1 comprising feature extraction, feature processing, feature selection and model training including hyperparameter optimization, with particular focus on feature selection, whereas Fig. 2 shows the steps from feature processing to correlation analysis with more detail. The steps are described in the following.

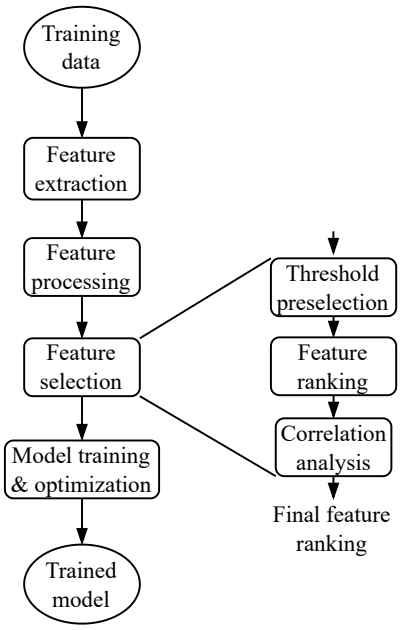

Figure 1. Overview of the applied training process.

2.1. Feature Extraction

Feature extraction is applied to each measurement and channel to extract information regarding system's degradation over time. To address a variety of a system's characteristics, a multitude of features are computed, aiming to encompass a wide range of potential applications where any given feature may capture the system's degradation process. To extract features from time series data, the publicly available Python package tsfresh is used (Christ, Braun, Neuffer, & Kempa-Liehr, 2018). tsfresh is utilized for an automatic extraction of time series features which comprises features from the time, frequency, and time-frequency domains.

In the review of (Goyal et al., 2021), several use cases regarding rotating mechanical systems are consolidated, highlighting the frequent utilization of the fast Fourier transform (FFT) for analysis. This underlines the capacity of FFT to extract information from data, particularly from systems with rotating components, to infer health-related insights. Therefore, additional frequency-dependent features are calculated by dividing the frequency spectrum into sections defined by a constant percentage bandwidth (CPB). Maximum and average FFT coefficients are extracted from the corresponding sections to capture amplitude changes in smaller frequency spectrums. A CPB analysis has been utilized, among other fields, in the field of acoustics (Gram-Hansen, 1991), providing the opportunity to efficiently consider the entire frequency spectrum within comprehensive feature extraction.

2.2. Feature Processing

Feature processing encompasses feature smoothing and feature scaling. Feature smoothing is utilized to reduce noise and variability from the feature data, making underlying patterns and trends more apparent. The moving average is often applied for this purpose. Feature scaling involves scaling the computed features based on the median value of their initial feature data points as shown in Eq. (1). Here, $f_{i,j}$ represents feature i of system j, $f_{i,j,init}$ contains the initial feature points, and $f^*_{i,j}$ denotes the scaled feature data. This process aims to eliminate unwanted influences and facilitate bet-

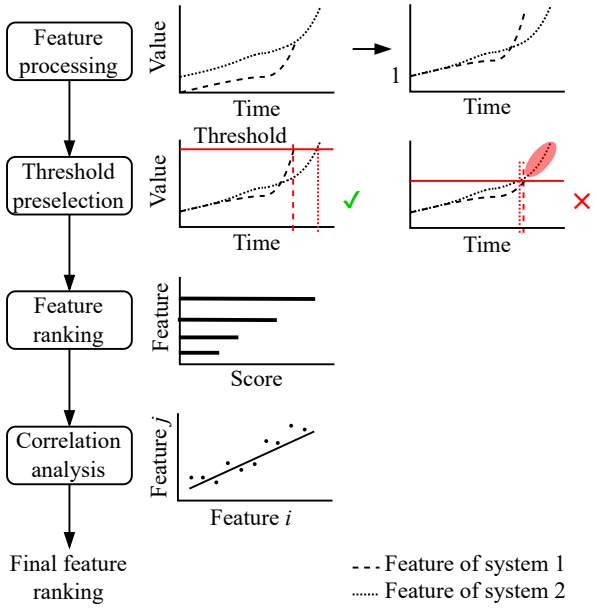

Figure 2. Overview and illustration of the feature processing and selection process.

ter comparability among different systems.

$$f^*_{i,j}(t) = \frac{f_{i,j}(t)}{\text{median}(f_{i,j,init})} \tag{1}$$

2.3. Feature Selection

Feature selection can be divided into filter, wrapper, embedded and hybrid methods (Hoque, Bhattacharyya, & Kalita, 2014) and is necessary for information concentration. This paper focuses on filter methods, as they are less computational intensive in general (Hoque et al., 2014). Feature selection utilized comprises the steps threshold preselection, feature ranking and correlation analysis. Threshold-based preselection retains features with similar failure thresholds and discards those without. It is followed by feature ranking and correlation analyses to remove highly correlated features. The steps are described in the following.

Threshold preselection: Subsequently on feature processing, a preliminary selection is conducted based on a common threshold value for each feature across the systems. Thresholds for system failure are often determined using a predefined HI, often as linear, e.g. in (Yang et al., 2016), or constructed based on selected features, e.g. in (Thoppil, Vasu, & Rao, 2021). In more rare cases, only one feature is directly used if it is sufficient to reflect the degradation process, provided that it can be used to define a system-wide failure threshold, e.g. in (Li, Huang, Gao, Zhao, & Li, 2023; Bender & Sextro, 2021). With limited data, it is difficult to evaluate

Table 1. Metrics considered to determine feature ranking.

Source	Mon.	Trend.	Rob.	Name
(Carino et al., 2015)	×			Spearman
(Nie et al., 2022)	×	×		Cori-Score
(Chen et al., 2019)	×	×	×	MTR_C
(Zhang et al., 2016)	×	×	×	MTR_Z

an individual feature for use as a reliable HI, as well as to construct a HI with respect to a failure threshold. Specific, multiple features that indicate a common threshold across the systems are often not explicitly sought out. To do this, a criterion based on the thresholds for each feature and system is introduced. Firstly, a threshold τ_i regarding Eq. (2) is calculated for each feature i with respect to the systems denoted by j. Here, $\widetilde{f}^*_{i,j,end}$ denotes the median value of the scaled feature points within the final portion, defined by α, of the RUL. The thresholds are reached at different points in the lifetime of each system. If the minimum reached lifetime, as determined by the specified threshold, is below β of the total lifetime of one of the systems, the feature is discarded. An example is given in Fig. 2, where a feature is marked with a cross, signifying that the systems 2 reaches the threshold prematurely, leading to the exclusion of this specific feature.

$$\tau_i = \begin{cases} \min\limits_j(\widetilde{f}^*_{i,j,\text{end}}) & \text{if } \widetilde{f}^*_{i,j,\text{end}} \geq 1 \\ \max\limits_j(\widetilde{f}^*_{i,j,\text{end}}) & \text{if } \widetilde{f}^*_{i,j,\text{end}} < 1 \end{cases} \tag{2}$$

Feature ranking: Feature ranking is crucial in predictive analysis as it allows to identify the most relevant and informative features. Evaluation metrics employed typically encompass assessment of monotonicity and trendability analysis (Carino, Zurita, Delgado, Ortega, & Romero-Troncoso, 2015; Nie, Zhang, Xu, Cai, & Yang, 2022). Moreover, these metrics can be combined with a metric to consider the robustness (Chen, Xu, Wang, & Li, 2019; Zhang, Zhang, & Xu, 2016). A short overview of considered metrics by source to perform feature ranking is given in Tab. 1 and described in the following.

In (Carino et al., 2015) the monotonicity is calculated using the Spearman correlation coefficient, while monotonicity in (Nie et al., 2022; Chen et al., 2019; Zhang et al., 2016) is assessed through the counts of positive and negative derivatives. Trendability is assessed usually through calculating the Pearson correlation coefficient (Chen et al., 2019; Nie et al., 2022; Zhang et al., 2016). Here, (Zhang et al., 2016) used smoothed feature values to encompass monotonicity and trendability, while all others evaluate the original feature data set. The robustness of a feature is assessed through comparison the raw feature values with their smoothed values (Chen et al., 2019; Zhang et al., 2016). The evaluation across multiple considered metrics is conducted using either the average score or the equally weighted sum. In this paper, all of the named fea-

Table 2. Fictional correlation matrix of the best 3 ranked features.

Feature	1	2
1	-	-
2	0.955	-
3	0.892	0.851

ture ranking methodologies are considered to get insight into the potential of the proposed feature selection methodology.

Correlation analysis: Correlation analyses, specifically the Pearson correlation, are often used, besides for feature selection, for similarity analyses (Guo, Li, Jia, Lei, & Lin, 2017; Nie et al., 2022). In this paper, the Pearson correlation is used to determine the similarity between features. Based on the similarity, highly similar features are classified as redundant and discarded, while the best-ranked features are retained. Tab. 2 provides a fictional example showing a correlation matrix for the ranked features 1, 2 and 3. Feature 2 correlates with a coefficient of 0.955 with feature 1. Feature 3 shows correlations of 0.892 and 0.851 with feature 1 and 2 respectively. A parameter can be used to specify which correlation is acceptable. Features that exceed this parameter across all systems are discarded, ensuring that only unique and informative features are retained. If the parameter in the example shown is set to 0.95, feature 2 is discarded, as it exceeds the parameter for feature 1.

2.4. Model training and test

Different ML algorithms are applied and optimized with regard to their hyperparameters applying a Bayesian optimizing algorithm provided by the scikit-optimize library (Head, Kumar, Nahrstaedt, Louppe, & Shcherbatyi, 2021). This technique is based on probabilistic modeling to explore the hyperparameter landscape and find the best parameter combinations (Garnett, 2023). The main goal is not to compare ML algorithms against each other. Instead, the focus lies on assessing the effectiveness and obtaining the best possible prediction result based on the introduced feature selection method. The ML algorithms employed include GP, LR, MLP with one hidden layer consisting of 100 neurons, RF and SVM from the sklearn library (Pedregosa et al., 2011). These algorithms are trained on processed and selected features and are optimized within a cross-validation process to predict a linear HI. The hyperparameter ranges used for optimization are given in the appendix, with standard values employed if a hyperparameter is unspecified.

The predictions are constrained between 0 and 1, where 0 denotes system failure. Evaluation of the models is based on the RMSE as calculated in Eq. (3). Here, $y_{true,i}$ denotes the true and $y_{predicted,i}$ the predicted HI for each observation i of n total observations.

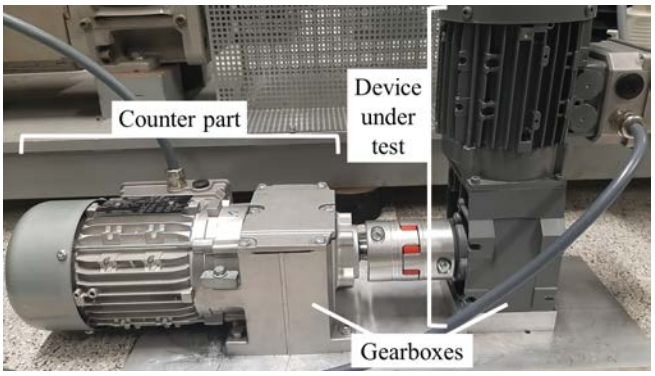

Figure 3. Experimental setup. On the left side, the counter part is shown, which is a helical geared motor. The geared motor on the right side is the device under test, which is a bevel gear.

Table 3. Overview of the gearboxes and their nominal values.

Name	**Type**	**Usage**	**Torque**	**Gear ratio**
H110	Helical	Counter part	110 Nm	28,738
B45	Bevel	Device under test	45 Nm	25,051
H45	Helical	Device under test	35 Nm	10,033

$$\text{RMSE} = \sqrt{\frac{1}{n}\sum_{i=1}^{n}(y_{true,i} - (y_{predicted,i})^2} \qquad (3)$$

3. Case-Study

To facilitate the presented studies, a run-to-failure experiment for geared motors is introduced. A geared motor is installed in healthy condition and operated until it fails. Throughout the experiment, a data acquisition system is active to monitor the signals of all degradation states. In order to complete the experiment in limited time, the geared motors nominal torque is exceeded. The experiment is conducted three times in total and each with multiple operation states during measurement.

3.1. Experimental Setup

The mechanical part of the setup consist of a first geared motor, the device under test, and a second geared motor, the counter part, shown in Fig. 3. All gearboxes consist of two gear stages with in sum four toothed wheels. The function of the counter part is to create a load for the device under test. An overview of the nominal values of the gears is given in Tab. 3. Thereby the counter part has significant higher nominal torque, to make sure, that the device under test will cause failure, while the counter part stays in healthy condition. The actual torque is selected to lie in the mid of the finite life fatigue of the Woehler characteristic of the second and last gear stage of the device under test to accelerate degradation. During the experiment, the device under test runs with nominal speed.

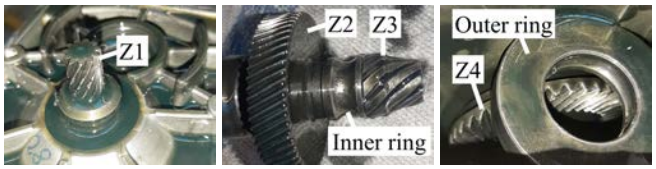

Figure 4. Failure of gearbox B45. Shown are the gears from left to right Z1 with moderate wear, Z2 with minor wear, Z3 with destructive wear and Z4 with moderate wear. As well as the destroyed bearings' inner ring next to Z3 and outer ring next to Z4.

Figure 5. Failure of gearbox H45. Shown are the gears from left to right Z1 and Z2 with minor wear, Z3 with moderate wear and Z4 along with the gearbox full of the deteriorated oil. As well as the destroyed bearings inner ring next to Z3.

In sum, three run-to-failure experiments were conducted, one with B45 gearbox and two with H45 gearbox. In the following, one of the H45 gearboxes will be referred to as H45I and the other as H45II, if they are considered separately. A run-to-failure experiment ends when the gearbox failed, which means its transmission is interrupted. Here, gearbox failure occurred after around 200 hours (H45II) to 790 hours (B45). Subsequently, the gearboxes are opened to evaluate the failures. In the following, the gears are named beginning from the motor-shaft with Z1 transmitting over Z2 to the middle-shaft with Z3 transmitting to the output-shaft over Z4.

The B45 gearbox shows a destructive wear at the Z3, while Z1 and Z4 also show moderate wear, but they stay functional. Z2 only shows minor wear. All of which is shown in Fig. 4. This observation can be explained by the higher torque transmitted by Z3 and Z4 than the first gear stage with Z1 and Z2 and the higher rotation speed of Z1 and Z3 resulting in sum to the high wear of Z3. In addition, the bearing of the middle shaft most close to Z3 is destroyed.

The failure of the runs with H45 shows only minor wear at the gears, except Z3 which shows moderate wear, see Fig. 5. The failures are caused by destroyed bearings next to Z3. Overall, both gear wearing and a destroyed bearing in all cases is observed.

3.2. Data Acquisition

Once per hour, the steady operation of the experiment is interrupted to gather signal measurement of four operation states. These four states are aligned with the nominal values of the induction motor for star connection of the device under test. The states are the combinations of positive or negative nominal speed with nominal or idle torque. Each observation takes measurement with constant sampling rate of 8 kHz and for 2^{15} sampling points, which defines a time period of about 4 s. During this time period, 8 channels are stored in parallel, which are shown in Tab. 4.

Table 4. Overview of the channels acquired by the inverter.

Channel	Type
1	Direct current
2	Quadrature current
3	Effective current
4	Effective voltage
5	Quadrature voltage
6	Phase current U
7	Phase current V
8	Phase current W

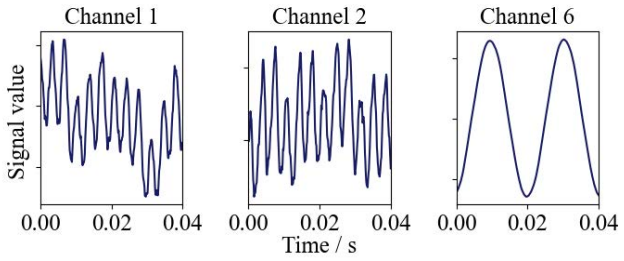

Figure 6. Overview of different derivatives of the current signal. Channel 1: direct current, Channel 2: quadrature current and Channel 6: phase current. All signals are in an internal normalization and thus unit free.

In contrast to vibration and acoustic signals, the original three phase currents are alternating, which may negatively influence some fault detection approaches. Further, the signals of at least two phases would be needed to cover all necessary information. To counter this, also the current in D-Q-coordinates as well as the effective current, calculated by the inverter, are stored, which is briefly shown in Fig. 6. Note that the direct current is related to the magnetic field, while the quadrature current is related to the motors torque. In addition, also the effective and quadrature target voltage are stored, however which are highly quantized and therefore may be of limited relevance.

4. Application

In this section, the presented methodology outlined in section 2 is applied on the gearbox data.

Firstly, only the data recorded at nominal speed in the loading direction with idle torque is considered. Additionally, the running-in process is discarded from the data. A running-in process is particularly well known for gears and causes volatile system behavior in the data shortly after machine commissioning. This can be caused by deforming or breakage of the highest asperities on the tooth surfaces (Feng et al.,

Table 5. Numbered overview of considered feature ranking methods.

4	MTR_C	×
5	MTR_Z	
6	Spearman	

Table 6. Minimum, maximum and mean value of the average RMSE for prediction on the training dataset within cross-validation across all feature selection variations.

Algorithm	Minimum	Maximum	Mean
GP	1.2e-9	9.8e-9	4.6e-9
LR	0.0956	0.2178	0.1458
MLP	0.0345	0.1220	0.0529
RF	0.0114	0.0314	0.0167
SVM	0.0571	0.0991	0.0662

2019). A running-in process is estimated at 50 hours. Therefore, the initial 50 feature data points, approximately two days of measurements, are rejected. Subsequently, 20,296 features are computed from the 8 channels of each gearbox data. The feature data set is then divided into a training and a test dataset, using the data from the H45 gearboxes for training and the B045 for testing. The target is to select meaningful features using the data from the H45 gearboxes to train ML algorithms, as discussed in section 2.4, and to apply them on the data from the B45 gearbox to finally predict its HI. In the following, the application of the proposed feature processing and selection methodology presented in sections 2.2 and 2.3 is described.

Within feature processing, the feature data undergoes smoothing, where a window size of 15 points seems appropriate. This window size is also used to determine the initial feature data points $f_{i,j,init}$ to scale the data. For threshold preselection, α is set to 1 % and β to 85 %. A small value for α can be selected as the running-in process has been removed. The value for β is chosen to consider the strong and varying increase of feature values towards the end of life. Threshold preselection leads to the exclusion of 19,572 features.

To rank the features, the feature ranking methods discussed in section 2.3 are employed. Due to the positive experience with the Spearman correlation specifically regarding capturing the HI of a system in (Aimiyekagbon, Bender, & Sextro, 2021), an additional version is employed, where the Spearman correlation is used for evaluating the monotonicity. An overview of the feature ranking methods is given by Tab. 5, where the additional versions are marked as modified. In the following, the numbers assigned in Tab. 5 are used as representatives for the mentioned ranking methods.

Lastly, for the correlation analysis to reject highly correlated features, the threshold value for the correlation coefficient is set to 0.98. A high value is chosen to remove strongly correlated features, thereby leave room for selection based on feature ranking. The selected threshold leads to the exclusion of 273 of 724 features. Subsequently, the top 5 ranked features are selected from the remaining 451 features, standardized and utilized for training and testing. A shuffle split with 5 splits is employed for cross-validation, as only two systems are given for training. To ensure the reproducibility of the results, the random seed is fixed. For optimization, 200 iterations are set.

For comparison purposes, additionally, the proposed feature selection methodology is replaced by feature ranking only. Feature selection consisting of feature ranking only represents the classical feature selection process, which is predominantly followed in the literature such as in (Carino et al., 2015; Nie et al., 2022). That means that out of the total of 20,296 features the top 5 ranked ones are used for training allowing a direct comparison with the proposed feature selection methodology.

5. RESULTS

The selected features, results and insights gained from further analysis are discussed in more detail in the following.

When inspecting the selected features, the channels 1, 2 and 3 show a significant higher relevance as they are selected 19, 24 and 10 times of 60 in sum respectively through feature selection. This observation leads to the conclusion that the current in D-Q-coordinates is particularly suitable for predicting the system's condition in contrast to the phase current. As assumed, the effective and quadrature voltage is of minor importance. Further, it can be observed that abrupt changes, reversed direction of feature progression and large differences in the endpoints between same features of the train and the test set cause confusion in prediction.

The minimal, maximal and mean RMSE of the predictions on the training data within cross validation is shown in Tab. 6 and Fig. 7 presents the prediction errors from predicting the HI of the gearbox B045. Primarily, all algorithms show low error values on the training dataset, which in combination with the results in Fig. 7 indicates, that some algorithms generalize better (RF) than other (MLP). MLP and SVM generate the highest RMSE, probably increased by the small amount of training data. SVM performs better evaluating the selected features from feature ranking only, although the predictions get particularly worse towards the end of life. The full potential of the MLP may not be exploited, as the iterations during its training and optimization are both limited to 200. In addition, the layer size and depth is not varied during optimization.

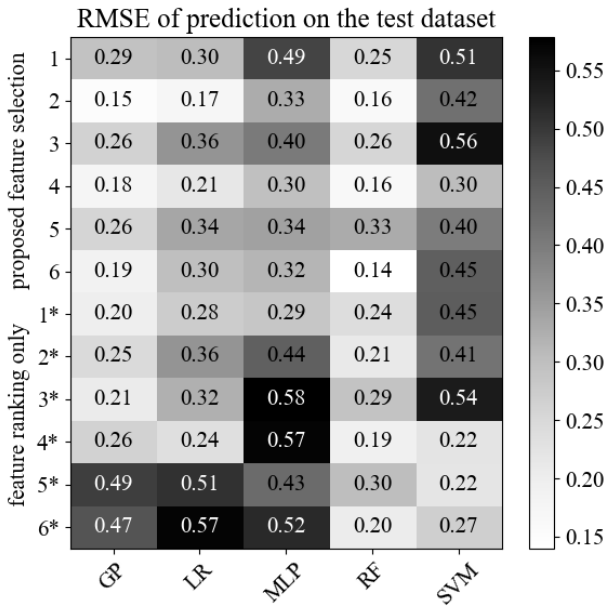

Figure 7. Results based on the estimation of the HI of gearbox B45, which provides the test data. The results are marked with an asterisk "*" when classical feature selection is applied and without when the proposed feature selection methodology is utilized.

The best performing algorithms are GP and above all RF. Especially noticeable is that the proposed selection method performs most effectively in combination with Spearman correlation for ranking the features as can be seen in rows 2, 4, and 6. To summarize, the best RMSE is reduced from 0.19 to 0.14 by around 26 % when the proposed feature selection method is utilized. The worst RMSE is reduced from 0.58 to 0.56 by around 3 %, whereby results with an RMSE of 0.5 and higher occur 6 versus 2 times and an RMSE of 0.4 and higher occurs 12 versus 7 times. Results with an RMSE of 0.2 and lower appear 2 versus 7 times. This indicates a higher robustness capabality using the proposed selection method.

The RF achieves the best result with an RMSE of 0.14 in row 6, where feature ranking within the proposed feature selection methodology is applied by assessing the Spearman correlation. The hyperparameters of the RF set by the hyperparameter optimization are given in Tab. 7 including a brief description. The selected features are shown in Fig. 8 where the feature values are plotted over the HI. The features are briefly described in Tab. 8. For detailed information on feature calculations, reference is made to the official documentation of tsfresh (Christ, Maximilian and Braun, Nils and Neuffer, Julius, 2016).

The prediction of the HI for the B45 gearbox data, generated by the RF trained on the presented features, is visualized in Fig. 9. The horizontal axis represents the actual HI values, while the vertical axis represents the predicted HI values. The diagonal line running from (1,1) to (0,0) represents the ideal prediction. The prediction of the test system shows a certain variance of the points, especially in the ranges 0.9 to 0.5 and 0.3 to 0.1 of the actual HI. The underestimated HI in the range 0.9 to 0.5 can be explained by the stronger gradient observed for the features 1 and 5. The overestimated HI in the range 0.3 to 0.1 is possibly caused by feature 2.

Table 7. Hyperparameter values and descriptions for the RF model set by the optimization algorithm.

Hyperparameter	Value	Description
n_estimators	149	Number of decision trees in the ensemble.
max_features	sqrt	Maximum number of features used to determine the best split. Here it is the square root of the number of features.
max_depth	27	Maximum depth of a single decision tree.
min_samples_split	1e-6	Minimum number of observations required to split a node in the decision trees. This number is defined by a fraction of the total number of observations.
min_samples_leaf	1e-6	Minimum number of observations required to form a leaf node. This number is defined by a fraction of the total number of observations.

Despite the observed variability, the prediction is deemed satisfactory considering the limited availability of training data and the structural differences between the systems for training and testing. The results presented underscore the ability of the proposed feature selection methodology in capturing the differences between the systems, especially in combination with the RF. Although certain challenges persist and continue to impact the overall results, the better results tend to align with the utilization of the proposed feature selection methodology, particularly shown in the upper half of the color map in Fig. 7.

6. Conclusion and Future Work

The effective use of available data is crucial, especially in scenarios characterized by data scarcity. The optimal use of available information is essential to improve the accuracy and reliability of prognostics and ensure efficient decision-making and resource allocation in the industry.

To tackle this challenge, comprehensive feature engineering with focus on feature selection is adopted, wherein the features are adapted to their initial values by scaling and feature selection is performed involving several successive steps. These steps encompass threshold-based preselection, feature ranking and cross-correlation analysis. Subsequently, training of ML-based models is conducted to predict the HI of the

Table 8. Description of the selected features obtained through the proposed feature selection methodology, wherein Spearman correlation was utilized for feature ranking.

Feature	Description
1	Value of the evaluated partial autocorrelation function at lag 6 of the quadrature current signal.
2	The highest order coefficient of a polynomial function the order 3 derived from the deterministic dynamics of the Langevin model, where 30 quantiles are used for averaging, based on the direct current data.
3	Complexity calculated by the Lempel-Ziv compression algorithm in the direct current data divided into 100 bins.
4	Custom feature explained in section 2.1, where direct current data is used. Bin 78 represents a frequency range from 26.12 to 26.86 Hz, where the FFT coefficients were aggregated by the mean.
5	The feature quantifies the maximum standard error of the linear trend over sections of length 5 in the direct current data.

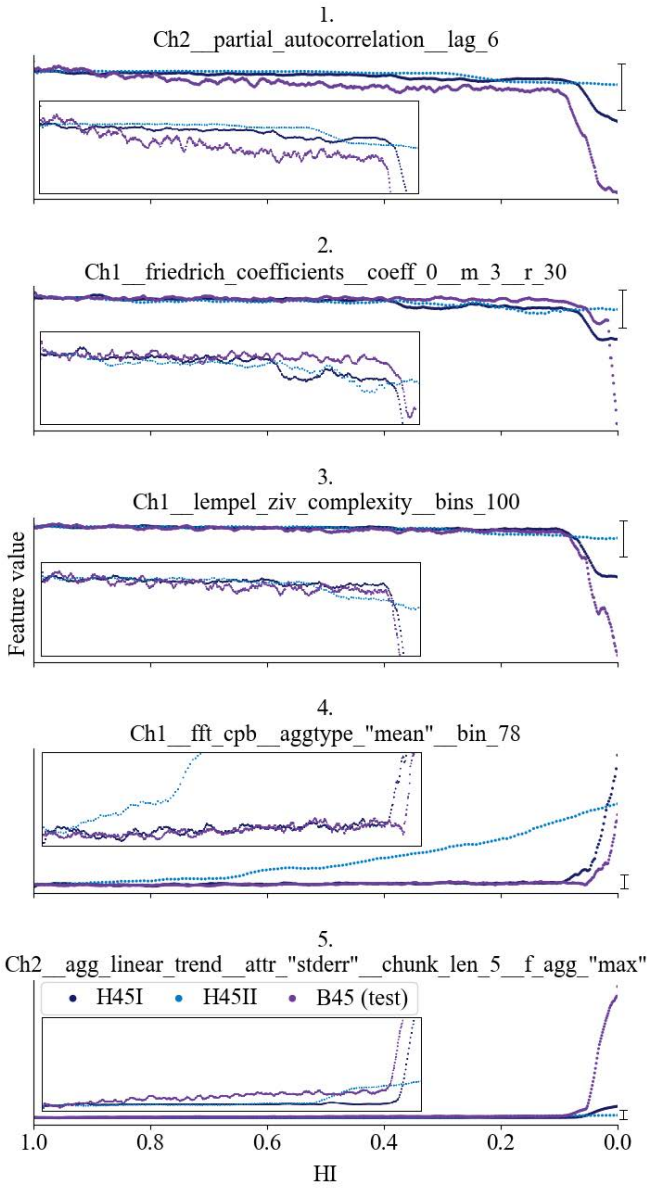

Figure 8. Best 5 features assessed by the proposed feature selection methodology based on the feature data from the H45 gearboxes, wherein the Spearman correlation was utilized for feature ranking. The boxes added indicate zoomed-in views of the features. The range is marked on the right edge. The feature values are unit free as they have been scaled.

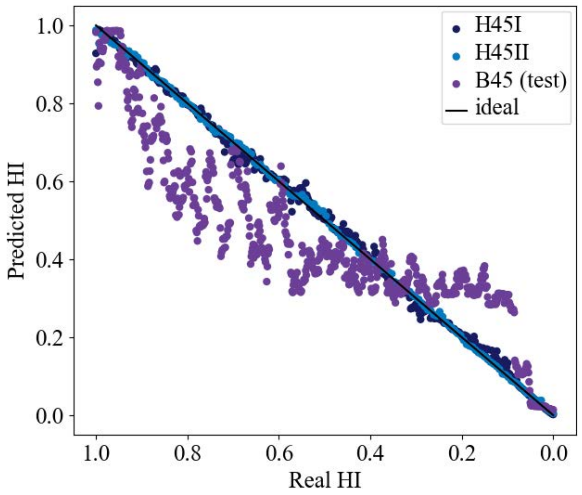

Figure 9. Test results generated by estimating the HI of the gearboxes H45I, H45II and B45, with the H45 gearboxes providing the training data and B45 gearbox the test data.

systems.

In order to evaluate the proposed methodology, a new dataset is introduced and utilized, which contains current, voltage and phase current data from run-to-failure experiments of gearboxes. The dataset is notable for considering two structurally different gearboxes and for addressing the challenge of data scarcity, as it is sourced from only three systems. The aim is to use the data from the two similar gearboxes to estimate and select features to infer the HI of the dissimilar gearbox over its entire operating time based on a ML algorithm. By publishing the novel dataset, other researchers are inspired to contribute to this specific problem setting.

It is observed that, the classical feature selection is able to select features capturing the degradation of the systems in some cases leading to an RMSE of 0.19 in the best case. However, the proposed feature selection methodology apparently supports overcoming system differences especially in combination with the RF by selecting appropriate features better leading to the best result overall with an RMSE of 0.14. Therefore, a great potential in applying the proposed methodology

to further problems in the field RUL-estimation is seen. It can enable more effective training based on ML training, as features are selected not only based on capturing the degradation of individual systems separately but also considering a common threshold for failure while avoiding redundancies.

The next research steps will include validation of the proposed methodology using further data or different test conditions to check the limitations, reliability and robustness of the results. The exploration of alternative methods, such as mutual information, should also be considered at the last step of the proposed feature selection process to replace the Pearson correlation analysis. These methods have the potential to enhance the methodology. Furthermore, the applicability of the proposed method to different types of gearboxes or even to other technical systems should be explored. This would contribute to demonstrating the scope and versatility of the proposed approach.

ACKNOWLEDGMENT

This research and development project is funded by the Ministry of Economy, industry, climate action and energy of the State of North Rhine-Westphalia (MWIKE) in the context of the Leading-Edge Cluster ‚Intelligent Technical Systems OstWestfalenLippe (it's OWL)' and supervised by Project Management Jülich (PtJ). BIOGRAPHIES

Alexander Loewen obtained his BSc and MSc in mechanical engineering at the Paderborn University, Germany. Since 2022, he is part of the Chair for Dynamics and Mechatronics at the Paderborn University. His research focuses on the automated training of ML based models for technical systems, particularly in anomaly detection, classification, and regression tasks under stationary operating conditions.

Peter Wissbrock is currently working as a researcher at the Innovation Department of Lenze SE. He obtained his BSc and MSc in electrical engineering at the OWL University of Applied Sciences and Arts, Germany. He is pursuing Ph.D. from Leibniz University Hannover, Germany in field of industrial analytics. He works in domain of drive train fault diagnosis, machinery anomaly detection and data acquisition infrastructure.

Amelie Bender studied mechanical engineering at RWTH Aachen University, Germany, and one semester abroad at the University of Newcastle, Australia. Since 2015 she is with the research group Dynamics and Mechatronics at Paderborn University, Germany. During her doctoral studies in mechanical engineering, her research focusses on condition monitoring of rubber-metal-bearings. She was awarded the academic degree Dr.-Ing. in 2021. As a team leader at the research group Dynamics and Mechatronics at Paderborn University, her research covers the topics condition monitoring, data analytics and reliability engineering.

Walter Sextro studied mechanical engineering at the Leibniz University of Hanover and at the Imperial College in London. Afterwards, he was development engineer at Baker Hughes Inteq in Celle, Germany and Houston, Texas. Back as research assistant at the University of Hanover he was awarded the academic degree Dr.-Ing. in 1997. Afterwards, he habilitated in the domain of mechanics under the topic Dynamical contact problems with friction: Models, Methods, Experiments and Applications. From 2004-2009 he was professor for mechanical engineering at the Technical University of Graz, Austria. Since March 2009 he is professor for mechanical engineering and head of the research group Dynamics and Mechatronics at the University of Paderborn.

ABSTRACT

This study introduces an integrated framework for conceptualizing the design of negative stiffness honeycomb (NSH) structures, specifically considering the durability and performance of their unit cells. Unlike conventional energy-absorbing structures that rely on plastic deformation, NSH offers a promising alternative for reusable energy absorption (EA) and high initial stiffness, making it suitable for a wide range of engineering applications. The research considers the variability in characteristics of NSH based on the shape of the configured negative stiffness beam (NSB), selecting a single curved-beam unit cell as the focal point. Extensive testing, including quasi-static and cyclic compression tests, is conducted on NSH unit cell fabricated using polylactic acid/polyhydroxy alkenoate (PLA/PHA) filament, to analyze performance under stress and to assess degradation over time. Central to the study is the use of multi-objective optimization (MOO) to explore the trade-off between performance and operational durability, thereby emphasizing the significance of degradation in the design process. The results demonstrate the potential for NSH structures, particularly in terms of their reusability and efficiency, highlighting the viability of incorporating durability considerations in the early stages of design, especially for structures intended for additive manufacturing processes.

1. INTRODUCTION

NSH structures exhibit unique characteristics when compared to traditional hexagonal honeycombs. While hexagonal honeycombs effectively absorb energy through plastic deformation, they fall short in terms of reusability post-deformation. (Correa et al., 2015) NSH structures, composed of NSBs, stand out for their recoverable energy absorption, as highlighted by (Klatt et al., 2013; Correa et al., 2015), their high initial stiffness (Correa et al., 2015), and their capabilities in impact isolation (Shan et al., 2015; Debeau et al., 2018), creating opportunities for their use in many engineering fields.

Many studies have been conducted on the characteristics of such NSBs. Qiu et al. (2004) studied a bistable mechanism with a curved beam, whereas Klatt et al. (2013) demonstrated negative stiffness behavior and recoverable energy absorption through vertical axial compression in an additively manufactured structure with a curved beam. Correa et al. (2015) optimized the dimensions of NSH, achieving a structure with similar relative density and force threshold as traditional hexagonal honeycomb, but with better energy absorption per unit mass, closely matching the performance of the hexagonal honeycomb. Chen et al. (2021) showed that NSH, comprising curved beams of varying thicknesses, not only improved energy absorption per mass but also enhanced shock absorption and vibration isolation compared to uniform-thickness NSH. Zhang et al. (2021) proposed a lattice and hollow structure for the curved beam, showing better energy dissipation than conventional curved beams of the same volume. Liu et al. (2020) used machine learning methods to achieve enhanced results in curved beam thickness optimization. In addition, research on cylindrical structure (Wang et al., 2020), cubic structure (Ha et al., 2019), and composite negative stiffness structure (Chen et al., 2020) shows various negative stiffness structures and different features depending on the shape and dimensions of NSBs.

A key feature of negative stiffness structures like NSH, distinguishing them from other structures, is their reusability. The studies in Correa et al. (2015), Tan et al. (2019), and

Chen et al. (2020) show the properties of negative stiffness structures, such as force thresholds and energy absorption or dissipation under repeated compression. Chen et al. (2020) shows that the degree of reduction in force threshold for cyclic compression depends on the dimensions of the NSB's thickness. However, there has been limited research on quantifying the performance reduction of negative stiffness structures relative to the NSB dimensions under cyclic compression, which is crucial for predicting the operational end of life (EOL) of these structures.

To address this gap, we propose an integrated design framework that considers both the performance and operational aspects of negative stiffness structures like NSH, including performance degradation. In this study, we targeted the unit cell of NSH for design and manufactured it using PLA/PHA filament through 3D printing. To consider both performance and operational aspects, we conducted quasi-static compression tests and cyclic compression tests to acquire data. Based on this data, we developed a model to estimate the performance and EOL of the NSH unit cell according to its dimensions. Finally, through the Multi-objective Optimization (MOO) design process considering the estimated performance and EOL of the NSH unit cell, we not only confirmed the relationship between the structural performance and operational aspects but also provided insights into the design considering both aspects.

2. DESIGN OF EXPERIMENT

The unit cell of NSH, as illustrated in Figure 1, was employed in this study. The structure of the curved-beam is assumed to be based on Eq. (1). (Qiu et al., 2004) The design variables defined for this structure are the thickness (t) and central height (h) of the curved beam.

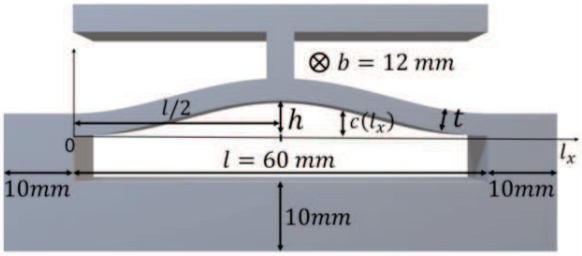

Figure 1. Geometry and dimension of unit cell of NSH

$$c(l_x) = \frac{h}{2}\left[1 - cos\left(2\pi\frac{l_x}{l}\right)\right] \qquad (1)$$

Considering that Zhakatayev et al. (2020) and Tan et al. (2019) have confirmed that the influence of the thickness (t) and height (h) of NSB on the strength, absorbed energy per unit mass, and force threshold of negative stiffness structure, and Qiu et al. (2004) have established a relationship between force-displacement of the curved-beam and geometric parameters as per Eq. (2),

$$F = \frac{3\pi^4 Q^2}{2} d_n \left(d_n - \frac{3}{2} + \sqrt{\frac{1}{4} - \frac{4}{3Q^2}}\right)\left(d_n - \frac{3}{2} - \sqrt{\frac{1}{4} - \frac{4}{3Q^2}}\right) \qquad (2)$$

Klatt et al. (2013) observed that negative stiffness initiates when the numerical value of $Q(= h/t)$ reaches 1.5, when Q exceeds 2.31, the bi-stable characteristics become evident. Therefore, t and h can be considered as important design factors for the negative stiffness structure like Fig 1.

Therefore, we defined the range of t as $1.2[mm] \leq t \leq 3.2[mm]$ and h as $1.2[mm] \leq h \leq 6.4[mm]$. Subsequently, we sampled samples using the design of experiment (DOE) method to train and test the surrogate models and classification models for the characteristics of NSH unit cell, which will be discussed later in section 4 and 5. First, 25 samples were sampled for the training data using the full factorial design (FFD) method. For the test data, 10 samples were sampled through the optimal Latin hypercube design (OLHD) method. The results are illustrated in Figure 2.

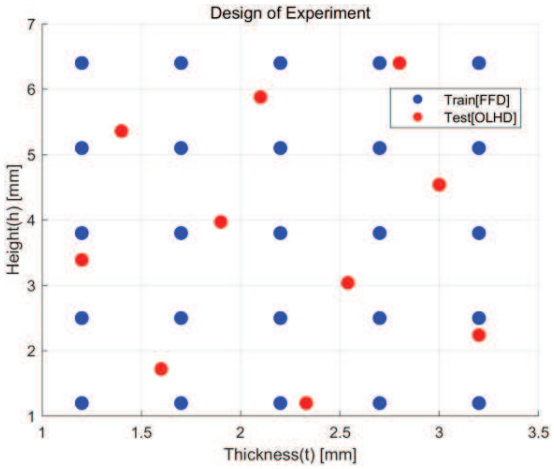

Figure 2. Result of design of experiment

3. FABRICATION AND TEST

We manufactured NSH unit cells with dimensions obtained through the DOE process using a fused filament fabrication (FFF) 3D printer and PLA/PHA filament. Liu et al. (2023) demonstrated that variations in manufacturing features, such as building direction, fill pattern, and wall layers influence printing quality and performance of the NSH cell through the FFF method. Therefore, we considered three different infill angles for 3D printing. We utilized Simplify 3D software for 3D printing, and detailed printing settings can be found in Table 1.

3.1. Material Properties

In this study, Colorfabb's PLA/PHA filament was utilized for fabricating NSH unit cell. Research conducted by Morettni et al. (2022), Letcher & Waytashek et al. (2014), Zouaoui et al. (2021), and Gonabadi et al. (2020) have confirmed that the physical properties of FFF 3D printing can

vary depending on manufacturing parameters such as infill angle or pattern. Therefore, to account for these manufacturing characteristics, five specimens were printed with three different infill angles (0°, 45°, and 90°) to assess the physical properties of the PLA/PHA filament through ASTM D638. An example of specimens is depicted in Figure 3, and the result of ASTM D638 are presented in Table 2.

Table 1. 3D Printing setting.

Nozzle Temperature	210 ℃
Bed Temperature	60 ℃
Infill Density	100 %
Infill Pattern	Rectilinear
Infill Angle	[0°, 45°, 90°]
Layer height	0.2 mm
Printing Speed	50 mm/s
Cooling Fan Speed	100 %
Building direction	Flat
Material	PLA/PHA

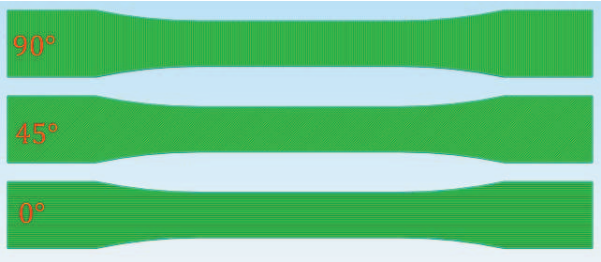

Figure 3. ASTM D638 specimen with three angles of infill

In Table 2, the average values and standard deviations of the ASTM D638 test results show that the average values of Young's modulus, yield strength, and elongation decreases as the infill angle increases from 0° to 45° and 90°. This is because as the infill angle increases, the force applied to the specimen and the direction of the stacked filament become more closely perpendicular. Therefore, when manufacturing the unit cells of NSH through 3D printing, we set the infill angle to 0° and produced 5 unit cells of NSH per sample. An example is illustrated in Figure 4.

Table 2. Material properties according to infill angles

Infill angle	Young's Modulus [GPa]	Yield Strength [MPa]	Elongation [%]	Poisson's Ratio
0°	2.84 (0.059)	52.11 (0.548)	5.84 (1.629)	0.34 (0.005)
45°	2.59 (0.019)	37.86 (0.833)	5.75 (1.561)	-
90°	1.99 (0.062)	16.48 (1.250)	1.65 (0.366)	-

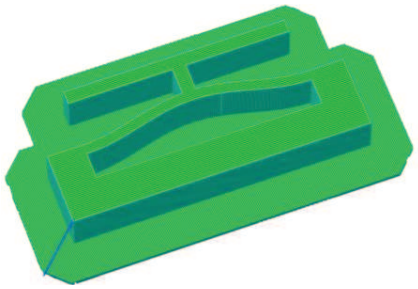

Figure 4. A unit cell for NSH with 0° infill angle

3.2. Compression Test for Data Acquisition

Quasi-static compression tests and cyclic compression tests were conducted to acquire experimental data, considering the performance and operational aspects of the NSH's unit cell. In both tests, compression was applied by inducing a displacement of $2h$ to the unit cell of NSH. The compression test equipment comprised a JSV-1000 stand and a HF-100 force gauge. Additionally, consistent compression test conditions were maintained throughout by securing both ends of the structure using a support structure, as depicted in Figure 5.

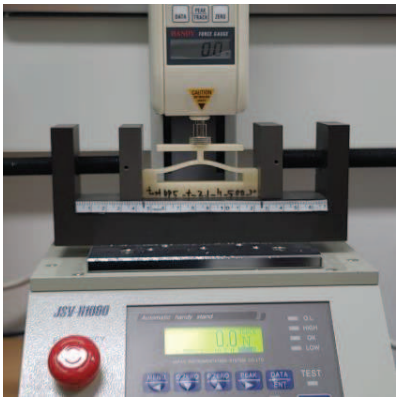

Figure 5. Compression test equipment and environment

However, different types of NSH unit cells were utilized in the two types of tests, as shown in Figure 6. The structure depicted in Figure 6 represents a configuration designed for quasi-static compression test. Unlike Figure 1, an additional structure is incorporated at the compression center of the T-shaped support to minimize asymmetric buckling mode in the curved-beam behavior. Conversely, for the cyclic compression test, these additional structures may interfere with the cyclic compression process, hence a configuration similar to Figure. 1 was employed.

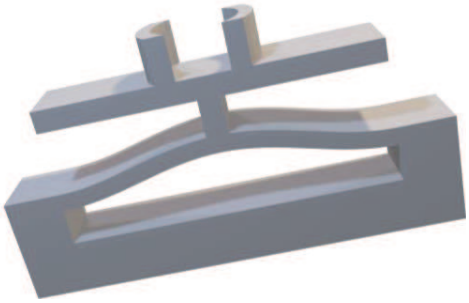

Figure 6. Shape of the NSH unit cell used in quasi-static compression test

3.2.1. Quasi-static Compression Test

To assess the performance aspect of NSH unit cell, a quasi-static compression test was conducted at a speed of 10 mm/min. The obtained force-displacement data were preprocessed using a moving average filter to generate five force-displacement curves for each sample, as illustrated in Figure 7.

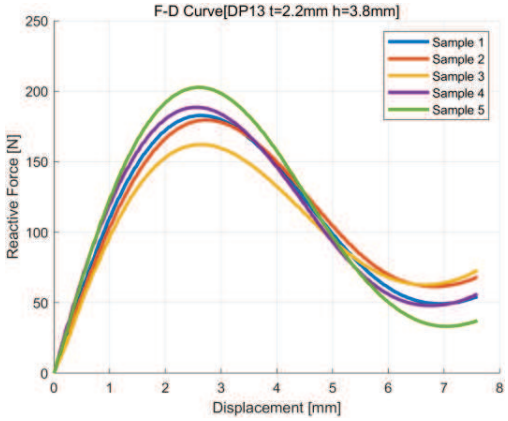

Figure 7. Force-displacement curve for quasi-static compression test

Then, specific energy absorption (SEA) was obtained by dividing Eq. (4) by Eq. (3), with the average SEA value designated as the representative value for the corresponding sample.

$$m = \rho b\left[\left(\int_0^l (c(l_x)+t)dw\right)-\left(\int_0^l c(l_x)\,dw\right)\right] \quad (3)$$

$$EA = \left(\int_0^{2h} f(w)dw\right) \quad (4)$$

These data were also used to examine the occurrence of negative stiffness for five samples of each design point employed in the experiments, as detailed in Section 5. The occurrence of negative stiffness was assessed using Eq. (5), as established by Qiu et al. (2004), and Eq. (6) based on the force-displacement data.

$$w_{mid} = \frac{4}{3}h \quad (5)$$

$$\begin{cases} max_{w<w_{mid}}(f(w)) - f(w_{mid})) > 0 \rightarrow Negative\ stiffness \\ otherwise \rightarrow Non-Negative\ stiffness \end{cases} \quad (6)$$

This allowed us to classify whether negative stiffness occurred based on w_{mid} in the force-displacement curve.

3.2.2. Cyclic Compression Test

In this experiment, 30 cycles of compression were repeatedly applied at a speed of 60 mm/min. The force-displacement data obtained underwent the same data preprocessing as the quasi-static compression test. The average force-displacement curve for each sample is depicted in Figure 8. Using mean force-displacement data, EA for each cycle was calculated using Eq. (4); mean force-displacement data was also utilized as the health index (HI) for estimating the end of life (EOL), a topic discussed in detail in Section 6.

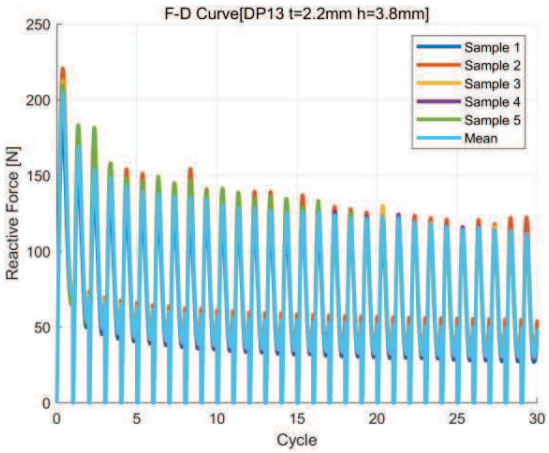

Figure 8. Reactive force for each cycle of the cyclic compression test

4. SURROGATE MODEL

A surrogate model replaces a high-cost test-based or simulation model with a relatively low-cost alternative. By creating a surrogate model for a specific factor of interest, predictions can be made without the need for costly tests or simulations for any given sample. In this study, the Kriging method, implemented in the PIAnO 2024 software, was used to develop a surrogate model for the performance and operational factors of the NSH unit cell. This approach enabled the prediction of the values of these factors for a specific design point.

4.1. Kriging

Kriging is one of the most widely used methods for constructing a surrogate model or metamodel, also known as Gaussian process regression. Based on the references to

Forrester et al. (2008) and Kim et al. (2017), the explanation of Kriging would be as follows: In Kriging, the predicted output of a Kriging model is typically represented as Eq. (7).

$$\hat{y}(\mathbf{x}) = \mathbf{g}(\mathbf{x})^{\mathrm{T}}\boldsymbol{\theta} + \delta(\mathbf{x}) \tag{7}$$

Here, $\mathbf{g}(\mathbf{x})^{\mathrm{T}}\boldsymbol{\theta}$ represents the global function, and $\delta(\mathbf{x})$ represents the local departure. In our study, $\mathbf{x}$ denotes the dimensions of the NSH unit cell, such as t and h, while $\hat{y}$ represents the value we want to predict, such as SEA. We have defined the correlation function for two points ($\mathbf{x}, \mathbf{x}'$) as shown in Eq. (8).

$$\Gamma(\mathbf{x}, \mathbf{x}') = \prod_{i=1}^{ndv} \exp\left(-p_i |x_i - x_i'|^{1.5}\right) \tag{8}$$

where ndv indicates the number of design variables, and p_i represents the parameter of the correlation function. Other types of covariance functions can be found in Rasmussen & Williams (2006) and Xu (2020). Therefore, the correlation matrix is expressed as shown in Eq. (8), and the correlation between the point $\mathbf{x}$ to be predicted and the observed points is expressed as shown in Eq. (9).

$$\boldsymbol{\Gamma} = \begin{pmatrix} \Gamma(\mathbf{x_1}, \mathbf{x_1}) & \cdots & \Gamma(\mathbf{x_1}, \mathbf{x}_N) \\ \vdots & \ddots & \vdots \\ \Gamma(\mathbf{x}_N, \mathbf{x_1}) & \cdots & \Gamma(\mathbf{x}_N, \mathbf{x}_N) \end{pmatrix} \tag{9}$$

$$\boldsymbol{\gamma} = \begin{pmatrix} \Gamma(\mathbf{x_1}, \mathbf{x}) \\ \vdots \\ \Gamma(\mathbf{x}_N, \mathbf{x}) \end{pmatrix} \tag{10}$$

To estimate the parameters of the Kriging model, $\boldsymbol{\theta}$, s^2, and $\mathbf{h}$, we use maximum likelihood estimation (MLE). So, the logarithmic likelihood can be expressed as Eq. (11).

$$\begin{aligned} &\ln\left(L(\mathbf{y}|\boldsymbol{\theta}, s^2)\right) \\ &= -\frac{N}{2}\ln(2\pi) - \frac{N}{2}\ln(s^2) - \frac{1}{2}\ln(|\boldsymbol{\Gamma}|) \\ &- \frac{(\mathbf{y} - \mathbf{G}\boldsymbol{\theta})^{\mathrm{T}}\boldsymbol{\Gamma}^{-1}(\mathbf{y} - \mathbf{G}\boldsymbol{\theta})}{2s^2} \end{aligned} \tag{11}$$

Taking the derivatives of Eq. (11) for $\boldsymbol{\theta}$ and s^2 respectively, and setting them to zero, yields the estimation results via MLE as shown in Eqs. (12) and (13).

$$\hat{\boldsymbol{\theta}} = (\mathbf{G}^{\mathrm{T}}\boldsymbol{\Gamma}^{-1}\mathbf{G})^{-1}(\mathbf{G}^{\mathrm{T}}\boldsymbol{\Gamma}^{-1}\mathbf{y}) \tag{12}$$

$$\hat{s}^2 = \frac{(\mathbf{y} - \mathbf{G}\boldsymbol{\theta})^{\mathrm{T}}\boldsymbol{\Gamma}^{-1}(\mathbf{y} - \mathbf{G}\boldsymbol{\theta})}{2N} \tag{13}$$

The parameter h is determined by substituting Eqs. (12) and (13) into Eq. (11), and the resulting value is maximized by the optimization algorithm (Differential evolution, DE), as expressed in Eq. (14).

$$p = argmax\left[-\frac{N}{2}\ln(\hat{s}^2) - \frac{1}{2}|\boldsymbol{\Gamma}|\right] \tag{14}$$

Given a vector $\hat{\mathbf{y}} = [\mathbf{y}^{\mathrm{T}}, \hat{y}\,]^{\mathrm{T}}$, which includes the new predicted value $\hat{y}$ at $\mathbf{x}$, the correlation matrix can be written as Eq. (15).

$$\hat{\boldsymbol{\Gamma}} = \begin{pmatrix} \boldsymbol{\Gamma} & \gamma \\ \gamma^{\mathrm{T}} & 1 \end{pmatrix} \tag{15}$$

Based on this, we obtain the logarithmic likelihood, as shown in Eq. (16).

$$\begin{aligned} &\ln(L) \\ &= -\frac{N}{2}\ln(2\pi) - \frac{N}{2}\ln(\hat{s}^2) - \frac{1}{2}\ln\left(|\hat{\boldsymbol{\Gamma}}|\right) \\ &- \frac{(\hat{\mathbf{y}} - \mathbf{G}\hat{\boldsymbol{\theta}})^{\mathrm{T}}\hat{\boldsymbol{\Gamma}}^{-1}(\hat{\mathbf{y}} - \mathbf{G}\hat{\boldsymbol{\theta}})}{2\hat{s}^2} \end{aligned} \tag{16}$$

Differentiating Eq. (16) with respect to $\hat{y}$ and setting it to zero, the final output of a Kriging model is expressed as Eq. (17):

$$\hat{y}(\mathbf{x}) = \mathbf{g}(\mathbf{x})^{\mathrm{T}}\hat{\boldsymbol{\theta}} + \boldsymbol{\gamma}(\mathbf{x})^{\mathrm{T}}\boldsymbol{\Gamma}^{-1}(\mathbf{y} - \mathbf{G}\hat{\boldsymbol{\theta}}) \tag{17}$$

4.2. SEA Prediction Model

We formed a surrogate model for SEA to consider the performance aspect of the NSH unit cell. To do this, we first performed a quasi-static compression test on the 25 samples collected by the FFD method, with 5 samples per test point. The average SEA results for each sample were successfully obtained.

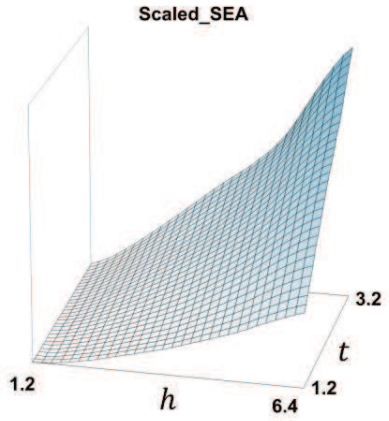

Figure 9. Response surfaced of Scaled SEA_{mean}

Prior to creating the surrogate model using 25 datasets, we set the design variables of the NSH unit cell, t and h, as the inputs for the surrogate model, with SEA_{mean} as the output. Both input and output data were scaled to have values between 0 and 1 using min-max scaling. Finally, we set the global function type to constant, and the results of this surrogate model are depicted in Figure 9. As shown in Figure 9, SEA_{mean} tends to increase as the values of the design variables t and h increase. The root mean square error (RMSE) for this surrogate model was computed using Eq. (18) with 10 test data points, resulting in an RMSE of 0.0276.

$$RMSE = \sqrt{\frac{1}{N}\sum_{i=1}^{N}(y_{pred,i} - y_{true,i})} \quad (18)$$

4.3. Energy Absorption over Cycles Prediction Model

Similar to Section 4.2, Kriging was utilized to generate surrogate models for predicting EA over the compression cycle using average force-displacement data from about 25 samples collected via FFD method.

Initially, EA for each compression cycle was computed using Eq. (19):

$$EA_{cycle} = \left(\int_0^{2h} f_{cycle}(w)dw\right) \quad (19)$$

Following this, it was assumed that there was no degradation in the NSH unit cell prior to cyclic compression test, and Eq. (20) was used to scale based on 1 cycle of EA as a reference.

$$EA_{sc} = \frac{EA_{cycle}}{EA_{\,1\,cycle}} \quad (20)$$

An example of EA_{sc} is shown in Figure 10, where it is crucial to note that for any sample, EA_{sc} is 1 at 1 cycle. EA_{sc} was used as the HI for estimating EOL.

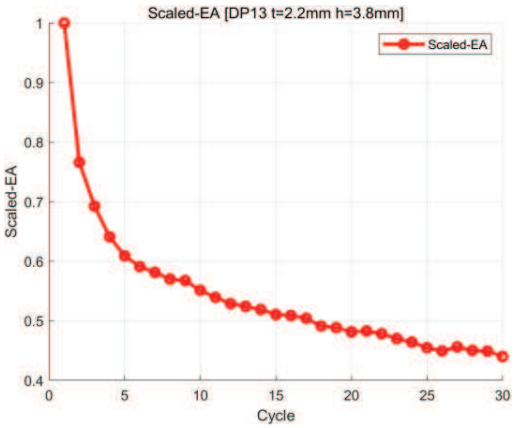

Figure 10. Scaled EA over cycles

The EA_{sc} was further processed by Eq. (21) for samples with a EA_{sc} exceeding 0.9 at 30 cycles:

$$\begin{cases} EA_{sc} = 1, \quad for \ \ cycle = 1 \\ EA_{sc} = EA_{sc-1} - |EA_{sc} - EA_{sc-1}|, otherwise \end{cases} \quad (21)$$

The input data, consisting of t and h, was used to train the model, aiming to predict EA_{sc} for a specific cycle. Unlike the surrogate model for SEA_{mean}, only min-max scaling was applied to the input data, and a simple quadratic function was utilized as the global function to construct the surrogate model. The corresponding response surface for this is shown in Figure 11.

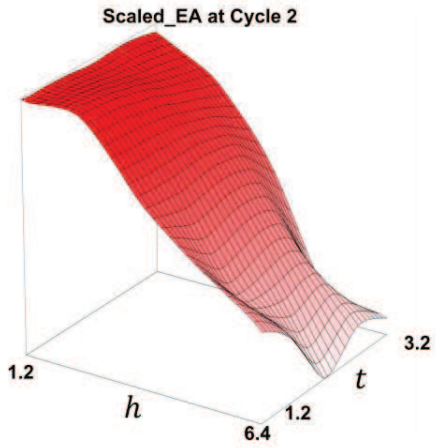

Figure 11. Response surfaced of EA_{sc} at cycle 2

The surrogate model predicts EA_{sc} for each cycle, which is then utilized to estimate the EOL for NSH unit cells. This will be discussed in detail in Section 6.

5. CLASSIFICATION MODEL

A classification model was developed based on the findings discussed in Section 3.2.1, where the design of NSH unit cells exhibits negative stiffness depending on certain design variables. Previous studies by Shahan et al. (2012), Morris et al. (2018), and Matthews et al. (2016) demonstrated that a set-based approach using the Bayesian network classifier method can be used to explore the boundaries of the design space and identify designs that meet specific performance criteria. Based on this, we utilized the Bayesian classifier as a classification model to determine the presence of negative stiffness. We formed the classification model using the results from quasi-static compression tests on 25 samples. Furthermore, this classification model was used as a constraint in the MOO design process, which will be discussed in detail in Section 7.

5.1. Bayes classifier

The results from all five test points in the quasi-static compression test were incorporated into the Bayesian classifier model. Specifically, the prior probability, as defined by Eq. (22) from Shahan et al. (2012), was established based on the frequency of occurrence of negative stiffness.

$$\begin{cases} P(c_{NS}) = \dfrac{N_{NS} + 1}{N + 2} \\ P(c_{NNS}) = \dfrac{N_{NNS} + 1}{N + 2} \end{cases} \quad (22)$$

For the likelihood, multivariate kernel density estimation was employed as described by Scott (2015) and can be expressed using Eq. (23):

$$\begin{cases} P(\mathbf{x}|c_{NS}) = \frac{1}{N_{NS}\beta_{1,NS}\cdots\beta_{N_d,NS}}\sum_{i=1}^{N_{NS}}\left\{\prod_{j=1}^{N_d}K\left(\frac{x_j - x_{ij}}{\beta_j}\right)\right\} \\ P(\mathbf{x}|c_{Non-NS}) = \frac{1}{N_{NNS}\beta_{1,NNS}\cdots\beta_{N_d,NNS}}\sum_{i=1}^{N_{NNS}}\left\{\prod_{j=1}^{N_d}K\left(\frac{x_j - x_{ij}}{\beta_j}\right)\right\} \end{cases} \quad (23)$$

The Gaussian kernel K is used, and the bandwidth β values are calculated using Eq. (24):

$$\begin{cases} \beta_{j,NS} = s_j\left\{\frac{4}{(N_d+2)N_{NS}}\right\}^{1/(N_d+4)} \\ \beta_{j,NNS} = s_j\left\{\frac{4}{(N_d+2)N_{NNS}}\right\}^{1/(N_d+4)} \end{cases} \quad (24)$$

The posterior probabilities for the two classes are given by Eq. (25).

$$\begin{cases} P(c_{NS}|\mathbf{x}) = P(c_{NS})P(\mathbf{x}|c_{NS}) \\ P(c_{NNS}|\mathbf{x}) = P(c_{NNS})P(\mathbf{x}|c_{NNS}) \end{cases} \quad (25)$$

$$\lambda_1 P(c_{NS})P(\mathbf{x}|c_{NS}) - \lambda_2 P(c_{NNS})P(\mathbf{x}|c_{NNS}) > 0 \quad (26)$$

Then, the decision rule for class for classifying a sample regarding the occurrence of negative stiffness is defined by Eq. (26) below. According to the study by Shahan et al. (2012), it has been confirmed that the loss factor λ_1 and λ_2 can shift the decision boundary of the classifier. Therefore, setting $\lambda_1 = 0.66$, $\lambda_2 = 0.34$ accounts for cases where negative and non-negative stiffness may occur simultaneously in the samples. This setting allows the classification of such samples into the class indicating the occurrence of negative stiffness. With $\lambda_1 = 0.66$ and $\lambda_2 = 0.34$, the difference between the two posterior probabilities is illustrated in Figure 12.

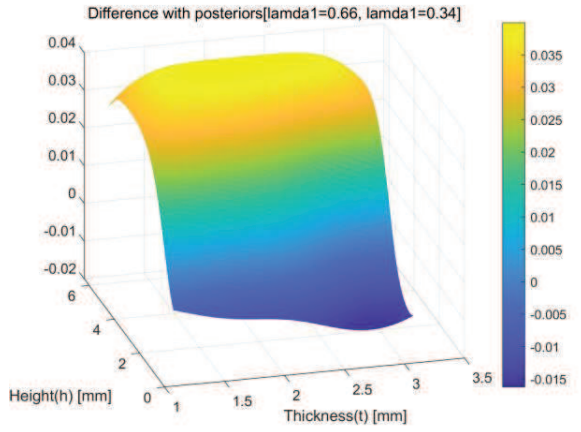

Figure 12. Difference between the two posterior probabilities

6. PREDICTING EOL OF NSH UNIT CELL

In order to consider the operational aspects of the NSH unit cell, prognostics methods were utilized to estimate the EOL. According to Kim et al. (2017), prognostics methods can be categorized into physics-based and data-driven approaches. Kim et al. (2017) also introduced nonlinear least square (NLS), Bayesian method (BM), and particle filter (PF) within physics-based prognostics. In this study, the NLS method demonstrated by Kim et al. (2017) was used to estimate the EOL by considering degradation, as shown in Figure 10, through EA_{sc}, which serves as the HI of the NSH unit cell.

First, to estimate the EOL via NLS, the degradation equation was defined as Eq. (27):

$$\varphi = exp\left(-|\xi_1| \cdot (cycle - 1)^{\xi_2}\right) \quad (27)$$

The parameters ξ_1 and ξ_2 were estimated using the 'lsqnonlin' function in MATLAB R2023b, employing the Levenberg-Marquardt method. To consider the uncertainty of the estimated model parameters in NLS, the 95% confidence intervals for the model parameters were obtained from 1.0E7 random sampling from the multivariate t-distribution using Eqs. (28) and (29), with degrees of freedom $N - N_p + 1$. Here, Eq, (28) represents the variance of noise in measured data, and Eq. (29) represents the variance of estimated model parameters.

$$s_n^2 = \frac{\{\mathbf{y} - \boldsymbol{\varphi}\}^{\mathrm{T}}\{\mathbf{y} - \boldsymbol{\varphi}\}}{N - N_p} \quad (28)$$

$$\mathbf{M}_{\xi} = s_n^2[\boldsymbol{\Psi}^{\mathrm{T}}\boldsymbol{\Psi}]^{-1} \quad (29)$$

The challenge in EOL estimation lies in determining amount of EA_{sc} data needed to estimate the EOL using the surrogate model from Section 4.3, and how to estimate parameters ξ_1 and ξ_2 using NLS. To address this, a model was developed to predict EA_{sc} for design variables t and h across 2 to 15 cycles using the Kriging model from Section 4.3. For the 10 test data, the EA_{sc} data estimated by the surrogate model from 3 to 15 cycles was progressively added, calculating the median of the confidence interval of NLS and the mean RMSE of the actual experimental data. The results of mean RMSE are depicted in Figure 13.

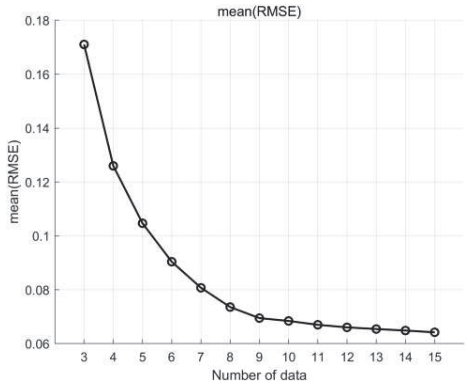

Figure 13. Mean RMSE by number of data

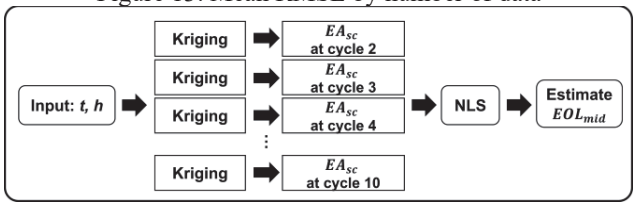

Figure 14. EOL Estimation Process

It was observed that utilizing more than 10 cycles of data predicted from surrogate model (i.e., beyond 1-10 cycles) did not significantly affect the estimation error in degradation estimation via NLS. Consequently, EA_{sc} values were estimated for 2-10 cycles through a surrogate model as shown in Figure 11, considering that at 1 cycle, the EA_{sc} value is consistently 1 across all samples. This process is illustrated in Figure 14. Therefore, this process was utilized to estimate the EOL of the NSH unit cell, and the median of the EOL confidence interval (EOL_{mid}) was used in the MOO design process, which will be discussed in detail in Session 7.

7. MULTI-OBJECTIVE OPTIMIZATION DESIGN

A MOO design was implemented to address both the performance and operational aspects of the NSH unit cell. SEA_{mean} was considered for the performance aspect, while the estimated EOL_{mid} served as the objective function for the operational aspect. Constraints included the strain of the curved beam, the threshold for HI, and the presence or absence of negative stiffness. The problem was formulated accordingly, and the results of the MOO design were analyzed using the NSGA-2 optimization algorithm (Deb et al., 2002), implemented in the PIAnO 2024 software. The overall flowchart is depicted in Figure 15.

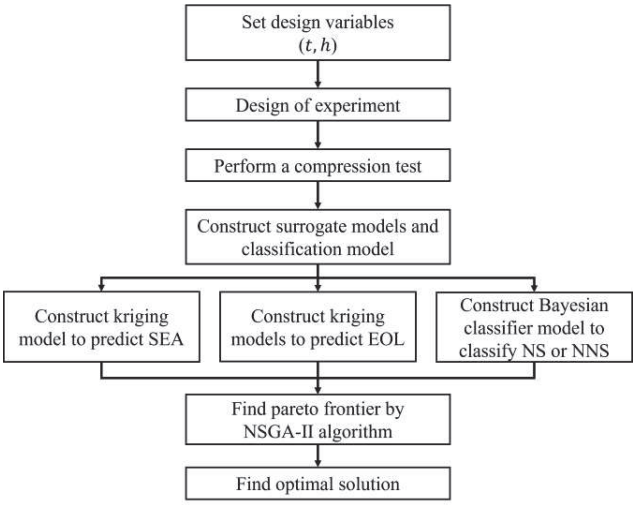

Figure 15. Flowchart of multi-objective optimization design

7.1. Problem Formulation

For the MOO design, the problem formulation is defined as Eq. (30). Initially, the surrogate model for SEA_{mean}, as discussed in Section 4.2, was employed to address the performance aspect of the NSH unit cell. Maximizing the SEA_{mean} implied enhancing the capacity of the unit's curved beam to absorb energy relative to its mass. Subsequently, the EOL_{mid} estimated through the approach outlined in Section 6, was considered for the operational aspect. To ensure comparability in scale between the scaled SEA_{mean} by min-max scaling and the estimated EOL_{mid}, we utilized the EA_{sc} obtained from cyclic compression tests from 1 to 30 cycles on the 25 samples extracted using the FFD method to estimate EOL_{mid}. Based on this estimation, we performed min-max scaling on the estimated EOL_{mid}. At this point, it was assumed that the EOL_{mid} from 25 samples provides sufficient information about EOL_{mid} for the entire design space.

The first constraint was defined using the maximum strain, determined from the mean elongation when the infill angle is 0°. The second constraint was defined as the occurrence of negative stiffness, where $\lambda_1 = 0.66$ and $\lambda_2 = 0.34$. The threshold for EA_{sc} as HI was assumed to be 0.7, indicating that the structure has degraded to 30% of its original performance.

$$\begin{aligned} &Find && t, h \\ &maximize && f(\mathbf{x}) \\ &&& = SEA_{sc,mean}(t_{sc}, h_{sc}) \\ &&& + EOL_{sc,mid}(t_{sc}, h_{sc}) \\ &subject\ to && 2\pi^2 \frac{th}{l^2} < 0.0584 \\ &&& 0.66P(c_{NS})P(t,h|c_{NS}) \\ &&& - 0.34P(c_{NNS})P(t,h|c_{NNS}) > 0 \\ &&& Threshold = 0.7 \\ &&& 1.2\ mm \le t \le 3.2\ mm \\ &&& 1.2\ mm \le h \le 6.4\ mm \end{aligned} \tag{30}$$

7.2. Result of Multi-Objective Optimization Design

In the MOO design process, we considered an initial design point for the NSH unit cell with $t = 2.2\ mm$ and $h = 3.8\ mm$. NSGA-2 was employed as the optimization algorithm in the PIAnO 2024 software, with settings summarized in Table 3.

Table 3. The settings for NSGA-2

Population Size	100
Crossover Rate	0.9
Mutation Rate	0.5
Maximum Number of Generations	250

The results are displayed in Figure 16, where the lower constraints pertain to the condition for the occurrence of negative stiffness, while the upper constraints relate to the maximum strain. When plotting the Pareto frontier for the objective function, it appears similar to Figure 17.

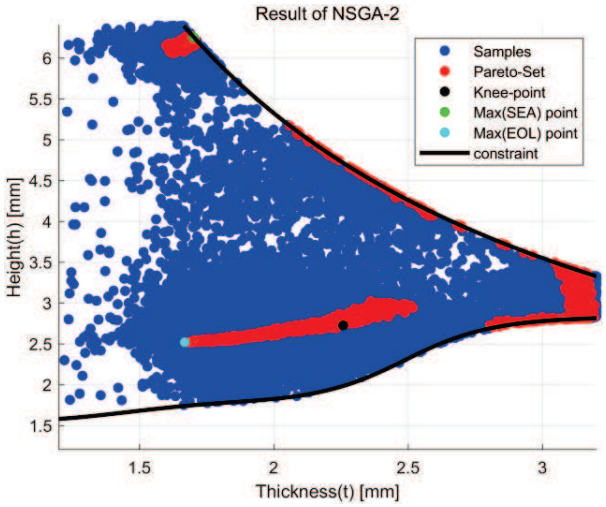

Figure 16. Optimum results using NSGA-2

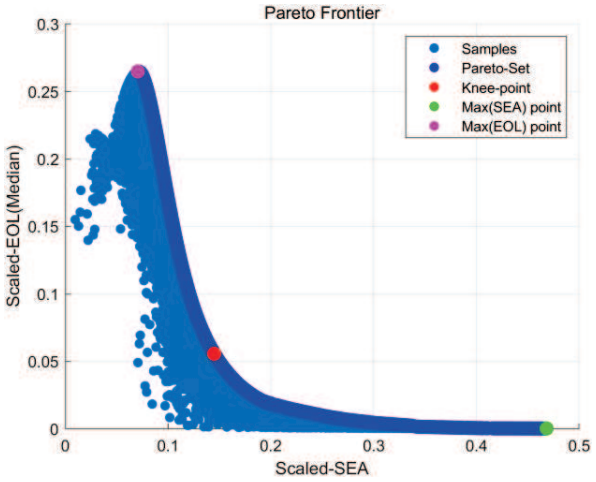

Figure 17. Results of Pareto frontier

Figure 17 illustrates that, despite aiming to maximize the objective functions, EOL and SEA exhibit an inverse relationship within the Pareto optimal set. As EOL increases, SEA decreases, and vice versa. Therefore, to identify the knee point, a horizontal line was extended from the point with the maximum SEA_{mean}, and a vertical line from the point with the maximum EOL_{mid}. The knee point was determined as the intersection of these lines, selected as the closest point from the Pareto optimal set. The dimensional information for the points with the maximum SEA_{mean}, maximum EOL_{mid}, and the knee point is provided in Table 4.

Table 4. Dimensions for three points

	Max (SEA_{mean})	Max (EOL_{mid})	Knee Point
t [mm]	1.702	1.669	2.258
h [mm]	6.255	2.52	2.725

After manufacturing, quasi-static compression tests and cyclic compression tests were conducted for these three points, as discussed in Section 3. All three points satisfied maximum strain constraint as defined in Eq. (29) and exhibited negative stiffness in five samples per point during the test. The results for SEA_{mean} and EOL_{mid} were summarized in Tables 5 and 6.

Table 5. SEA_{mean} results of 3 points

	Initial point	Max (SEA_{mean})	Max (EOL_{mid})	Knee point
True [mJ/g]	425.96	641.06	116.05	207.34
Predict [mJ/g]	-	760.93	128.27	246.42

Table 6. Estimated EOL_{mid} results of 3 points

	Initial point	Max (SEA_{mean})	Max (EOL_{mid})	Knee point
Estimated EOL_{mid} [95% C.I] by proposed method (Cycle)	-	1.49 [1.47 ,1.52]	102.08 [50.21, 266.95]	22.56 [14.78, 39.04]
Estimated EOL_{mid} from 30 cycles of true test data (Cycle)			127.91	31.44
True EOL (Cycle)	2.90	1.48	-	-

According to Table 5, the SEA_{mean} value at the point where it reaches its maximum is approximately 50.5% higher than the initial design point, as predicted by the surrogate model.

Table 6 displays the estimated EOL_{mid} results for the three points. The median result estimated by the proposed method was compared with actual compression test data collected over 30 cycles. However, it is important to note that since cyclic compression test data are available only up to 30 cycles, the EOL beyond this point cannot be accurately determined. Therefore, for the three design points, considering the average RMSE of 0.0073 between the NLS results using actual data from 1 to 30 cycles and the actual data, it is assumed that the extrapolated median results using the NLS method do not significantly differ from the actual EOL. The results presented in Table 6 demonstrate that the EOL_{mid} obtained with the actual data falls within the 95% confidence interval of the EOL estimated by the proposed method.

When comparing the maximum EOL_{mid} point with the initial point, Table 6 shows an increase of approximately 99.17 cycles in EOL_{mid}, based on the estimated EOL_{mid} in

the operational aspect. However, there is a notable decrease of about 72.75% in SEA_{mean}, representing the performance aspect. This trend is also observed at the knee point, where the operational aspect shows an EOL_{mid} increase of approximately 19.66 cycles, but a performance decrease of around 51.32% in SEA_{mean}. These observations highlight the trade-off between SEA_{mean} (performance) and EOL_{mid} (operational aspect, including degradation) in NSH unit cells. The initial design point has a high SEA_{mean} value but a very low EOL_{mid} value in terms of service life, presenting a risk of breakage in case of repeated use. The results of the MOO show that the expected EOL_{mid} result for the SEA value at the initial design point and the corresponding value is 4.72 cycles at t = 3.147 mm h = 2.926 mm, which is an improvement in life and performance compared to the initial design point.

Moreover, analyzing the data from Tables 5 and 6, it can be inferred that if the target life is set to 20 cycles, the knee point emerges as the most reasonable design, considering the estimated EOL_{mid}. Conversely, if reusability is not a priority, the point with the maximum SEA_{mean} value appears to be the optimal design choice. Consequently, this suggests that the most reasonable design can be determined from the Pareto optimum set, depending on the target life set by the designer.

8. CONCLUSION

In this study, a novel design framework for NSH unit cells was proposed, focusing on energy absorption and reusability. SEA_{mean} was considered as a performance metric, while EOL_{mid} estimation relied on operational degradation from cyclic compression. Using the repeated compression test data of 3D-printed NSH unit cell, a trade-off relationship between SEA_{mean} and EOL_{mid} was identified through Pareto frontier analysis employing the NSGA-2 optimization algorithm. From the MOO results, it is evident that establishing a criterion for the target life enables the identification of a viable design point for that lifespan. This approach not only facilitates the lifespan-oriented design of NSH unit cells but also highlights the potential for its application in the design of multi-layer NSHs or similar negative stiffness structures. In the application of these structures, the lifespan of the structure is factored into the design process so that the time to repair or replace the structure can be considered and reflected in the design phase. This framework can be expected to facilitate decision-making based on information about the predicted health of the structure at the design stage and provide possibilities for prognostics and health management (PHM) for design.

Finally, future work aims to develop a PHM framework for robust design that can account for uncertainties or noise that may occur during the manufacturing process and in the testing or operational environment, as efforts continue to predict the health more precisely and EOL of these structures.

ABSTRACT

The German state-funded aviation research project "Real-time Analytics and Prognostic Health Management" (RTAPHM) envisioned fully automated urban air services executed by autonomous drones and infrastructure controlled by a digital system. Research was focused on utilizing onboard real-time diagnostics to enable AI-driven UAV capability predictions. These predictions increased the reliability of upfront service commitments. The use case selected to demonstrate these elements was organ transport. The project delivered an end-to-end demonstrator incorporating a virtual fleet of drones with onboard diagnostics to provide data for the platform decision logic.

The project followed a „digital-twin-first" approach to overcome a common bootstrapping problem faced by data-driven applications. That is, the lack of in-service data for exploration, prototyping and training of diagnostic and prognostic approaches during the concept and early development phases. Due to the upfront development of physical high-fidelity simulation models for the monitored components, a digital twin – of the portion of the twin that resembles the physical behavior – was used to generate data and facilitate preliminary exploration, prototyping and training. Digital twins were further employed to allow evaluation of what-if scenarios and identify the optimal future operation parameters of a drone.

Development of the RTAPHM digital twin involved a multi-disciplinary team of members distributed across different organizations and locations. Successful realization of the digital twin depended on early integration testing, performed in high frequencies, which generated continuous feedback regarding technical and conceptual issues. Within the research project we developed MOLE, an engineering tool for automating the integration of distinct simulation components, into a single system simulation driven by commercially available flight simulator software. Here, we showcase the internal mechanisms of the tool and demonstrate its abilities to generate a Docker-based executable for efficient data generation in the cloud. We also show our approach to online visualization, fault insertion, batch integration testing and debugging the digital twin executable. We also report on the utilization of MOLE in assembling the final RTAPHM demonstrator (Löhr, 2023).

1. OUTLINE

The document first introduces the RTAPHM project with a focus on the use and purpose of digital twins. This leads to our primary project contribution: MOLE, a software tool assisting in the fast integration of digital twin components. After describing the core principles of MOLE, we report from our experience in using MOLE to build the digital twin for the RTAPHM demonstrator. We conclude with a suggestion for areas of future work.

2. INTRODUCTION

The project Real-time Analytics and Prognostic Health Management (RTAPHM) was a joint government-funded research endeavor in Germany It was in the aviation domain and included SMEs, academia, and industry as partners. The project concluded in June 2023. We participated as an SME partner focused on simulation and software engineering IVHM systems.

The project contributed to the field of urban air services, such as person and cargo transport, imaging services, etc. The vision of a fully automated urban air services platform drove the work. Here, customers could book a variety of different services via low-threshold access channels, e.g., via their smart phone. Once booked, the service would be carried out by autonomous unmanned air vehicles (UAVs) supported by autonomous infrastructure, e.g., for mounting payload or loading cargo. The platform would have to work digitally to

benefit from automation. AI technologies would support the orchestration multiple booked services in parallel and the handling of problems which could not be sufficiently formalized upfront.

Obviously, such a bold vision cannot be accomplished by a single research project. Therefore, project research focus was narrowed to a single use case highlighting a specific problem within that use case. The project selected organ transport as that use case. By the means of a digital service platform, the personnel of a donor hospital would book (air) transport to a specific receiver hospital, as depicted in Figure 1. The last mile between the hospitals and the next logistics hub should be covered with transport UAVs.

Figure 1. Synopsis of selected use case.

Within the use case, the project focused on the issue of how to make reliable service commitments given a fleet of UAVs (or other transportation vehicles for long haul routes) depending on their current and future health state. That is, build a platform capability to assess whether a specific service request can be completed with the available resources. This question should be answered by a comprehensive situational awareness picture of the fleet's conditions, mainly driven by real-time diagnostics and prognostic capabilities, integrated into the onboard data processing of the UAVs. Figure 2 depicts the research focus on a high level: for selected components of an artificial UAV (fuel cell, servo and pusher motor) a monitoring concept should be established and implemented. The obtained (gradient of the) health data should be used to make reliable maintenance predictions for the components. Finally, by having predicted the future maintenance burden – thus, the availability of individual UAVs – incoming service bookings for organ transports would be committed reliably within a timeframe where the selected UAV is available and maintenance free.

3. RTAPHM DIGITAL TWIN

The project selected three components to be monitored: servo motors, a fuel cell and pusher propeller system. For all components, a monitoring concept, including diagnostics and prognostics, was developed, and included in the laboratory demonstrator.

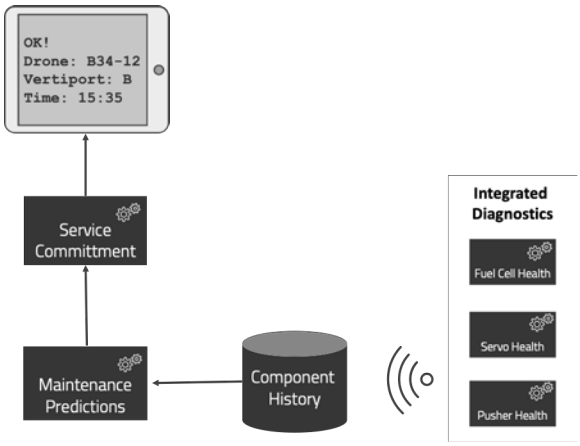

Figure 2. Research focus.

3.1. Motivation

The project faced a common bootstrapping problem, as depicted in Figure 3: incomplete, insufficient, or total absence of operational data from the components in question (the specific configuration of the targeted UAV, as well as the reason for the data absence, is out of the scope of this writing). There was no foundation for conducting exploration or conceptual studies.

Figure 3. Problem statement.

3.2. Digital-Twin-First Approach

The concept of a digital twin is known in both academia and industry. A digital twin is typically derived by observing (data from) an existing system using specific frameworks and methodologies, as for instance Vuckovic, Prakash, and Burke (2023) have shown. The project decided to overcome the bootstrapping problem by employing simulation. The project already incorporated the usage of digital twins within the digital platform. This existing capability and the absence of existing physical components informed the decision to proceed with a "digital-twin-first" approach instead of creating the digital twin afterwards.

To accomplish this, the partners agreed to provide validated high-fidelity component simulation models adapted from previous undertakings. These models formed the bases of the

digital twin. Within the project, these models were adapted according to the performance requirements of the targeted UAV platform and equipped with additional technical features to facilitate integration. Additionally, to stimulate the models with realistic input data, the project decided to use a commercially available flight simulator software.

The solution approach is depicted in Figure 4: a commercial flight simulator should be equipped with a plugin, to extract and send specific data streams (e.g., electrical power demand, thrust demand, environmental data, etc.) to the simulation models as input. Optionally, the models should be operated in a closed loop with the flight simulator, depending on its capabilities. Being stimulated in a realistic way, the simulation models should provide simulated sensor data for the health assessment algorithms. Also, as Darrah, Frank, Quinones-Grueiro, and Biswas (2021) have pointed out, simulation allows generation of run-to-failure data – which would be an unsafe undertaking for a real system.

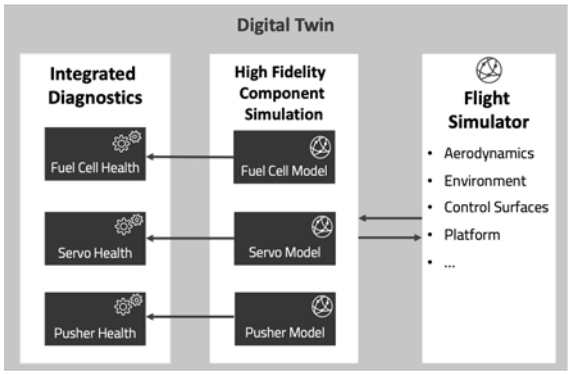

Figure 4. Solution approach.

3.3. Conceptual Challenges

Performing digital-twin-first imposes certain challenges to the modeling process and the overall concept.

This approach is used to obtain data from something that does not yet exist. But how can something that does not yet exist, be modeled? The project addressed this challenge by adapting existing work and narrowed the challenge down to finding the right scaling for the target environment.

There is a further challenge of modeling the right inputs and output of each simulation component. This was addressed by employing agile development techniques, such as a high frequency of iterations and many integration attempts with close feedback amongst all partners.

Finally, the challenge of representativeness and validity remains. Additionally, one must answer the question of how credible the resulting diagnostic and prognostic approaches can be, if they are developed on pure simulated data. There is a risk that simulation development is driven to produce what the exploiting modules expect and vice versa rather than reflecting a realistic and useful abstraction of the potential platform. This challenge was addressed by using (adapting) simulation models which had been created independently and validated in isolation. However, using simulations in this context can only be a first measure to parallelize development. As soon as the first set of "real" operational data becomes available, it must be used to tune the simulation.

3.4. Integration Challenges

Our task in the RTAPHM project, amongst others, was the provision of an integrated executable digital twin to be used by the partners to generate data according to their scenarios. Along with the task itself came the necessity to not only perform the physical integration just once towards the end of the project, as it would have been in a waterfall organized project. Instead, to adhere to the agile mindset of the digital twin development process, we had to be able to perform the physical integration as often as possible. We identified a set of challenges in the context of a multi-organization project that we had to address.

- in what form should a model be delivered?
- how can the intellectual property of a component providing partner be protected?
- what needs to be provided so that a specific model can be integrated with others?
- how can the interaction of two models be tested?
- how to be test the nominal and erroneous behavior?
- how can a quick turnaround be performed

4. MOLE

While the conceptual challenges were addressed by our partners, we worked on providing a solution to the integration challenges that the project was facing. We provided that solution on the form of MOLE – a desktop software tool for automating large portions of the digital twin integration process. Besides the capability to automatically create an executable digital twin from the provided simulation models, the tool provided support for the actual development cycle, and could be used directly by the partners.

4.1. Model Format

Our partners agreed to deliver the models as C code. Some chose to generate the C code using graphical modeling tools, such as Matlab/Simulink, while others provided custom code. Whatever the source, all models to adhered to a common interface concept, which was derived from the way that Matlab exports models. It consisted of:

- structures representing the internal state of a model
- an initialization function for the structures
- a stepping function, accepting (pointers to) the structures

- a custom naming scheme for parameters to establish semantic consistence

Intellectual property was protected by giving the partners the option to provide their models in pre-compiled object code, accompanied with their respective header files. Partners whose models depended on the models of other partners agreed on the specific information to be exchanged, and then specified the required technical parameters. We acted as a central parameter registry to enforce consistency.

As part of the conventions, simulated fault behavior was triggered via a set of up to four parameters. This set consisted of one input parameter acting as a plain on/off switch, a second defining the degree (severity) of the simulated fault, a third setting the point in time at which the fault should become effective, and a fourth setting whether the fault should become effective immediately, or if a degradation towards the specified severity should be simulated.

4.2. Automated Wiring

A significant portion of the integration work consists in the correct wiring of a model's outputs to one or mode inputs of dependent models, according to a specification given by the model creators. By "wiring" in the technical sense, we mean the temporal storage of a model's output in memory, so that it can be read by all dependent models once they start calculating their next cycle. Figure 5 shows an example of MOLEs mapping browser, a visualization of all detected inputs of a specific model, and the assigned outputs for each inputs based on naming conventions.

Model Variables	Type	Source	Initial Value	Internal Resolution
EMA_CBS	Simulink			1.0E-5
Inputs				
EMA_DBBs_PsBll[120]	double			
EMA_DNt_PsNtl[12]	double	EMA_DNt.EMA_DNt_PsNtl[12]		
EMA_DSc_PsScl[12]	double	EMA_DSc.EMA_DSc_PsScl[12]		
EMA_TRM_TNt[9]	double	EMA_TRM.EMA_TRM_TNt[9]		
EMA_TRM_TSc[9]	double	EMA_TRM.EMA_TRM_TSc[9]		
SIMCONTROL_DMG	double		1	
Outputs				
EMA_CGB	Simulink			1.0E-5
EMA_CPB	Simulink			1.0E-5

Figure 5. Component I/O and mapping browser.

To relieve the burden of creating specification documents and harmonizing those documents among the partners, we exploited the project wide naming conventions for model parameters (inputs/outputs). Having established the conventions, we programmed MOLE to use them in inspecting (parsing) each provided simulation module and generating "glue" code for correct parameter exchange. To cater for exceptional cases, we incorporated the ability to manually override the automated wiring.

Figure 6 aims at illustrating what we mean with "wiring". The figure depicts a simulation of two aircraft systems, the hydraulic system and the fuel system. Each system simulation is decomposed into smaller simulation blocks, such as pumps, circuitry, and actuators. Each block exposes specific inputs (upper ports of each block) and outputs (lower blocks), whereas each output models either a sensor (e.g., a pressure sensor) or a specific physical property (e.g., a specific pressure) that provides input for another simulation block (e.g., the pressure output of the pump acts as the input of various actuators). A specific interface block models the interdependency between the two systems. Finally, some of the inputs will be fed from an external aircraft simulation. MOLE is able to generate code (glue code) for the data exchange, even for high exchange frequencies (see section 4.3).

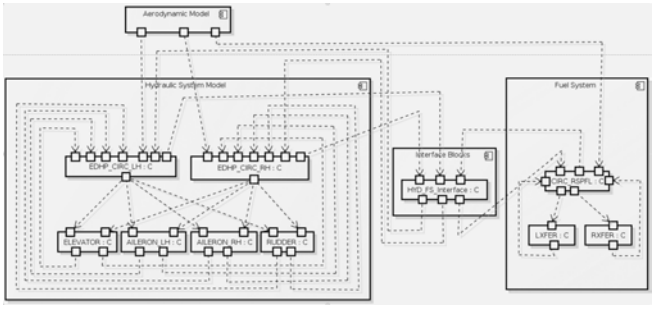

Figure 6. Glue code for automated wiring.

4.3. Parallel Computing

Due to their intended use as source for health assessment algorithm training data, the models performed complex calculations demanding high CPU power. The necessity for small temporal solutions, in the magnitude of 10^{-4}s – 10^{-6}s, drove the need for computational resources. Additionally, different models exhibited different temporal solutions, which were in general not multiples of each other. To benefit from multi-core processors, we introduced a concept for executing each model block in isolation with constant inputs for a maximum number of steps before the model block becomes unstable, and then halting the execution while each model block was updated with external inputs according to the specified wiring (while respecting overrides by expression). The concept was based on two frequencies. The "internal I/O frequency" determined the rate by which the model block execution was halted for the sake of parameter updates. As this lower frequency is reduced, overall execution time is also reduced, as a smaller relative fraction of time was used for parameter exchange and threading overhead. The "external I/O frequency" determined the rate in which supporting functions like graph plotting, data recording or other custom plugins were triggered. Based on that concept, MOLE supported setting a constant number of utilized CPU cores or dynamically adjust this number based on runtime performance analysis.

Figure 7 depicts the main parallel execution loop. First, each simulation block is iterated in its own thread, with constant input values for a block-individual maximum number of iterations that leaves the block numerically stable. Once each block is finished, the respective block outputs are copied to

the inputs according to the wiring. Then, further supporting functions are executed (typically on the current outputs), see sections 4.4 and 4.5. Then the loop repeats.

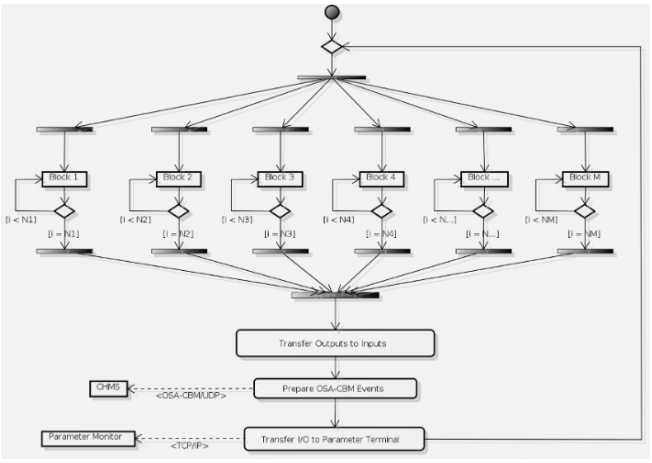

Figure 7. Main execution loop.

4.4. OSA-CBM Sampling

Based on our experience with implementing MIMOSA standards (Löhr & Buderath, 2014) we encouraged the project to follow the OSA-CBM design principles for the data processing chain. Consequently, the integrated diagnostics component of the digital twin was equipped with an OSA-CBM compliant sensor data interface, which was implemented using our proposed implementation of the binary OSA-CBM messaging protocol described by Drever, Naughton, Nagel, Löhr and Buderath (2016), which also discuss challenges and opportunities of MIMOSA standards in general. To drive the integrated diagnostics with data from the simulation, we enhanced MOLE with an OSA-CBM-compliant sampling function that was tied to the external I/O frequency. Selected model outputs, specifically those that simulated sensors, were sampled with the frequency required by the defined monitoring concept in the diagnostics layer. Then, the samples were automatically wrapped into OSA-CBM DM DataSeq events and transmitted to the integrated diagnostics via UDP.

4.5. Supporting Features

The core features of MOLE kept the inputs and outputs consistent, and ensured all models could be compiled. This allowed for quick iterations. Further, we added the following functions to enhance the testing process:

- Stepping: running a single model or a set of models, and halting/resuming the execution on demand, to inspect the current parameter sets
- Recording: marking a set of model inputs and outputs to be written to a CSV file for offline inspection, or for exchange within the project
- Fault Insertion: picking up on the naming conventions for faults, the fault input quadruples were recognized, and presented to the developer in a graphical user interface for interactive control
- Visualization: plotting the development of selected parameters over time to visually inspect the behavior of the model. An example is given in Figure 8.
- Parameter Override: we added an online compiler for simple expressions bound to model parameters. If set, the result of the expression was set (input parameter) or distributed (output parameter), resulting in a dynamic override of the original model wiring.
- Scripting: we added a simple scripting feature which allowed the association of model executions with time-indexed parameter overrides for that execution. By supporting an operation mode in which MOLE executes all scripts in a certain directory tree, users could generate data for different constellations, thus, having a set of repeatable test cases at their disposal.

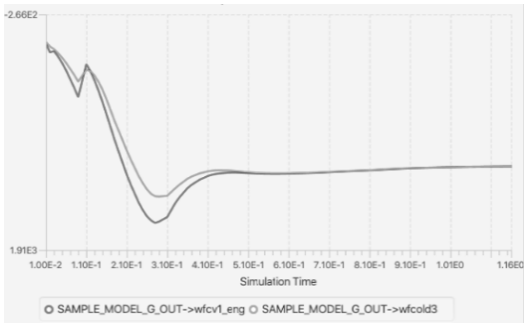

Figure 8. Integrated visualization.

5. VALIDATION

Validation of MOLE functionality was accomplished by its use in supporting the projects continuous integration process and building of the final deliverables. The constituents of the RTAPHM digital twin were:

- model of a pusher motor in several blocks
- model of a fuel cell in several blocks
- model of a servo motor in several blocks
- diagnostic module for pusher motor
- diagnostic module for fuel cell
- diagnostic module for pusher motor
- prognostic module for fuel cell
- interface module for pushing telemetry data to digital platform

- interface module for exchanging data with COTS flight simulator software
- bundled flight simulator module consisting of Gazebo, PX4, and a communication adapter towards the RTAPHM interface module

As validation evidence and as deliverables to the RTAPHM project, we created two artifacts.

First, a MOLE-based integration process for the digital twin. Here, Gazebo/PX4 was used as the "aerodynamics driver" to stimulate three high-fidelity physical simulation models. These models, in turn were used to generate sample and training data for three individual implementations of monitoring concepts.

Second, an interactive digital twin was created as a result of the integration process. This was used during project demonstration runs to create a live feed of (simulated) sensor data into the running diagnostic and prognostic modules, to show the interactive reaction to different fault scenarios.

Figure 9 depicts the result: simulation models for fuel cell, servo and pusher motor formed the RTAPHM system simulation. Some of the system simulation's inputs were fed with data from a customized fixed wing VTOL-capable UAV of which the physical and aerodynamic properties were simulated using Gazebo. Both system simulation and Gazebo were step-synced. PX4 was used to auto-pilot the UAV along a set of waypoints.

Figure 9. RTAPHM virtual aircraft.

6. Future Work

The validation work points out paths for future work. The most significant findings, which we are currently pursuing, are presented below.

- ***support further modelling tools***: to enlarge the possible target audience for MOLE users, the support of further modelling tools, other than just Matlab/Simulink, seems promising.
- ***support open standards***: another aspect of widening the target audience of MOLE emerges from the support of open interface standards, such as the Functional Mockup Interface (FMI), instead of relying on parsing proprietary coding patterns.
- ***integrate with Asset Administration Shell***: the current efforts around (AAS) focus on standardizing the digital representation of assets. MOLE could be integrated with AAS compliant repositories to allow users to choose from pre-build simulation components.
- ***cloud-native technology***: currently, MOLE is designed as a desktop-based tool, and thus is limited by the resources of the computing platform it runs on. By extracting the headless MOLE computing core and basing in on state-of-the-art cloud-native technology, these limitations can be overcome, and data stakeholders can scale the required resources on demand.
- ***service platform***: finally, combining all the previously mentioned streams of future work, we envision a cloud-based service platform, where stakeholders can upload own contributions, and build complex simulations from own and 3rd party simulation components, depending on their specific needs for training) data, and – by employing AAS and FMI concepts – without having to expose their intellectual simulation property to the public.

Using the MOLE digital twin, the project was able to showcase a core use case for automated functional dependency analysis: the injection of a fault in the cooling system's filter (clogging) caused the relevant areas to heat up, causing a decrease in the efficiency of the fuel cell, in turn, decreasing the remaining useful life of the fuel cell.

7. Conclusion

We presented MOLE, a tool for supporting the automation of the integration of software-based system simulations. The tool facilitates short integration cycles for agile project setups and provides specific debug and testing features. We showed the benefits of a structured and automated integration process for distributed research projects with different interests of individual partners.

We reported on the benefits of MOLE for rapid assembling of demonstrators for PHM research projects (though MOLE is not limited to that application domain). MOLE was used to support the integration process of the RTAPHM digital twin, consisting of commercial flight simulator software driving high-fidelity models of aircraft components.

We also showed that the bootstrapping and early development phases of data-driven application projects can benefit from artificially generated data to overcome the lack of initial data for first exploration and training. In particular, the data and communication architecture of the envisioned system can be explored regardless of the origin of the utilized data.

We finally recommend that OSA-CBM design principles and communication standards should not only be adopted for productive modules of a data processing chain. Designing data generators as OSA-CBM compliant data sources (see 4.4) facilitates integration testing, as the productive interface of the modules can be transparently stimulated.

BIOGRAPHIES

Andreas Löhr received his M.Sc. degree in Computer Science from the Technical University of Munich in 2001 (Informatics, Diplom) and earned his doctoral degree in Computer Science from Technical University of Munich in 2006. For 6 years he worked as a software engineer at Inmedius Europa GmbH in interactive technical publications and researched in the field of wearable computing. He co-founded Linova Software GmbH in 2008 as managing director and worked as coding architect and consultant in both industry and academia projects in the field of aircraft maintenance and fleet optimization. Next to growing his company and concentrating on its strategic development, he specializes in aircraft MRO topics, with a research focus on condition-based maintenance, digital twins and data architectures.

Conor Haines received his B.Sc. degree in Aerospace Engineering from Virginia Polytechnic Institute and State University in 2003 and his M.Sc. degree in Computational Science from the Technical University of Munich in 2011. For 3 years Conor was a test engineer supporting the NASA Near Earth Network, providing simulation support used to guide system development. At his current post with Linova Software GmbH, he is focused on designing and developing embedded IVHM/ISHM architectures, along with a special interest in the application of digital twin simulation frameworks for the generation of early training data for data-driven application, such as enhanced embedded diagnostic and prognostic capabilities.

Model-Based Loads Observer Approach for Landing Gear Remaining Useful Life Prediction

Jonathan Jobmann[1] and Frank Thielecke[2]

ABSTRACT

Implementing health monitoring methods for aircraft landing gears holds the potential to prevent premature component replacements and optimize maintenance scheduling. Therefore, this paper introduces a fundamental framework for fatigue monitoring and subsequent steps for predicting the remaining useful life of landing gears. A key component of this framework is the model-based load observer, which lays the groundwork for subsequent remaining useful life prediction steps. This load observer will be analysed in detail in this paper. The model-based approach is specifically designed for observing the loads on civil aircraft landing gears during touchdown, utilizing signals from in-service sensors. To evaluate the load observation method, a flexible multibody simulation model is introduced to generate synthetic data sets of aircraft in-service data and the corresponding landing gear loads, given the unavailability of real in-service and recorded landing gear load data. The load observation method is applied to synthetic in-service data across various virtually performed landing scenarios, offering a proof of concept along with extensive analysis of parameter uncertainties and additional factors influencing observation quality. Through this analysis, certain challenges to the observation method are identified that require further investigation in subsequent research efforts.

1. INTRODUCTION

Optimizing aircraft life cycle management significantly contributes to enhancing profitability and maintaining competitiveness within the aircraft industry, while also facilitating the achievement of ambitious climate objectives. One essential aspect of an aircraft's life cycle involves its operational life, including maintenance. Emerging maintenance strategies, such as condition-based, predictive, and prescriptive maintenance, prioritize health-oriented approaches aiming to optimize aircraft operating life by enhancing performance and safety. The advancement of processes and methodologies for these strategies is facilitated by the growing digitization and improved IT infrastructure, notably through digital platforms that address aircraft operational life and maintenance needs. This technological advancement enables the intensive computation and memory utilization required for certain health monitoring methods, which contribute to an optimized aircraft life cycle management. Especially structural components, such as aircraft landing gears (LG), offer high potential for the meaningful implementation of health monitoring methods.

LG systems must endure a variety of severe loads across different loading conditions. To ensure the structural integrity of the LG, with no detectable fatigue cracking throughout its operational lifespan, the safe life design philosophy is commonly employed in structural LG design (Schmidt, 2021). In this context, the safe life denotes the duration during which the components can operate without experiencing fatigue cracking. At the latest, when this point in time is reached or exceeded, the components are retired from service. Designing with the safe life philosophy entails incorporating scatter factors and estimating fatigue load spectra (SAE International, 2020), often resulting in underestimated individual LG lifespans.

However, by gaining detailed insights into actual loads and fatigue experienced during service, the assessment of LG condition and the prognosis of remaining useful life (RUL) can be performed. Consequently, implementing Structural Health Monitoring (SHM) for LGs through fatigue monitoring methods may help avoid premature replacements and optimize maintenance scheduling. Furthermore, the comprehensive understanding of the actual loads experienced in service opens up opportunities to improve future LG designs (Schmidt & Sartor, 2009).

In recent years, several fatigue monitoring approaches have been developed for aircraft, with some specifically tailored for LGs. One common feature among many of these aircraft fatigue monitoring approaches is the observation of loads prior to fatigue calculation. In (Boller & Buderath, 2007), (Boller & Staszewski, 2004), (Buderath & Neumair, 2007), (Buderath,

2009) and (Schmidt & Sartor, 2009) aircraft load observation approaches for fatigue monitoring are described.

One load monitoring approach involves using flight parameters monitored on the aircraft. Another SHM strategy utilizes additional sensors implemented on the aircraft, such as strain gauges. The data collected from these sensors can then be input into a ground-based digital loads model based on the finite element method. A similar approach, employing strain gauges, is addressed in (Chabod, 2022).

However, this approach incurs additional costs as it requires the installation of extra sensors on each LG to be monitored. Moreover, it increases the risk of sensor failures due to these additional sensors, which could affect aircraft availability or compromise the reliability of the implemented SHM methods. Conversely, employing model-based methods reliant on flight parameters extracted from sources like quick access recorder presents a promising strategy for observing LG loads and fatigue and can effectively mitigate these drawbacks. This approach is also already utilized for detecting transient overloads in LGs (Schmidt & Sartor, 2009).

Explicit research on fatigue monitoring of LGs primarily focuses on the utilization of machine learning methods. In (El Mir & Perinpanayagam, 2021), a machine learning model was proposed to determine load histories of the LG based on sensors onboard the aircraft. Additionally, (Holmes et al., 2016) presented results of a machine learning model calculating LG loads on different runway surfaces using sensor data collected from sensors attached to the LG. However, this approach has the disadvantage of requiring additional sensors to be installed on the LGs.

Addressing this limitation, (Jeong, Lee, Ham, Kim, & Cho, 2020) utilized a landing simulation model to generate synthetic flight parameters and related synthetic LG loads and strains for training machine learning models. Nonetheless, model-based methods offer several advantages over black box models like machine learning models. On the one hand, they are typically more robust and interpretable which is a great advantage within the certification process of aircraft systems. On the other hand, model-based approaches can be more efficient in using data, particularly in scenarios with limited data availability, as they often incorporate prior knowledge about the problem domain.

Therefore, this paper presents a model-based loads observer approach designed specifically for monitoring civil aircraft LG loads without the need for additional sensors, primarily utilizing in-service sensor signals as a foundational element. As the load observation of LG operations is very extensive and comes with various challenges, this paper aims to focus solely on the first landing impact of the main LGs. The developed method constitutes a key component of a comprehensive framework for fatigue monitoring in LGs. This framework, along with the steps for remaining useful life (RUL) prediction, is fundamentally introduced. The overall approach aims to lay the foundation for LG lifecycle management optimization through effective fatigue monitoring and prediction in future work.

The paper is organized as follows. The fatigue monitoring framework and subsequent steps for RUL calculation are introduced in Section 2. For detailed analysis of the model-based loads observer as a key component of the LG fatigue monitoring framework, Section 3 outlines the simulation model utilized for generating synthetic data. This synthetic data is essential for evaluating the loads observation method. Section 4 presents the description and analysis of this method. Finally, the paper concludes with Section 5, which provides a summary and a brief outlook.

2. FATIGUE MONITORING AND PREDICTION

In the following section the LG fatigue monitoring framework and an approach for downstream RUL prediction is presented.

2.1. Fatigue Monitoring Framework

There have been numerous publications addressing fatigue monitoring of aircraft structures, such as (Boller & Staszewski, 2004), (Buderath, 2009), (Dziendzikowski et al., 2021), (JIAO, HE, & LI, 2018), and (Stolz & Neumair, 2008). Additionally, publications by (El Mir & Perinpanayagam, 2021) and (El Mir & Perinpanayagam, 2022) have focused specifically on fatigue monitoring of LG systems. What most of these publications have in common is the proposed application of the Miner rule for calculating a health index of the structures. This rule calculates the cumulated damage D of structures over their life cycle using the equation

$$D = \sum \frac{n_i}{N_i}. \tag{1}$$

Applying n_i cycles with a certain stress amplitude i and the corresponding fatigue life endurance N_i on a structural component is equivalent to the consumption of n_i/N_i of fatigue resistance (Schijve, 2009). When the cumulated damage D reaches 1, failure is expected. Given that the Miner rule is presently utilized in the safe life fatigue analysis for LG certification processes (El Mir & Perinpanayagam, 2022), its application in the fatigue monitoring process of the LGs is evident. Therefore, the proposed fatigue monitoring framework in this paper also relies on the damage calculation using the Miner rule as a central element. By utilizing the Miner rule, many aspects of the fatigue monitoring framework are implicitly defined.

The LG fatigue monitoring framework, as illustrated in Figure 1, is based on the remaining life calculation scheme outlined in (Tinga, 2010) and the steps for safe-life analysis presented in (El Mir & Perinpanayagam, 2022). The objective of the

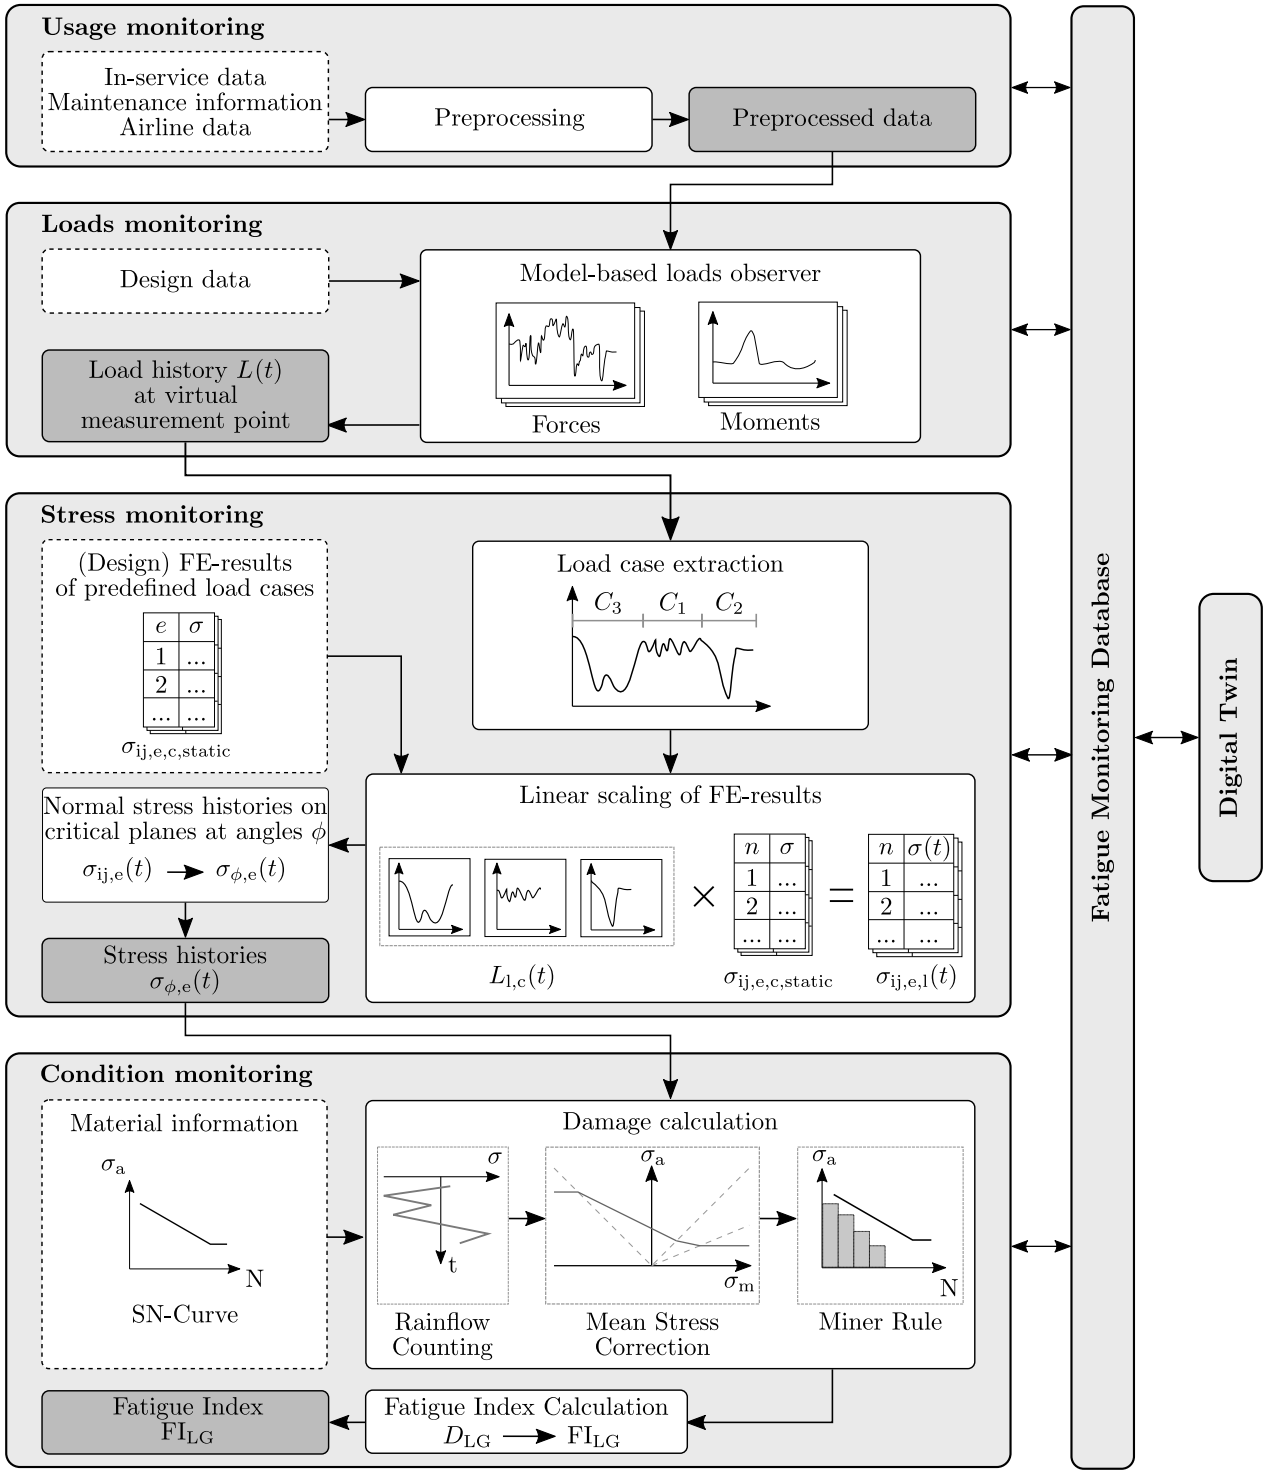

Figure 1. Schematic presentation of the LG fatigue monitoring framework

outlined framework is to present a comprehensive monitoring process for LGs, spanning from raw in-service data recordings over observing LG loads to monitoring LG fatigue and integrating digital twin technology. The framework serves as a basis for subsequent RUL calculation. Since real-time onboard aircraft fatigue monitoring is unnecessary and requires considerable storage and computing capacity, the framework operates offboard. Initially, usage monitoring is conducted within the framework, entailing the recording and storage of essential data, primarily in-service data. This data undergoes

preprocessing, including data cleansing and noise filtering. Subsequently, the preprocessed data is utilized to observe loads on the LG using simulation models constructed with LG design data, thereby virtually emulating the actual LG dynamics (model-based loads observer). The simulation model generates load histories at virtual load measurement points of the LG geometry. These specific locations are also used as load application points in finite element (FE) models for structural analysis. Thus, load histories and FE-models can be combined for subsequent stress monitoring.

To monitor LG structural stress based on LG load histories, stress tensors $\sigma_{\text{ij,e,c,static}}$ are calculated for selected 'hot spots' or across all finite elements e for different load cases c (e.g. specific steering, braking or landing conditions) using static FE design calculations, as depicted in Figure 1. The index ij represents the respective matrix entry of a stress tensor. To associate these stress tensors with observed loads, the load histories from the model-based loads observers are analysed, and specific load cases are extracted. The load histories are segmented into load events $L_{\text{l,c}}(t)$, where the additional index l denotes the index of the load event within the overall load history, and c links the load event to a specific FE load case. The stress tensors are then linearly scaled based on the load histories for each specific load event, resulting in a stress tensor history $\sigma_{\text{ij,e,l}}(t)$ for each finite element e and each load event l. This scaling is achieved through linear superposition by multiplying each load event with its corresponding stress tensor:

$$L_{\text{l,c}}(t) \cdot \sigma_{\text{ij,e,c,static}} = \sigma_{\text{ij,e,l}}(t). \tag{2}$$

It is important to note that each load event $L_{\text{l,c}}(t)$ is characterized by three force time series and three moment time series along the principal axes. However, the stress tensor is scaled by only one time series, which is selected based on the predominant force specific to the load case. Therefore, for each load event $L_{\text{l,c}}(t)$, the load case-specific predominant load is identified and used for scaling.

Afterwards, the stress tensor histories for all load events are chronologically ordered and concatenated for specific finite elements e, resulting in the combined stress tensor histories $\sigma_{\text{ij,e}}(t)$. To ensure accurate fatigue monitoring under complex, multiaxial loading conditions, the critical plane method is employed (Lee & Barkey, 2012). This method assesses stress across various potential planes to identify those where stresses and strains are most likely to cause damage. The stresses $\sigma_{\phi,\text{e}}$ on various planes of finite element e, oriented at angles ϕ under biaxial stress, are calculated using the formula:

$$\begin{aligned}\sigma_{\phi,\text{e}} =& \frac{\sigma_{\text{xx,e}} + \sigma_{\text{yy,e}}}{2} + \frac{\sigma_{\text{xx,e}} - \sigma_{\text{yy,e}}}{2} \cdot \cos 2\phi \\ &+ \tau_{xy,e} \cdot \sin 2\phi.\end{aligned} \tag{3}$$

Here, $\sigma_{\text{xx,e}}$ and $\sigma_{\text{yy,e}}$ represent the normal stresses on the x and y axes of the finite element, respectively, contributing both their average and their difference to the formula. Additionally, the formula includes the shear stress $\tau_{xy,e}$ across the plane. The output from the stress monitoring layer, as depicted in Figure 1, thus consists of the stress histories $\sigma_{\phi,\text{e}}$.

In order to apply the Miner rule, as stated in Equation 1, to the stress histories $\sigma_{\phi,\text{e}}$ within the condition monitoring layer depicted in Figure 1, the rainflow counting method is first performed. This method decomposes complex stress histories into a series of simple, reversed stress cycles, each representing an individual stress response that could potentially lead to material fatigue (Schijve, 2009). The output of the rainflow counting method includes the number of stress cycles n at specific stress amplitudes σ_{a} and mean stress levels σ_{m}. Additionally, the SN-Curve, schematically depicted in Figure 1, is crucial for applying the Miner rule (Schijve, 2009). This curve illustrates the relationship between stress amplitude σ_{a} (with mean stress level $\sigma_{\text{m}} = 0$) and the number of cycles to failure N for a given material. It is essential for implementing the Miner rule, which requires knowledge of the cycles to failure N for specific stress amplitudes. Each point on the SN-Curve represents a specific stress level and its corresponding fatigue life or life expectancy in terms of number of cycles.

Given that simple SN-Curves only address fatigue life under conditions of zero mean stress, mean stress correction is crucial for accurate fatigue life monitoring. The stress cycles n at specific stress amplitudes σ_{a} and mean stress levels σ_{m}, as determined by rainflow counting, are subject to mean stress correction, such as the Goodman mean stress correction method (Schijve, 2009). Once the stress amplitudes are corrected, the Miner rule, shown in Equation 1, can be applied. To assess the LG structural fatigue based on the stress histories $\sigma_{\phi,\text{e}}$ from the stress monitoring layer, the rainflow counting, mean stress correction, and Miner rule must be conducted for the stress histories on every plane at angle ϕ for each finite element e. Consequently, Equation 1 is extended to:

$$D_{\phi,\text{e}} = \sum \frac{n_{\phi,\text{e,i}}}{N_i}. \tag{4}$$

The maximum damage or fatigue D_{LG} experienced by the LG is calculated as follows:

$$D_{\text{LG}} = \max_{\phi,\text{e}} \left(D_{\phi,\text{e}} \right). \tag{5}$$

While calculating the maximum LG fatigue D_{LG} is critical, it is equally important to account for uncertainties in material performance and load observation, as outlined in (Schmidt, 2021). This consideration is implemented using a scatter factor (SF), which, for large civil aircraft, is a minimum of 3, corresponding to material properties with 99 % probability of survival and a 95 % confidence level, as specified by (European Union Aviation Safety Agency, 2020). Therefore,

the safe-life fatigue index $\mathrm{FI_{LG}}$ of the LG is calculated by:

$$\mathrm{FI_{LG}} = \mathrm{SF} \cdot D_{\mathrm{LG}}. \tag{6}$$

This health index serves as the health indicator within the condition monitoring layer of the framework.

The fatigue index, along with data from the usage, loads, stress, and condition monitoring blocks depicted in Figure 1, is stored in a fatigue monitoring database. This database ensures the availability and traceability of all information pertinent to the fatigue monitoring process. For enhanced traceability, it also includes additional information not shown in Figure 1, such as log cards detailing component removals. In conclusion, this database can be integrated into a digital twin or selectively transfer specific data to other systems.

2.2. Fatigue Prediction

The fatigue monitoring framework can be extended by incorporating a prognostics layer, as schematically depicted in Figure 2. Taking the fatigue index $\mathrm{FI_{LG}}$ as input, the RUL calculation

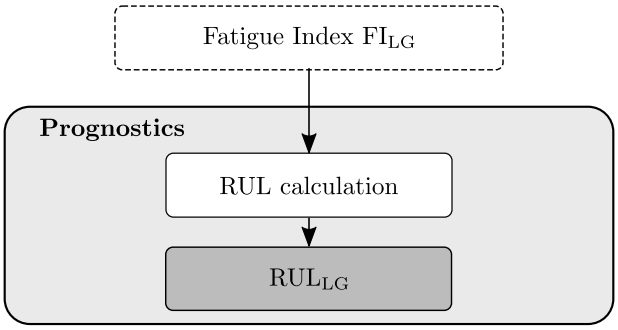

Figure 2. Schematic presentation of LG fatigue prognostics

is straightforward and requires only one main calculation step. Based on the remaining fatigue life estimations by (JIAO et al., 2018), the RUL of the LG is determined by

$$\mathrm{RUL_{LG}} = \frac{1 - \mathrm{FI_{LG}}}{\mathrm{SF} \cdot d} = \frac{1 - \mathrm{SF} \cdot D_{\mathrm{LG}}}{\mathrm{SF} \cdot d}, \tag{7}$$

where d is the predicted mean damage rate in subsequent service. If there is no difference in subsequent service expectable, then $d = 1$. The parameter $\mathrm{RUL_{LG}}$ indicates how much remaining life is left relative to 1, where a value of 1 corresponds to LG failure. To convert this RUL calculation into remaining flight cycles, the equation can be extended by the overall flight cycles n_{FC} experienced by the LG to predict the RUL in terms of remaining flight cycles $\mathrm{RUL_{LG,FC}}$:

$$\mathrm{RUL_{LG,FC}} = \frac{1 - \mathrm{SF} \cdot D_{\mathrm{LG}}}{\mathrm{SF} \cdot d} \cdot \frac{n_{\mathrm{FC}}}{D_{\mathrm{LG}}}. \tag{8}$$

Due to the various sources of uncertainties the precise determination of especially the scatter factor is demanding. The literature provides suggestions (Schmidt, 2021) but a probabilistic estimation of the scatter factor regarding the specific use should be performed when possible.

3. Base model for synthetic data generation

The development of monitoring methods typically requires some sort of data for evaluation. In this case, to assess the model-based LG loads observer, a combination of in-service data recorded by the quick access recorder and dedicated LG loads data is necessary. For this work, method development and evaluation should focus on a narrow-body airliner model with around 100-180 passengers serving as the reference aircraft.

However, due to the unavailability of in-service data and recorded dedicated LG loads, it is essential to generate plausible synthetic in-service and LG loads data. To achieve this, a base model was created using MATLAB/Simulink and the integrated library Simscape Multibody. Simscape Multibody facilitated the implementation of aircraft and LG components within a multibody simulation environment and provided seamless integration with Simulink.

The overall base model consists of the multibody LG model, the airframe, a runway and tyre model as well as an aircraft movement and control subsystem. Figure 3 provides a visualization of the basic model in Simscape Multibody. Further details regarding the structure of the base model are described in the subsequent section.

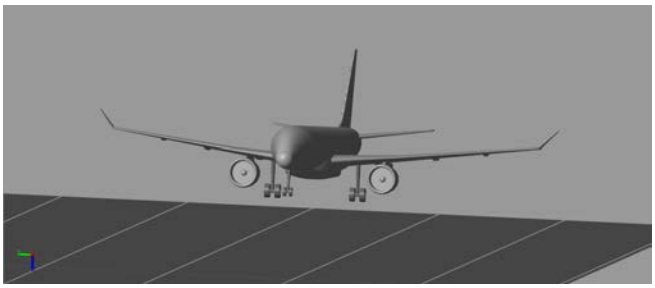

Figure 3. Visualization of the base model: multibody LG model, airframe and runway model

3.1. Multibody landing gear model

The implementation of the multibody LG model was based upon industrial design data, which was made available within the research project OBSERVATOR. Figure 4 illustrates the schematic representation of the implemented bodies and joints for a single main LG in the multibody model. The connection between the aircraft/airframe (AC) and the main fitting (MF) is modeled as a fixed joint (with no degrees of freedom) to represent the LG in an extended and locked state. Given that only load measurements at the LG wheel axle midpoint are of interest, as specified in Section 2.1 due to only one load

application point in the FE assembly model, no additional components connecting the LG and the aircraft, such as side stays, are modeled. However, the impact of these omitted components on LG flexibility is still addressed by integrating their flexibility into the overall LG flexibility matrices which are introduced later in this work.

For simulating translational shock absorber movement, a prismatic joint is installed between the MF and the sliding tube (ST), providing one translational degree of freedom. This design choice simplifies the multibody assembly, obviating the need for additional torque links to prevent ST rotation relative to MF along the rotational axis. Despite this design simplification, the loads calculation at the wheel axle midpoint is not affected. Moreover, to emulate LG flexibility, a single 6-DOF joint is utilized, condensing the LG flexibility into a single flexible point at the wheel axle midpoint. Additionally, revolute joints are employed to constrain the movement of LG wheels W1 and W2 to one rotational degree of freedom each.

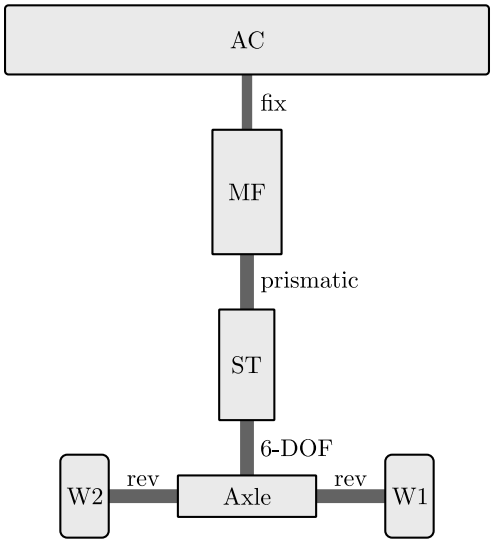

Figure 4. Schematic representation of the bodies and joints of a single main LG

One of the key components of the modeled nose LG configuration is the oleo-pneumatic shock absorber, which primarily provides spring suspension and damping of impact and recoil energy (Schmidt, 2021). To represent the vertical shock absorber dynamics, the shock absorber force, defined by

$$F_{\mathrm{SA}} = F_{\mathrm{spring}}\left(s_{\mathrm{SA}}, T_{\mathrm{amb}}\right) + F_{\mathrm{damp}}\left(s_{\mathrm{SA}}, \mathrm{sgn}(v_{\mathrm{SA}}), v_{\mathrm{SA}}^2\right) + F_{\mathrm{fric}} + F_{\mathrm{limit}}\left(s_{\mathrm{SA}}, v_{\mathrm{SA}}\right) \quad (9)$$

was implemented. Here, F_{spring} represents the force exerted by the gas spring, dependent on the shock absorber travel s_{SA} and ambient temperature T_{amb}. The term F_{damp} is a function of the shock absorber travel s_{SA}, shock absorber velocity $v_{\mathrm{SA}} = \dot{s}_{\mathrm{SA}}$, and the direction of velocity $\mathrm{sgn}(v_{\mathrm{SA}})$, reflecting the oil-induced damping force. Both, the gas spring and the damping force are modelled by the application of lookup tables. Additionally, the shock absorber force accounts for the friction force F_{fric} at the upper and lower bearings of the sliding tube by using simple friction coefficients, along with the translational limiting forces F_{limit} at the upper and lower stops of the shock absorber travel. These upper and lower limiting forces F_{limit} are modelled as simple spring-damper elements, dependent on s_{SA} and v_{SA}.

To implement a flexible LG model, the matrix equation of motion commonly employed in FE analysis was utilized in the LG model:

$$M\ddot{u} + C\dot{u} + Ku = F. \quad (10)$$

Here, F denotes the applied forces and the vector u represents the degrees of freedom of the FE model. M, C, and K denote the mass, damping, and stiffness matrices respectively. Due to computational complexity reduction reasons, only mass, damping and stiffness matrices of the order of 5 were available. With these system matrices reduced by the Guyan model order reduction method (GUYAN, 1965), the LG motion due to flexible structures could be simplified to only one point at the wheel axle midpoint. The computed LG motions were accurately replicated in the multibody model using the depicted 6-DOF joint in Figure 4. However, one translational degree of freedom along the shock absorber axis was disregarded due to the predominant shock absorber travel, leading to the utilization of only 5 degrees of freedom of the 6-DOF joint in Simscape Multibody.

What also had to be taken into account was the change in flexibility with varying shock absorber travel, so that Equation 10 changed to

$$M\left(s_{\mathrm{SA}}\right) \cdot \ddot{u} + C\left(s_{\mathrm{SA}}\right) \cdot \dot{u} + K\left(s_{\mathrm{SA}}\right) \cdot u = F. \quad (11)$$

This implementation issue was addressed by the usage of lookup tables as a function of the shock absorber travel in MATLAB/Simulink. The continuously calculated vector u of Equation 11 could then be input to the 6-DOF joint.

3.2. Tyre model

Tyres represent an essential component of vehicle dynamics such as aircraft LG dynamics. The forces and moments acting on the tyres during ground interaction greatly influence the vehicles dynamics. Thus, when developing multibody LG models, the tyre ground interaction has to be sufficiently represented by tyre models. In contrast to the multibody LG model, data for tyre modelling was not available. This proved to be a challenge, because tyre models in general rely on extensive input parameters. To address this issue, Fiala tyre models were chosen for modelling.The Fiala model is based on a brush-type tyre model and comes with the advantage, that it only requires 10 input parameters which are directly linked to physical properties of the tyre. Due to the fact, that Fiala tyre models for other aircraft types were available, the parameters of those

models could be used for parameter scaling so that plausible assumptions concerning the Fiala tyre models parameters could be made. Nevertheless, the usage of the Fiala model also comes with certain drawbacks as illustrated in (Blundell & Harty, 2004):

- Combined cornering and braking or cornering and accelerating is not considered in the model.
- Aligning moment and lateral force induced by the camber angle are not modelled.
- Varying cornering stiffness at zero slip angle with tyre load is not represented.
- At zero slip angle the offsets in lateral force or aligning moment due to conicity and ply steer are not considered.

Nevertheless, the Fiala tyre model represents a sufficiently good model for the usage of synthetic data generation for landing loads observation model evaluation. The exact mathematical representation of the model, which was used for implementation, is presented in (Blundell & Harty, 2004). The resulting forces and moments, calculated in MABLAB/Simulink, were used as inputs at the contact patches of the individual tyres in the multibody model.

3.3. Runway model

In order to simulate different tyre ground interactions for synthetic data generation, two different runways have been implemented in Simulink and visualized in Simscape Multibody:

- Even runway: A completely even runway with no bumps for optimal landing and taxiing conditions.
- San Francisco Runway 28R: The San Francisco Runway 28R before it was resurfaced was known for high loads on aircraft (European Union Aviation Safety Agency, 2020).

Both runway profiles were constructed using lookup tables in MATLAB/Simulink. The profile of San Francisco Runway 28R was developed based on specifications outlined in (European Union Aviation Safety Agency, 2020). Due to the lack of additional runway data, only these two profiles were employed for synthetic data generation. Within the simulation model, both runway profiles were linked with the tire models of each wheel to simulate tire-ground interaction. Figure 3 provides a visualization of a segment of the even runway.

3.4. Aircraft model and control

The aircraft, or airframe, was modelled as a single rigid body with specific mass and inertia properties. Since no information was available regarding the flight mechanics of similar-sized aircraft, aircraft movement was implemented using forces and moments primarily applied at the aircraft's center of gravity. By incorporating a six-degree-of-freedom joint at the aircraft's center of gravity, the aircraft could be maneuvered along all six degrees of freedom with the multibody LG model mounted on it. To simulate various landing scenarios, multiple controllers were developed. These controllers utilize the forces and moments acting on the aircraft as control variables, along with the aircraft's Euler angles and approach speeds in horizontal, lateral, and vertical directions as reference signals.

3.5. Synthetic data generation for different landing scenarios

The aim of this work, as mentioned in Section 1, is to present a method and evaluate it for observing landing loads in the context of LG fatigue monitoring and RUL prediction. Consequently, the generation of in-service data for various landing scenarios and the recording of dedicated LG loads were required. Simulated landing scenarios included level landings, one-gear landings, side load landings, and rebound landings. To create diverse landing conditions, different parameters were varied. These varied simulation parameters and their value ranges are outlined in Table 1. The variation limits represent plausible assumptions, partly based on knowledge of these parameters from similar aircraft or regulatory documents such as (European Union Aviation Safety Agency, 2020). For the variation of sensor sample rates, only rates up to 50 Hz are theoretically necessary, as higher sample rates are uncommon for aircraft quick access recorder data in today's commercial aviation industry. Nevertheless, additional in-service data sets with a sample rate of 200 Hz were recorded to assess the impact of higher sensor sample rates on monitoring performance.

Table 1. Overview of simulation parameter variations for synthetic data generation

Simulation parameter	**Variation limits**
Roll angle	± 5 deg
Pitch angle	$3 - 9$ deg
Yaw angle	± 5 deg
Aircraft mass	$50,000 - 60,000$ kg
Center of gravity	$22 - 28$ % MAC
Ground speed	$55 - 65$ m/s
Sinking speed	$0.3 - 3$ m/s
Sample rate (in-service data)	$20/50/200$ Hz
Measurement noise (in-service data)	no noise / white noise
Lift force	$0 - 1g$ (variable during touchdown)
Runway profile	even / San Francisco Runway 28R

4. Model-Based Loads Observation of Landing Gear Loads

The following section describes the model-based loads observer of LG loads at the initial landing impact. At first, the developed method is described. In a second step, results of the loads observation method are analysed and the method is evaluated.

4.1. Methodology

Aircraft model-based load observer approaches often rely on a Luenberger observer using specific system sensor data for state estimation, as demonstrated in (Montel & Thielecke, 2018) or (Luderer & Thielecke, 2022). Typically, in-service data recorded at the LG is limited to weight-on-wheel binary signals and rotational wheel speeds. However, employing state estimation within a Luenberger observer with feedback solely based on the the mentioned signals as the only LG signals is not feasible. Therefore, direct estimation of the LG dynamics and loads without state estimation feedback is utilized. A schematic representation of this method using a block diagram and a flow chart is depicted in Figure 5.

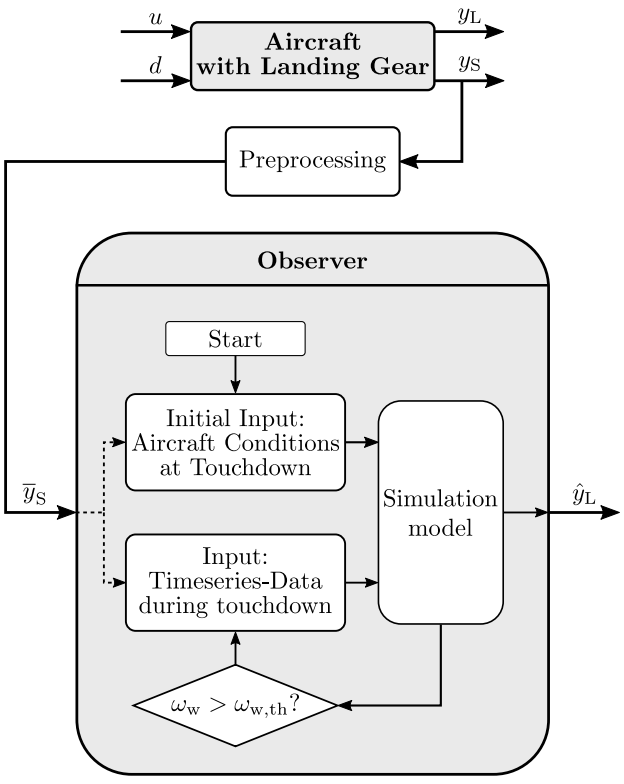

Figure 5. Block diagram of loads observer with data flow of schematic observer logic

During the landing phase and ground operations, the aircraft with the extended and locked LG is controlled with the aircraft inputs u and is simultaneously exposed to various external disturbances d. This results in various loads acting on the aircraft, and particularly in this work, loads y_L acting on the LG. The aircraft and LG dynamics are recorded by various sensors. The recorded in-service data y_S is preprocessed, as described in Section 2.1, so that the preprocessed data $\overline{y}_S$ can be used as loads observer input. The actual loads observer then tries to re-simulate the exact aircraft motion in an offboard simulation from the moment the rotational wheel speed ω_w of at least one main LG wheel exceeds the specified rotational wheel speed threshold $\omega_{w,th}$.

The loads observer begins simulating aircraft movement just above the runway. Initial inputs include the aircraft's roll and pitch angles and approach speeds recorded when the weight-on-wheel signal first changes to 'true' during touchdown. The observer simulates until the simulated rotational wheel speed ω_w of at least one main LG wheel exceeds the specified threshold $\omega_{w,th}$. After this point, the observer uses recorded time series data of longitudinal, vertical, and normal accelerations, roll, pitch, and yaw rates, as well as roll, pitch, and heading angles to reproduce the aircraft movement. The simulated loads are then output by the observer as the signal $\hat{y}_L$, as depicted in Figure 5.

4.2. Analysis

To assess the effectiveness of the proposed observer methodology, it was applied to various synthetic in-service data sets generated by the base model introduced in Section 3, with simulation parameters varied as detailed in Table 1. Initially, baseline simulations were conducted at a sample rate of 200 Hz on an even runway without measurement noise. This setup aimed to exclude potential influences such as uneven runways and low sensor sample rates, allowing for an analysis of the method's performance under 'ideal' conditions. Subsequently, the observer method was tested under more realistic conditions, including measurement noise, uneven runways, and sample rates of 20 Hz and 50 Hz.

A modified version of the base model was used as the simulation model for the model-based loads observer. After baseline and observer simulations, the simulated forces and moments at the main LG wheel axle midpoint during the initial load impact were compared. All observer simulations yielded highly accurate results, with deviations between the simulated baseline and observer loads being less than 2 %. Figure 6 illustrates the forces F_x and F_z at the wheel axle midpoint for a level landing scenario. Here, F_x denotes the force in the longitudinal direction, while F_z indicates the force in the vertical direction of the LG body-fixed coordinate system. The results show that the method performs well for various landing scenarios under conditions of no parameter uncertainties, no measurement noise, an even runway, and high sensor sample rates of 200 Hz or greater.

Subsequently, various parameters of the observer model were individually modified with plausible assumptions to account

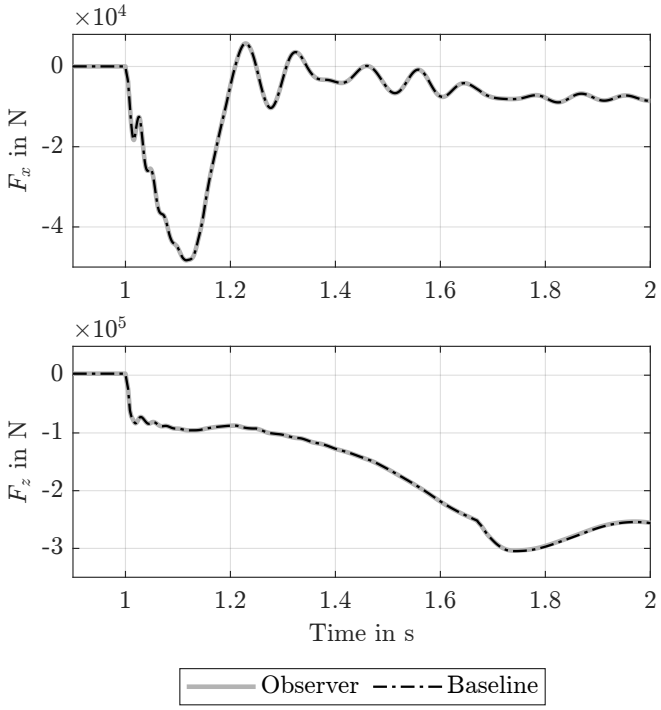

Figure 6. Load observation of longitudinal and vertical forces at wheel axle midpoint of one main LG at touchdown

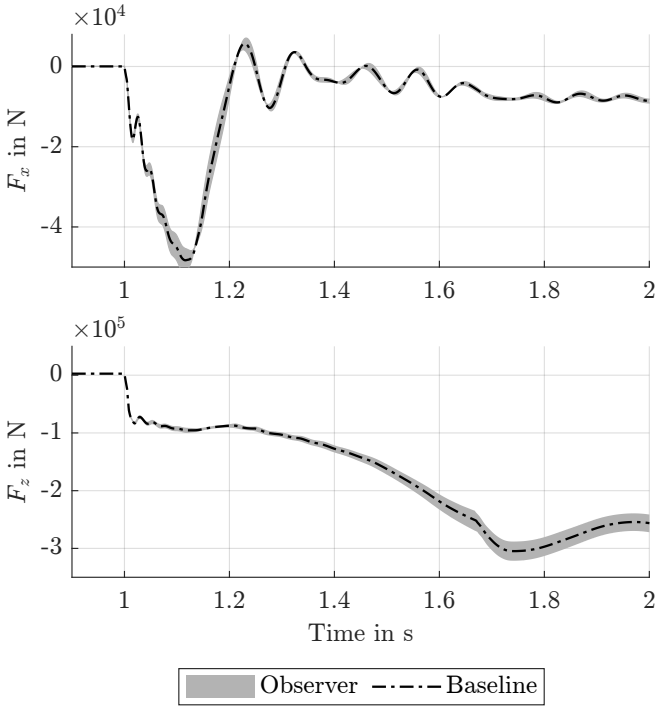

Figure 7. Load observation of longitudinal and vertical forces at wheel axle midpoint of one main LG at touchdown with shock absorber temperature uncertainty of $\pm 10^\circ$ C at 30° C

for observer model uncertainties. The simulations were also conducted with high sample rates of 200 Hz and even runways to avoid biases in the analysis of model uncertainties. The varied parameters include LG flexibility matrices, shock absorber temperature uncertainty, shock absorber spring lookup table, shock absorber damping lookup table, sensor signal offsets, sensor positions, tyre friction coefficients, and tyre stiffness and damping coefficients. Despite these model uncertainties, the deviations between the baseline LG loads and the observer LG loads for the initial landing impact were less than 10 % and were therefore deemed sufficient. For example, Figure 7 illustrates the load estimation bandwidth of the observer for $\pm 10^\circ$ C at 30° C shock absorber temperature uncertainty.

At the time of writing, the impact of the deviations between baseline and observer loads in the fatigue monitoring framework introduced in Section 2.1 is not fully known. Therefore, it is not yet possible to make exact statements about the quality of the observer results. Nonetheless, the initial findings indicate a potential for precise load monitoring despite model uncertainties.

Furthermore, the influence of sensor sample rates on the observer method has been examined. For example, the load observations of the longitudinal and vertical forces at the wheel axle midpoint are depicted for different sensor sample rates in Figure 8. While the observer performs well for load observation with sensor sample rates of 200 Hz, the quality of load estimation decreases with decreasing sample rate.

Figure 8 also reveals that both the observer with 20 Hz sample rate and the one with 50 Hz sample rate start to diverge from the baseline in F_z at approximately the same time. This occurrence can be attributed to a significant increase in the vertical deceleration of the aircraft about the same time, leading to imprecise recordings of vertical accelerations during observer simulations. Nevertheless, sample rates of 50 Hz, which are common in modern aircraft, still hold considerable potential for effective observation of LG loads during the initial landing impact at the main LGs for use in LG fatigue monitoring.

Another significant factor expected to influence load observation was landing on uneven runways. Baseline simulation results are depicted in Figure 9. These show the exemplary longitudinal and vertical forces at the wheel axle midpoint for a level landing scenario on the San Francisco Runway 28R profile (before resurfacing). This runway was known for inducing high loads due to its uneven nature. The figure also presents the corresponding observer loads simulated for an even runway, as the observer lacked information about the actual runway profile. An observer sample rate of 200 Hz was employed to mitigate potential inaccuracies from inadequate sample rates, thus excluding certain erroneous load estimations. At the beginning of the landing impact, when aircraft movement predominates and no critical runway bumps affect the LG, the observer estimates the LG loads quite accurately, albeit with higher frequency oscillations. However, as simulation time progresses, the loads begin to deviate significantly

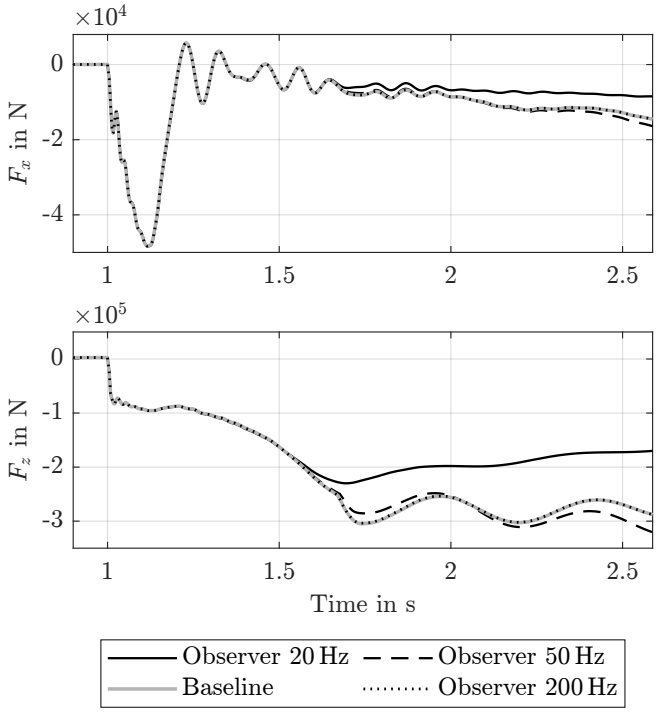

Figure 8. Loads observation of longitudinal and vertical forces at wheel axle midpoint of one main LG at touchdown for different virtual in-service data sample rates

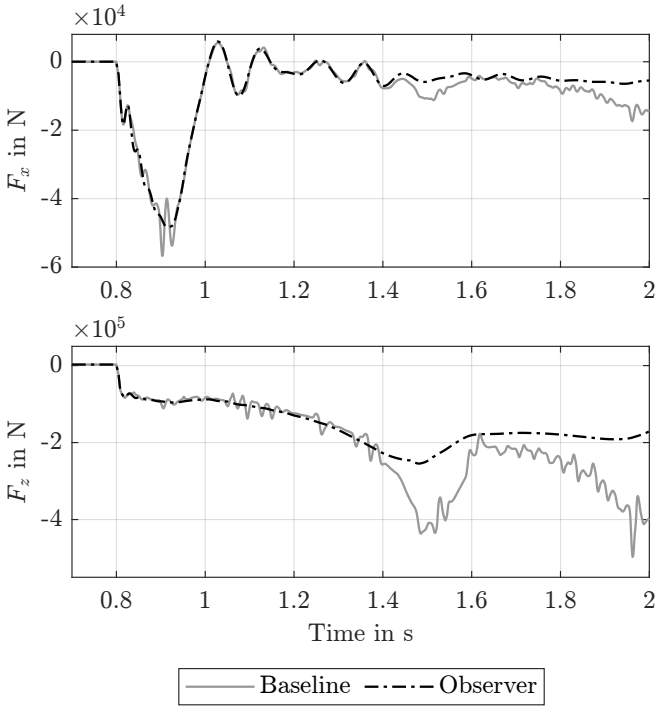

Figure 9. Loads observation of longitudinal and vertical forces at wheel axle midpoint of one main LG at touchdown: baseline touchdown on San Francisco Runway 28R profile, observer touchdown on even runway

due to runway bumps and variations in runway height.

The estimation results of the observer could be significantly improved by observer simulations with a known uneven runway profile and a known runway position of the aircraft during touchdown. However, if the precise landing position and especially the runway surface profile are unknown, which is usually the case nowadays, highly uneven runways can lead to significant variations in runway excitation. Despite maintaining the same vertical aircraft position in the observer as in the baseline, deviations in loads can be substantial due to these discrepancies.

5. Conclusion

This paper introduces a model-based LG loads observer method that operates exclusively on in-service data, thereby eliminating the need for additional sensors. The method is specifically evaluated with an emphasis on the first landing impact of the main LGs. It forms a key component of a comprehensive LG fatigue monitoring framework and the subsequent calculation of RUL for the LG. This paper also fundamentally outlines the foundational steps and further key components for LG fatigue monitoring and prediction, based on the 'safe life' design methodology commonly used for structural LG certification.

The application of the loads observer method on virtual in-service data with dedicated LG loads shows significant potential despite challenges, such as the unsuitability of LG feedback signals for state feedback observers and the heavy influence of sample rates on precision. For accurate load estimation, particularly for initial landing impacts, sample rates of at least 50 Hz are necessary. However, deviations between recorded and actual aircraft accelerations can lead to unacceptable estimation errors over time, suggesting that higher sample rates might be needed for longer monitoring durations.

A major challenge is the unknown runway profile, notably on uneven runways like the pre-resurfaced San Francisco Runway 28R, where load estimation accuracy drops significantly. The position inaccuracies in the observer model, due to integrating recorded aircraft accelerations, further distort load estimations on inclining runways. Precise runway profiles and exact touchdown coordinates are crucial for improving estimation accuracy.

While this paper demonstrates a basic proof of concept by applying the developed method to virtual in-service data, further analysis and development are required to address the challenges associated with load estimation. For instance, the exact effects of load estimation errors on fatigue and RUL determination need to be investigated. Additionally, knowledge about runway profiles and the exact touchdown position must be incorporated. Furthermore, combined effects of model uncertainties on load observation should be explored.

ACKNOWLEDGMENT

This work was funded by the German Federal Ministry for Economic Affairs and Climate Action within the project OBSERVATOR (contract code: 20D1903C) in the national LuFo program. Their support is greatly appreciated.

ABSTRACT

The railway infrastructure condition is a crucial factor for the safe and efficient operation of trains. Regular maintenance is inevitable as the track geometry degrades over time due to traffic and environmental effects. To restore the ideal position and provide sufficient durability of ballasted track so called tamping machines are used. These machines lift the track, correct the longitudinal level and the alignment of the track panel and tamp the ballast. During the tamping process the tamping tines penetrate the ballast bed, fill voids and compact the ballast underneath the sleepers by a squeezing movement with superimposed vibration. A detailed description of the tamping cycle can be found on section 2. Monitoring and evaluating this tamping process is essential for maintaining process quality. This can be achieved through a variety of sensors, such as incremental encoders, angle encoders, temperature, pressure, and acceleration sensors, coupled with a measurement unit (DAQ and edge device) to collect, locally store and transmit the data to a cloud. This paper explores the development of a rule-based algorithm for assessing the quality of the tamping process execution in reference to its nominal chronological sequence. The focus is on identifying tamping occurrences and classifying them into acceptable (OK) or non-acceptable (NOK) categories. This involves selecting relevant measurement parameters and processing them, considering the inherent imprecision in real-world processes. Empirical thresholds are established to differentiate between good and bad outcomes. The classification approach has to be sufficiently generic in order to cover a high variety of customized tamping machine types. As each machine is individually designed, the process of generalization is challenging and complex. The paper demonstrates the accuracy and universal applicability of the developed rule set across different tamping machines. The model's effectiveness is validated using the Hold-Out-Test-Set method. Furthermore, the rule-set-achieved outcomes are compared with results gained from an LSTM network. Both the rule-based approach and the neural network demonstrate precision, but the latter requires significantly more effort.

1. TRACK MAINTENANCE

For a safe and efficient operation of trains a proper track infrastructure is indispensable. Especially on high-speed rail links the quality of the track and its surroundings is crucial. Therefore not only the construction but also the maintenance of the track in order to prevent degradation due to traffic and environmental effects are important. This involves ensuring a clean and dry embedding, sufficient proper ballast underneath the rails, impeccable condition of the sleepers involved and restoring the vertical as well as the horizontal position of the rails. A very detailed description of several track maintenance methods can be found in (Hansmann, 2021).

In Figure 1 an acceptable condition of a track is depicted. Here a sufficient amount of appropriately sized, clean ballast is in place. The positioning of the rails in vertical and horizontal direction is within applicable limits. The durability of the track geometry is ensured through appropriate compaction of the ballast.

Figure 1. Acceptable condition

For the latter tasks so-called tamping machines are used. The process which results in appropriately compacted ballast is referred to as tamping. In Figure 2 an example for such a tamping machine can be seen.

Figure 2. Tamping machine

A crucial part of such working machines is the tamping unit which is visualized in Figure 3. The lower grey colored components are called the tamping tines. They constitute the only components which are in direct contact with the ballast.

Figure 3. Tamping unit

Ultimately, the focus of this paper is the automatized identification of tamping cycles. Subsequently also classifying tamping cycles into acceptable and non-acceptable cycles, hereinafter denoted as OK and NOK respectively, will be done.

In Figure 4 a track with an unacceptable positional deviation can be seen. The ballast condition regarding size, homogeneity and cleanness does not fulfil the minimum criteria either.

Figure 4. Unacceptable condition of the track

In Figure 5 it is obvious that the ballast is in an unacceptable condition. Neither the ballast size nor the cleanness meet the desired conditions. (Soleimanmeigouni I, Ahmadi A, Kumar U., 2018) provide a summary, discussion and classification of existing track geometry measures and track geometry degradation models. Machine learning approaches for diagnosis and prognosis of rail defects are reviewed by (Chenariyan Nakhaee, Hiemstra, Stoelinga, & van Noort, 2019).

Figure 5. Unacceptable condition of the ballast

2. TAMPING PROCESS

The main goal of tamping is to correct track faults in longitudinal level and alignment in order to guarantee the operating

reliability and ride comfort of the trains. The explanations given in this section are based on (Offenbacher, Koczwara, Landgraf, & Marschnig, 2023) and (Fellinger, 2017). Furthermore, ballast faults like voids beneath the sleepers should be corrected so that the load onto the sleepers is equally distributed and deployed to the underfloor. This also increases track quality before irreversible damages can occur.

A complete tamping cycle can be decomposed into the following sub-processes:

1. Positioning
2. Lifting and Lining
3. Penetrating
4. Filling
5. Compacting
6. Lifting

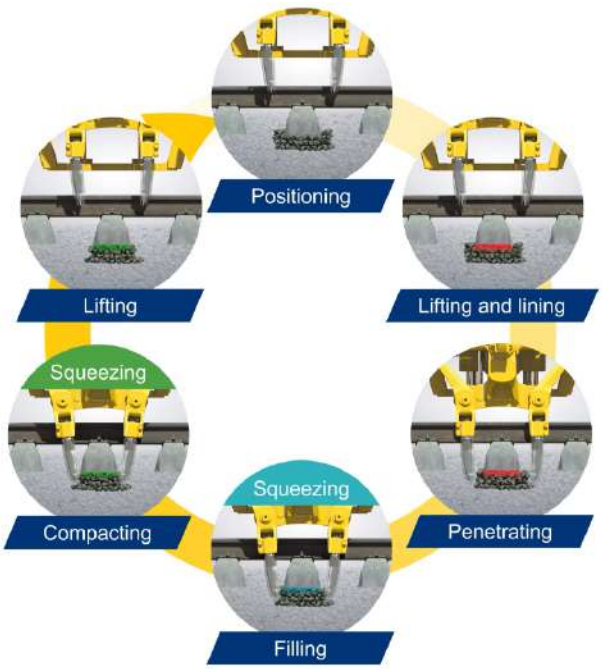

Figure 6. Tamping stages

In the Positioning phase it has to be ensured that the tamping unit is positioned exactly above a sleeper and there is no relative velocity between the unit and the track. Subsequently, in the Lifting and Lining phase the rails are correctly positioned by a separate working unit. Here the rails are lifted and brought into the desired longitudinal and lateral position. Then Penetrating is done and the whole tamping unit is lowered until the tamping tines sink into the surface and the lower position is reached. This is followed by the squeezing movement of the tines which basically comprises two sub processes, Filling (the void caused by the previous Lifting and Lining with ballast) and Compacting (the ballast under the sleeper). Finally, rails are released and the tamping unit is retracted again. This process is known as Lifting. During all of the stages the vibration has to be active. Thus the tamping tines are oscillating with 35 Hz for a smoother penetration and squeezing movement inside the ballast bed (Fischer, 1983).

3. Data Generation/Measurement System

A variety of sensors, such as incremental encoder, angle encoders, temperature, pressure, and acceleration sensors are connected with the control system. An Industrial Internet of Things (IIoT) edge device is fully integrated with the machine control system via the machine network. The device collects and records the data which is transferred to an online platform by means of a mobile broadband connection.

4. Tamping Abstraction

Unfortunately, there are not one-to-one relationships between the recorded measurement signals and the sub-processes as described in Section 2. Additionally, there are further conditions to be fulfilled to assess the quality of the tamping-process, e.g., squeezing (consisting of filling and compacting) shall only be performed when the tamping unit already rests in the down position and not during penetration. On the other hand, it is not relevant to distinguish filling from compacting, but only the process of squeezing and related key parameters as squeezing times are of interest. The sub-process “Positioning” can only be identified by means of the vehicle’s speed, in detail, whether the machine is at standstill or not, but it cannot be checked if it is positioned properly. There are separate assisting tools which deal with proper positioning. For example, there is a camera and image recognition system that makes suggestions to the operator for adjusting the tamping units properly, especially in turnouts. The operator only needs to confirm the suggestions (Plasser und Theurer, 2017). Concluding, the sub-processes as depicted in figure 6 need be represented by sequences based on and created by real signal data. Therefore, the signals are transformed into segments of Boolean representations by means of applying mathematical operations and threshold values, if required. The correct sequence of serial and parallel segments determines the quality or correctness of the tamping process. The proper sequence of segments for an acceptable tamping process is depicted in figure 7.

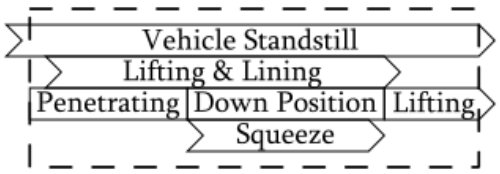

Figure 7. Tamping process based on measurement data

However, real data show deviations from theory, like the overlaps of segments or short unidentified periods between segments (i.e., pauses) which should be in series. Furthermore, differing start or end times of segments which should be synchronous may occur. The inaccuracies are caused by different sampling rates of the individual signals or temporal shifts induced by mathematical operations. Thus, there are parts in the sequences which do not follow the strict theoretical rules but can be considered as valid to a certain extent. The imprecision necessitates the definition of further rules to qualify a tamping process.

5. LONG-SHORT-TERM-MEMORY

The Long Short-Term Memory (LSTM) network was invented by Sepp Hochreiter and Jürgen Schmidhuber in 1997 (Hochreiter & Schmidhuber, 1997). Long Short-Term Memory (LSTM) is a type of Recurrent Neural Network (RNN) architecture used in the field of deep learning. LSTMs are designed to avoid the long-term dependency problem typical of standard RNNs, enabling them to remember information for long periods. This makes LSTMs particularly useful for tasks involving sequential data, such as time series analysis, natural language processing (NLP), speech recognition, and more. The key to LSTM's ability to retain long-term memory is its cell state, along with its various gates that control the flow of information. An LSTM unit typically comprises the following components:

- Forget Gate f_t
- Input Gate i_t
- Cell State c_t
- Output Gate o_t

The Forget Gate decides what information should be thrown away or kept. It looks at the current input and the previous hidden state and outputs numbers between 0 and 1 for each number in the cell state (C_{t-1}). A value close to 1 means to keep the information, while close to 0 means to forget it. The Input Gate decides what new information will be stored in the cell state. It involves two parts: one Sigmoid layer that decides which values to update, and a Tanh layer that creates a vector of new candidate values that could be added to the state. The cell state is the key innovation of LSTMs. It runs straight down the entire chain, with only minor linear interactions. It's very easy for information to just flow along it unchanged. The cell state is modified by the forget gate and the input gate. The Output Gate determines the next hidden state, which contains information on previous inputs. The hidden state can be used to make predictions. The output gate looks at the current input, the previous hidden state, and the current cell state, and decides what the output should be. These components work together to allow the LSTM to decide when to allow data to enter, when to forget data because it's no longer useful, and when to let it impact the output at the current timestep. This selective memory capability helps LSTMs to perform exceptionally well on tasks where the context or the sequence of data points is important.

A Bidirectional Long Short-Term Memory (Bi-LSTM) network is an extension of the traditional Long Short-Term Memory (LSTM) network. It enhances the original LSTM by providing two layers that process the input sequence in both forward and backward directions. By processing sequences in both directions, Bi-LSTMs can capture context from both the past and the future relative to a specific point in the sequence. The key idea behind a Bi-LSTM is that at any point in time, the network has access to information from both the beginning and the end of the sequence, making it especially powerful for tasks where context from both directions is crucial for understanding or predicting the elements of the sequence. Mathematically, a Bi-LSTM combines the outputs from two separate LSTM layers — one processing the input sequence from start to end and the other processing it from end to start. The outputs of these two LSTMs can be merged in various ways (e.g., concatenation, summation, or averaging) to form a single output that provides a comprehensive context-aware representation of each point in the sequence. Bi-LSTMs are widely used in various sequence modeling tasks, such as natural language processing for named entity recognition, sentiment analysis, and machine translation, as well as in bioinformatics and speech recognition, where understanding the context from both directions can significantly enhance model performance.

In Figure 8 a typical (vanilla-)LSTM is depicted. In the graph the σ stands for the Sigmoid activation and the $\tanh$ for Hyperbolic Tangent activation function. g_t represents the input activation and the x an element wise multiplication.

(De Simone et al., 2023) describe the application of a LSTM model for the failure prediction of rolling stock equipment, in detail of the traction converter cooling system, but also give a rough overview on other LSTM-based prediction algorithms in the railway industry.

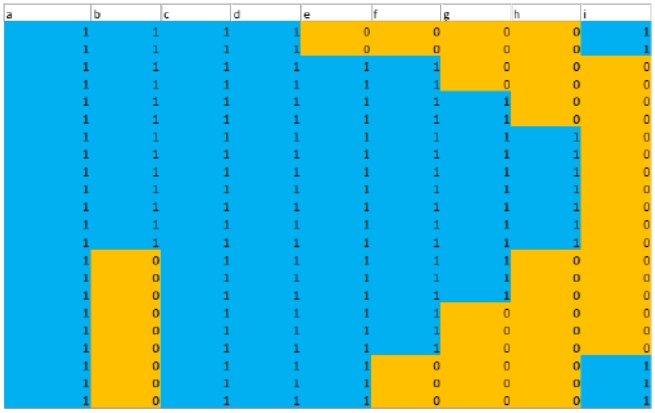

Figure 9. Tamping identification

6. Rule Based Detection

6.1. OK Tamping cycle detection

In order to identify and evaluate tamping cycles based on the time series of the measurement channels, boolean signals are created and assembled, as depicted in Figure 9. A sampling rate of 10 Hz was chosen in order to ensure an appropriate resolution of the signals. Each row of the visualization in Figure 9 is a time increment. Column **a** stands for "engine running", which means that the engine of the tamping machine has to be switched on and a minimum rotational speed has to be exceeded. The second column **b** represents the tamping cycle initialization which is done by the operator by means of a foot-operated pedal. In the **c** column it is listed whether the superimposed vibration of the tamping tines is activated or not. **d** indicates the proper lifting and lining of the rails. In **e** one can see if the tamping unit's relative velocity falls below a very low threshold value with respect to the rails. This means that "the tamping unit stands still" or it is in a very slow movement at least. The penetrating phase is described in column **f** via checking the downward movement of the tamping units, in detail, it is true if it moves and false if not. Column **g** shows if the tines are in the desired lower position. This is again realized by applying a threshold value to the tamping unit's positional encoder. In column **h** the squeezing movement is depicted. It is true if the tamping tines are moved towards each other to fill and compact the ballast under the sleeper and false else. In the last column **i** the retraction, the lifting of the unit, is depicted. For the consideration of measurement and transmission errors small deviations are tolerated. This means that also segments which are disconnected by only one or two time increments are regarded as one full coherent segment.

The following criteria are established for the tamping cycle identification and classification:

- duration of each individual segment
- simultaneity of segments
- duration of sections with overlapping segments which should not be simultaneous
- serial sequence of segments or detachment of consecutive signals
- duration between consecutive segments

The definition of permissible durations, serial sequences, concurrences etc. requires both profound domain knowledge about the tamping cycle and empirical insights based on real data. For example, the ideal minimum squeezing time, i.e., the duration from start of the filling phase until the end of compaction phase, is defined as about 1.2 seconds by a manufacturer of tamping machines. However, there can be national regulations which specify a deviating squeezing duration. Another example can be the temporal succession of the lifting and penetration phases. Ideally, these two sequences are strictly in series. However, the downward movement of the tamping unit can already start when the lifting of the rail is still in progress provided that a void has formed as soon as the tamping tines enter the ballast. Concluding, a certain duration of parallelism is permissible in this case. Furthermore, it is also acceptable that there is a short pause between the segments. Thus, the definition of such thresholds and tolerances requires experience and sensitivity from the engineers and data analysts. Usually the threshold values are determined empirically or are defined be national regulations depending on where the machine is operated.

In order to get an intuitive feeling about the identification process several consecutive tamping cycles are depicted in Figure 10, where blue sections represent boolean true and orange, boolean false. The columns are identical to those in Figure 9.

Figure 10. Tamping identification of multiple cycles

6.2. NOK Tamping cycle detection

In order to obtain the desired process quality all sub-processes have to have the appropriate duration and also the sequence of the consecutive sub-processes has to satisfy the correct order, which means that the subsequent signal has to follow the previous one within a certain amount of time. Therefore the following error scenarios can occur:

- vibration off
- incomplete vibration
- relative velocity
- no stand still
- incomplete stand still
- no leveling
- incomplete leveling
- no penetration
- no down position
- incomplete down position
- no squeezing movement
- penetration before lifting the rails
- squeezing before down position
- lifting the tamping unit before squeezing

The time-series signals of an example of detected NOK tamping cycles are depicted in Figure 11 - a better quality of the plot can be found in the Appendix 9, too - where the upper graph shows the lowering position of a tamping unit. Negative values indicate positions of the tamping tines above the rail, zero is approximately the level of the rail's surface and positions greater than 120 mm can be considered as the tines entering the ballast. The lower graph illustrates the machine's velocity in m/h. Based on the developed cycle identification an impermissible overlap of the two sections "vehicle stands still" and "tamping tines are in the ballast" could be detected. The overlap is highlighted in red colour in Figure 11. These overlaps indicate that the tines are already located in the ballast even though the machine is still moving can cause significant wear on or even severe damage of the tamping unit.

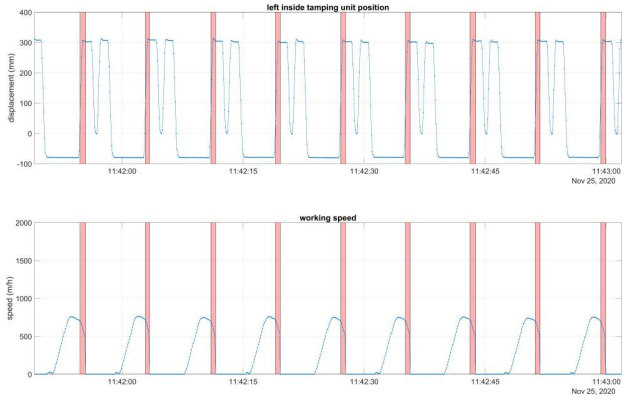

Figure 11. Identified NOK tamping cycle: The tamping unit is already in the ballast even though the machine is still moving (see also Appendix)

7. LSTM Detection

7.1. Architecture

After several trials regarding the structure of the network, the architecture depicted in 9 was chosen.

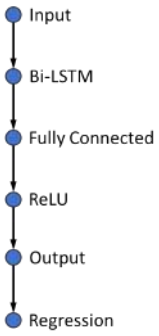

Figure 12. LSTM architecture

The network consists of:

- Input Layer
- Bi-LSTM Layer
- Fully Connected Layer
- ReLU Activation
- Output Layer
- Regression Output

The input layer is the bottom-most layer, where the input, the previously generated boolean signals, is fed to the network.

Subsequently data is passed to the Bi-LSTM layer which consists of 25 hidden units. Bidirectional LSTMs can be useful when the context of the input is needed from both the past and the future of a specific time step. This turned out to be the case in the cycle identification. Following the Bi-LSTM layer, there is a fully connected layer which takes the sequential output from the Bi-LSTM and transforms it into a fixed-size vector. This layer has 10 units, and it is likely responsible for integrating the features learned by the Bi-LSTM layer. After that a non-linearity in form of a ReLU activation function is applied. Therewith the model is allowed to account for non-linear relationships between the features. The next layer is another fully connected output layer with a single unit. This is because the network is designed to output a single continuous regression value. The final layer is a regression output layer with the mean squared error as loss function.

7.2. Training

The analysis workflow was implemented in Matlab and it turned out that training for only 10 epochs with 225 iterations each is sufficient. For the training the timeseries were split into windows of 10 seconds each and a step size of 5 seconds was chosen. Therefore an overlap of 50% occurred intentionally. The training was done with a learning rate of 0.001 on a single GPU. and the training in total only took a couple of minutes. The metric used in training was RMSE (root mean square error).

7.3. Results

In Figure 13 the cycle detection can be seen. This graph can also be found in the appendix. In this visualization the gray rectangles represent the tamping cycles and also their duration. A nearly perfect fit can be found here. There is no visible deviation between the LSTM and the rule based results.

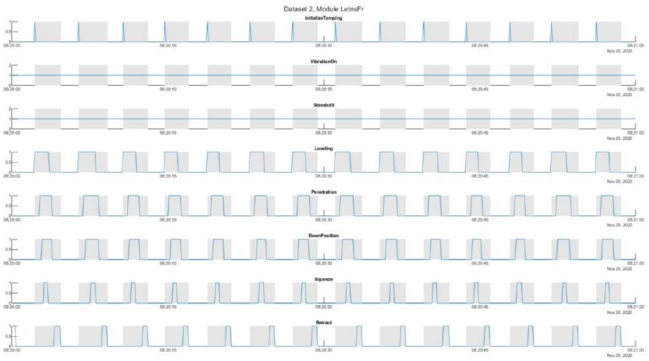

Figure 13. LSTM tamping cycle detection (see also Appendix)

Using the hold-out test set method, an accuracy of 0.98 was achieved.

8. Conclusions

The comparison of the two tested methods for tamping cycle identification, i.e. the rule-based vs. the LSTM approach, it can be concluded that:

1. The accuracy of the rule-based method is approx. 100%, whereas that of the LSTM model is approx. 98% taking only OK detections into consideration. Obviously, the rule-based approach, which basically consists of a set of subsequent if-queries, delivers better results due to the fact that the rules exactly represent the definition of a correct tamping cycle. But the exact representation requires profound domain knowledge of and experience on the tamping procedure and the data acquisition process. When lacking this knowledge and experience the neural network, which defines its own rules by adjusting its learnable parameters, the weights and biases, by evaluating the time series over and over, turns out to be a suitable alternative to still get very accurate results.

2. The implementation effort for the LSTM model is much higher as well as the required hardware and processing resources for training and evaluating the network.

3. The pre-processing of the data and the generation of the boolean sub-processes is the same for both methods.

4. The identification of the NOK tamping cycles is more difficult for the LSTM approach due to the lack of sufficient amount of NOK cycles in real world training data because operating errors rarely occur. A possible solution would be to artificially generate error cases in order to allow the model learn incomplete sequences.

9. Further steps

The LSTM approach as described is capable of identifying OK-cycles. However the NOK-cycles are of higher interest with regards of wear and resulting maintenance. However these cases do not occur sufficiently frequent in real world data. Therefore artificial samples could be generated and be fed to the training set. Another approach could be weighing the very rarely occurring failure cycles higher than the frequently occurring OK cycles in order to balance the training set. Furthermore it should be checked if the found algorithm is generic enough to also fit to other machines and surroundings. Thus it shall be enrolled to different machines operating in different regions of the world in order to compare results and performance subsequently. On the other side also other algorithms shall be implemented and compared. Therefore the time series should again be split into small segments e.g. 0.1s and each of these segments should be classified by different machine learning algorithms according to the features within the respective segment.

ABSTRACT

In this study, we evaluate the performance of a prognostic classification model for NOX sensors in diesel engines over one month by comparing its predictions against actual outcomes. We then construct a validation dataset to assess the model's performance. By analyzing instances where the model's predictions were incorrect, we determine new threshold values that could potentially reduce errors for each false positive (FP) and false negative (FN). Subsequently, we create a dataset where the threshold varies for each observation and train a regression model with the modified threshold as the target variable. Our findings indicate that incorporating this approach, where the model's performance is iteratively refined using the validation dataset, leads to a reduction in both false positives and false negatives.

Keywords – True Negative (TN), True Positive (TP), False Negative (FN), False Positive (FP), Receiver Operating Characteristic (ROC), Area Under ROC Curve - (AUC)

1. INTRODUCTION

Cummins Inc. is a global corporation that designs, manufactures, and distributes engines, filtration, and power generation products. Cummins Inc. is headquartered in Columbus, Indiana, and has a history dating back to 1919. The company serves customers in more than 190 countries and territories, with a focus on innovation and sustainability in its products and operations. Prognostics plays a crucial role for Cummins in the context of diesel engines by enabling predictive maintenance. By analyzing the condition and performance of diesel engines using data from sensors and other sources, prognostics can help Cummins predict when maintenance or repairs will be needed.

This predictive approach allows Cummins to schedule maintenance in advance, minimizing downtime and reducing the risk of unexpected failures. Overall, prognostics help Cummins optimize the performance, reliability, and longevity of their diesel engines.

Diesel engines, the preferred power source for commercial vehicles like trucks and buses, produce harmful NO and NO2 emissions due to high combustion temperatures. Mckinley, Somwanshi, Bhave, and Verma, (2020) in their study showed that, to meet stringent emission standards, after-treatment systems such as selective catalytic reduction (SCR) are used, which can reduce emissions by factors of 10 to 20. SCR involves injecting a Diesel Exhaust Fluid (DEF) into the exhaust to produce ammonia (NH3), which then reacts with NOX to form harmless nitrogen (N2). NOX sensors are crucial in this process, measuring conversion efficiency and guiding the injection rate of DEF. Errors in these sensors can lead to either excessive ammonia or NOX emissions, impacting air quality and health. Regulatory agencies require continuous monitoring of these sensors and their operation to ensure compliance.

Prognostics aims to suggest changing out a NOX sensor before it fails. Since the replacement NOX Sensor can be planned for a convenient time rather than dealing with the discomfort of an unexpected breakdown, the customer will ideally experience less downtime. To determine whether the NOX sensor will fail, the present prognostics methodology uses a classification model with a predetermined threshold which is set using AUC ROC curve analysis. Even with an appropriate threshold, there may be instances where the model's predictions are not entirely accurate, which could potentially lead to increased downtime and maintenance costs for the customer. Dynamic thresholding model is a field of research that focuses on developing efficient methods for altering decision thresholds in predictive models over time and over different units.

The goal is to reduce the cost of false positives and negatives (after observing the performance of the prognostic classification model) by accounting for changes in the underlying data distributions that can arise because of changes in the environment, warranty status, or other external factors. In this study, we investigated a dynamic thresholding strategy and measured its performance by evaluating the incremental financial impact on customers and businesses. We also suggested a method for constructing a target label based on prognostics likelihood and validation data by computing the optimum thresholds. Our results demonstrate the importance of dynamic thresholding in maintaining the accuracy and robustness of predictive models and highlight the potential for further improvements through continued research in this area.

In summary, the paper explains how to dynamically change the threshold to improve the performance of a classification model after observing its performance for some time.

The rest of the paper is organized as follows. Section 2 gives a literature survey. Section 3 elaborates proposed Dynamic Thresholding Model (DTM) followed by results and discussions in section 4. Section 5 gives conclusions and future scope.

2. LITERATURE SURVEY

In this literature review, we will explore some of the key research papers that use ROC and AUC, dynamic thresholding, and cost analysis to determine thresholds.

Threshold selection is a crucial step in binary classification models as it determines the balance between the trade-off of precision and recall. Receiver operating characteristic (ROC) curves and area under the curve (AUC) are commonly used metrics to evaluate the performance of binary classification models and determine the optimal threshold value. The concept of the ROC (Receiver Operating Characteristic) curve, from which AUC ROC is derived, originated in electrical engineering and signal detection theory. It was initially used to analyze the performance of radar systems during World War II. The ROC curve was later adopted in medicine to evaluate diagnostic tests' performance. In machine learning, the ROC curve is used to assess the performance of binary classification models. The AUC ROC is a numerical measure derived from the ROC curve and provides a single value to quantify the overall performance of a classifier.

The ROC curve and AUC ROC can help in deciding the threshold for a binary classification model by providing insights into the trade-off between the true positive rate (sensitivity) and the false positive rate (1 - specificity) at different threshold values. In their classic paper, Bradley (1997) emphasizes that AUC ROC provides a comprehensive measure of a classifier's performance across all possible thresholds, making it particularly useful for assessing the overall discriminatory ability of a model. The paper highlights that AUC ROC can be instrumental in threshold selection by illustrating the trade-off between true positive rate (sensitivity) and false positive rate (1-specificity) at different threshold values. This insight enables practitioners to choose an optimal threshold based on the specific needs of the classification problem, balancing the costs associated with false positives and false negatives. In addition, Bradley discusses how AUC ROC can help in selecting a threshold that best suits the application's requirements. By analysing the ROC curve, which plots the true positive rate against the false positive rate at various thresholds, practitioners can visualize the classifier's performance and make informed decisions about threshold selection. This capability is particularly valuable in scenarios where the cost of false positives and false negatives differs, as it allows for the customization of the classifier's behaviour to meet specific needs.

Alotaibi and Flach (2021) introduce a novel approach to extend the traditional AUC metric to incorporate misclassification costs, addressing limitations in existing settings. By treating costs as sampled data, the proposed method employs the Weighted AUC (WAUC) metric and a novel estimator to approximate it, enabling a more accurate representation of model performance in complex cost-sensitive scenarios. The approach establishes a correspondence between WAUC and the cost function using threshold weighting and presents a bilevel optimization formulation to couple them. This formulation ensures that WAUC can be optimized at the optimal threshold value based on the real-world cost distribution. A stochastic algorithm is proposed for optimizing this formulation, demonstrating convergence rates comparable to standard SGD. Experimental results validate the effectiveness of the method in extending AUC to cost-sensitive scenarios, highlighting its significant performance improvements.

Yang, Yu, Wang, Quddus and Xue (2018) introduced the thresholding methods: fixed, rate-driven, optimal, RCut, MCut, and two novel ones: score-driven and global optimal are introduced. Score-driven thresholds can be adjusted globally or per label, offering flexibility. It investigates selecting a single global threshold or multiple thresholds. Using real-world datasets, the study conducts an empirical review, finding that the global and label-wise score-driven methods excel. Tuning a global threshold with respect to per-label cost is not significantly worse than using a separate threshold per label. Some traditional approaches, like the label-wise rate-driven method, may not suit highly imbalanced multi-label data. The study recommends using score-driven thresholds, globally or per label, for superior performance. It calls for further research on misclassification costs, loss, and threshold choice in multi-label classification, particularly when costs vary across labels.

In their study, Johnson and Khoshgoftaar (2019) showed that class imbalance is a common issue in machine learning, addressed through algorithm-level, data-level, and hybrid methods. While extensively studied in traditional algorithms, its application to deep neural networks (DNNs) is limited. This paper fills this gap by studying thresholding in DNNs using a Big Data Medicare fraud dataset. Employing random oversampling (ROS), random under-sampling (RUS), and a hybrid ROS-RUS, 15 training distributions with varying imbalance levels are created. Optimal classification thresholds are identified for each distribution on random validation sets, outperforming default thresholds. They further showed that, statistical analysis reveals a strong linear relationship between minority class size and optimal threshold, highlighting the importance of thresholding in DNNs for imbalanced data.

The properties of the F1 performance metric in multilabel classification, particularly regarding optimal decision-making thresholds. In this study, Lipton, Elkan, and Narayanswamy (2014) discuss how the best achievable F1 score is linked to the optimal threshold and highlights the impact of classifier behaviour in uninformative scenarios. For instance, in such scenarios, predicting all instances as positive maximizes the expectation of F1, which is beneficial for some metrics but problematic for others, like macro F1 in the presence of rare labels. The study also reveals that micro F1, on the other hand, maximizes the expected score by predicting all examples as negative in similar scenarios. This insight is especially valuable in settings with numerous labels. Additionally, the study suggests that micro F1 may wash out performance on rare labels. The findings underscore the importance of carefully selecting and understanding performance metrics, especially when choosing a single metric to optimize in scenarios involving competing systems, as this choice can significantly impact optimal thresholding behavior.

For a different application, Hancock, Johnson and Khoshgoftaar (2022) investigate the impact of the TPR $\geq$ TNR constraint on threshold values in classification tasks. The constraint favors lower thresholds, closer to the prior probability of the positive class, leading to reasonable trade-offs in classification rates. The default decision threshold of 0.5 is found unsuitable for the imbalanced Kaggle Credit Card Fraud Detection Dataset, yielding low TPR and FNR scores. It is noted that this default threshold is much larger than the prior probability of the positive class in imbalanced data. No single metric provides a comprehensive view of classifier performance, with thresholds closer to the positive class prior probability generally yielding better performance across multiple metrics. Each threshold selection technique offers trade-offs between positive and negative class performance. Starting with the positive class prior probability as a benchmark, thresholds can be adjusted to balance TPR and TNR scores. For specific performance goals, the optimal threshold can be estimated using the training dataset, considering user-defined performance metrics and constraints. The choice of performance metrics and constraints for threshold optimization significantly impacts test performance, highlighting the importance of careful selection based on the classification task's requirements and goals.

Going back in time, Chen, Tsai, Moon, Ahn, Young, and Chen (2006) explore the impact of decision thresholds on sensitivity, specificity, and concordance in four classification methods: logistic regression, classification tree, Fisher's linear discriminant analysis, and weighted k-nearest neighbour. While standard classification algorithms aim to maximize correct predictions (concordance), this may not be suitable for all applications. Some applications prioritize high sensitivity (e.g., clinical diagnostics), while others prioritize high specificity (e.g., epidemiology screening studies). The study examines the use of decision threshold adjustment to enhance sensitivity or specificity under specific conditions. Through Monte Carlo simulations, the study shows that increasing the decision threshold leads to decreased sensitivity and increased specificity, with concordance values remaining stable within an interval around the maximum concordance. Optimal decision thresholds can be identified within this interval to meet specified sensitivity and specificity requirements. The study analyzes three example datasets to illustrate these findings.

Two variants are introduced: a novel neural network-based thresholding method called ThresNets for improving multi-label predictions from class scores obtained from external scorers as shown by Shao & Huiyang et al. (2024) ThresNets are designed to scale linearly with the number of labels and can be trained offline after the scorer training is completed. One variant incorporates classic CS/CSS thresholds into the neural model, serving as a form of transfer learning between heterogeneous models. Our method is particularly suitable for medium-sized multi-label classification (MLC) tasks where informative label score dependencies can be found, and the ground truth of label assignments is reliable. Experimental results on artificially created scores demonstrate the effectiveness of ThresNets, especially when the scoring phase allows for improvements. ThresNets outperformed popular nearest neighbor-based classifiers in recovering from scoring errors. Empirical evaluation on real datasets shows that ThresNets perform better than classical methods according to various metrics, especially when used in a hybrid approach. Despite its advantages, ThresNets face challenges such as the risk of overfitting and the difficulty of training with long-tail labels. Future work will focus on leveraging external knowledge of class structure to improve ThresNets' performance further.

In their classic Real-time crash prediction, Draszawka, Karol and Szymanski (2023) show how important the Threshold selection is, by determining the cut-off point for

the posterior probability used to separate potential crash warnings. Current research lacks methods for effectively determining an optimal threshold, often resorting to subjective approaches. This study proposes a theoretical method using the mixed logit model to develop crash risk evaluation models. The minimum cross-entropy method outperforms other threshold selection methods, providing a reliable and automatic approach for identifying optimal thresholds in crash prediction.

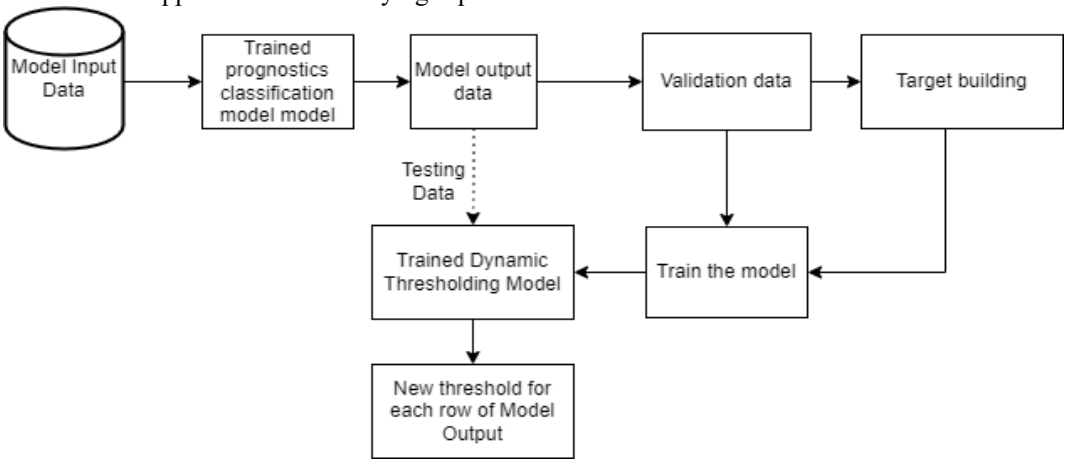

Figure 1. Block diagram of Dynamic Thresholding Model

In conclusion, this literature review has explored various aspects of threshold selection in machine learning, particularly in the context of class imbalance and multi-label classification. The reviewed papers have highlighted the importance of selecting an appropriate threshold for optimizing model performance and addressing specific challenges in different applications.

Several studies have proposed novel thresholding methods, such as ThresNets for multi-label classification and the use of the Area Under the ROC Curve (AUC ROC) metric for threshold selection. These methods have shown promising results in improving classification performance, especially in scenarios with imbalanced data and complex cost-sensitive considerations.

However, challenges such as overfitting and training with long-tail labels remain, suggesting the need for further research. Future studies could focus on leveraging external knowledge, such as class structure information, to enhance thresholding methods. Additionally, exploring the application of thresholding in emerging areas like real-time crash prediction and credit fraud detection could lead to valuable insights and advancements in the field.

3. PROPOSED METHODOLOGY

The prognostics model may make a future failure prediction for each component. We can run the prognostics model, determine the component's remaining useful life (RUL), and take preventive action. The model predictions for this classification model are based on the threshold and the likelihood for each data row. The threshold is often set using AUC-ROC curves, and that threshold is chosen for which the area under the curve for the TPR vs. FPR curve is highest. Our current prognostics algorithm alerts the client 90 days before the component's likely failure.

The dataset has two variations, pre-verified engine validation data, and post-verified engine validation data. Both have all engine status parameters, but they differ on when the actual status of the engine was captured. In the pre-verified engine validation data we predict engine health using a static threshold to classify an engine as healthy or faulty after we have the data about the actual status of the engine. In post-verified engine validation data, we predict before we have any ground truth for engine health using a static threshold to classify an engine as healthy or faulty, the ground truth is received later. The pre-verified engine validation data has been discarded due to data quality issues. The post-verified engine validation data has features such as the likelihood of an engine failure, the RUL of the engine, the classification threshold that was applied, the prediction by the predictive maintenance model, the actual status of the engine, and all other parameters of engine health.

Based on validation data in the suggested approach, we can choose the threshold dynamically. The validation data, with which, once the prognostics model has been run, we validate its performance during the following 90 days. Following the 90 days, we learn whether the failed event occurred. The confusion matrix, which we use to interpret the TPs, FPs, TNs, FNs, etc., is provided by the validation data. Our suggested methods can further reduce the FPs and FNs.

The order of events is depicted in the block diagram. The dynamic thresholding model is constructed utilizing features like odometer running, engine run duration, the likelihood of each row, the component's warranty status, and failure type (first or repeated failure), as opposed to setting a

threshold for the entire dataset. A regression model is the dynamic thresholding model. Concerning the validation data, the following algorithm is used to construct the regression model's target.

1. *For a TP and TN, there is no change in the threshold, fixed by the AUC-ROC curve.*
2. *E.g. - likelihood = 0.76, the fixed threshold is 0.8, which comes out to FN in the validation data, then, the new threshold is calculated as –*

$$Threshold_{New} = Threshold_{old} + |Threshold_{old} - Likelihood| - correction\_factor^{\#}$$

3. *Similarly, if likelihood = 0.86, the fixed threshold is 0.8, which comes out to FP in the validation data, then, the new threshold is calculated as –*

$$Threshold_{New} = Threshold_{old} + |Threshold_{old} - Likelihood| + correction\_factor^{\#}$$

4. *Repeat the procedure for each TP, FP, TN, and FN.*
5. # - The value can range between 0 to 1. This can be finalized after repeated training and testing of the model for different correction factors.

The target label, a continuous variable with a distinct threshold for each row of the output, is trained with the regressor model after we create the dataset containing the features as described before. After the model has been trained on the validation data, the DTM model that predicts dynamic threshold is given model out data with the same attributes as the validation data.

Extreme Gradient Boosting (XGBoost), a powerful machine learning method that we have used for this regression problem, is capable of handling complex non-linear interactions between features and targets as well as handling missing values and outliers.

The performance of the Xgb regressor used in DTM, the effect of changing the threshold, and the financial impact of this approach for each row are discussed in detail in the results and discussions.

4. Results and Discussions

The results (in Table 1) after applying Dynamic Threshold Modeling (DTM) show a notable improvement in various metrics. We have compared our results with traditional AUC ROC curves, as shown in column 2 of Table 1. We obtained the optimised threshold to be zero when we experimented with weighted AUC (WAUC) curves. This means that the model was recommending to replace every NOX sensor with even the smallest likelihood for failure. This is not a pragmatic solution. Also, The score-driven global thresholds proved to give no different results than the traditional AUC. Because of data availability constraints per the rest of the methodologies, we couldn't compare our methodology with them.

As compared to AUC, the True Positive Rate (TPR) has increased from 0.069 to 0.156, indicating that the model is better at correctly identifying positive instances. The Precision has also improved significantly, rising from 0.041 to 0.093, indicating a reduction in false positives. This improvement is further reflected in the F1 Score, which has increased from 0.074 to 0.14. Despite these improvements, the model still exhibits a relatively high False Positive Rate (FPR), albeit reduced from 0.397 to 0.373.

Table 1 shows the results for the EONOX sensor of a popular engine series. We observe that a reduction in FPs saves unnecessary repair of the engines and a reduction in FNs saves downtime cost of the engines which saves $0.3M for our customers and $13k for our company. In total, we save $313k. The methodology is highly scalable.

Overall, applying DTM has greatly enhanced the model's performance, particularly in correctly identifying positive instances and reducing false positives.

Table 1. Comparison of TPs, TNs, FPs and FNs before and after the use of DTM

	Using (AUC-ROC)	After DTM
TP	167	377
FP	3905	3670
FN	2246	2036
TN	5923	6158
TPR	0.069	0.156
FPR(or Recall)	0.397	0.373
Precision	0.041	0.093
F1 Score	0.074	0.14

5. Conclusions and Future Scope

The application of Dynamic Threshold Modeling (DTM) in our classification model has resulted in significant enhancements across key performance metrics, including accuracy, precision, and recall. By increasing the number of True Positives (TPs) and True Negatives (TNs) while decreasing False Positives (FPs) and False Negatives (FNs), the DTM has improved the model's overall effectiveness. We have implemented the DTM on one sensor from a specific family of engines used in a particular application. However, there is potential to expand this approach to multiple sensors across various engine families and to integrate it with other classification models. This scalability

could save substantial costs by minimizing unnecessary repairs and downtime. We estimate that such an expansion could result in savings amounting to millions of dollars.

BIOGRAPHIES

Rohit Deo received his Bachelor's degree in Electronics and Telecommunication from WIT, Solapur in 2011 and his Master's degree in Signal Processing from the University of Pune. He has eight years of professional experience. Rohit began his career as an Assistant Professor at Modern College of Engineering, Pune from July 2014 to May 2018. He then transitioned to industry, working as a Data Scientist at Montran Corporation, Mumbai from July 2018 to December 2021. Since December 2021, he has been a Senior Data Scientist at Cummins Technologies, Pune. His current and previous research interests include predictive analysis, pattern classification, machine learning, and deep learning for complex business problems. Rohit is highly skilled in signal processing and applied mathematics. He is a member of various professional societies.

Swarali Desai is a Data Science and Digital Engineering professional at Cummins. She holds a bachelor's degree in Electronics and Telecommunications Engineering from the University of Mumbai, India, and a Master of Science in Data Science from the University of Washington. With extensive experience in data analysis, machine learning, and business intelligence, Swarali has led several impactful projects in predictive maintenance, engine failure prediction, and supply chain optimization. Her recent work involves applying advanced data analytics techniques to enhance the performance and reliability of Cummins' engine systems, thereby contributing significantly to operational efficiency and customer satisfaction.

Subhalakshmi Behra holds a B.Tech in Mechanical Engineering from NIT Rourkela (2008) and an MBA in Business Management from XLRI Jamshedpur (2010). With over 14 years of industry experience, she currently serves as the Analytics Manager for the Analytics and Artificial Intelligence team at Cummins Inc. Her expertise spans advanced analytics, machine learning, digital product development, supply chain management, and project management. Subha is a Certified Six Sigma Green Belt and has numerous awards and honors for her contributions to the field.

Chetan Pulate, holds a Bachelor's degree in Electronics and Telecommunication from Smt. Kashibai Navale College of Engineering. With over 6 years of experience at Cummins Inc. as a Data Engineer, Chetan specializes in developing distributed, scalable, and reliable data pipelines. His expertise includes Apache Spark, Hive, Sqoop, Oozie, MapReduce, and various Hadoop stacks, along with working in Microsoft Azure. Chetan is skilled in feature engineering and deploying data science models at scale. He has also worked at Cognizant and Capgemini, enhancing his skills in big data and data engineering.

Aman Yadav holds a Bachelor of Technology degree in Computer Science from the University Institute of

Engineering and Technology, Kanpur (2021), and a Master of Technology degree in Artificial Intelligence from the Defense Institute of Advanced Technology (DIAT), Pune (2023). He is a Data Scientist at Cummins India, where he has been working since August 2023, after completing an internship as an M.Tech AI intern at the same company. Aman has experience in developing AI models, including an ASR model for Indian accents, gained during his internship at ProxMaq. His skills include machine learning, deep learning, NLP, and working with technologies like Apache Spark, Scikit-Learn, and Microsoft Azure. Aman is passionate about advancing AI and robotics, and holds several certifications in graph data science from Neo4j.

Nilesh Powar is the Advanced Analytics Director at Cummins. He holds bachelor in electronics engineering from University of Bombay, India, M.S in Computer Engineering from Wright State University and a doctoral degree in Electrical and Computer Engineering from University of Dayton, Ohio. He has over 20+ years' experience in field of image processing, machine learning, statistical pattern recognition and system integration. He had worked in the US as Distinguished Research Scientist for University of Dayton Research Institute, Dayton, OH, USA. Recent efforts involve data analytics for die casting, predictive analysis for supply chain management and video summarization using deep learning.

Design Of Digital Twins for In-Service Support and Maintenance

Atuahene Kwasi Barimah

Glasgow Caledonian University, Glasgow, G4 0BA, UK
abarim300@gcu.ac.uk

ABSTRACT

This research aims to examine the challenges in developing Prognostics and Health Management (PHM) analytics for Digital Twin (DT) use cases in industrial applications, with a particular focus on Multi-Component Degradation (MCD) scenarios. A hybrid methodology, integrating physics-informed and data-driven models, is employed, using limited asset degradation data for model development. Preliminary work includes an analysis of the impact of data quality on Fault Detection and Isolation (FDI) algorithm performance, as well as the proposal of a weighted ensemble hybrid approach for assets experiencing MCD scenarios Preliminary results indicate enhanced diagnostics in asset health management through the use of Physics-Informed models for FDI in MCD scenarios with limited prior degradation data. Expected contributions for this research are the development of physics-informed PHM analytics for DT applications in MCD scenarios, adaptive PHM analytics for evolving asset lifecycles in DT applications, and interpretable DT model analytics for PHM in systems facing Multi-Component Degradation.

1. BACKGROUND AND PROBLEM STATEMENT

Many high-value complex systems rely on advanced technologies, particularly the Industrial Internet of Things (IIoT), to monitor assets and carry out maintenance activities. Many stakeholders are increasingly turning to data-driven methods to monitor the condition of their assets, with Original Equipment Manufacturers (OEMs) offering various service packages in this regard (Barimah, Niculita, McGlinchey & Babakalli, 2021). These services leverage digital technology, particularly the concept of the digital twin (DT), to enable Prognostics and Health Management (PHM) applications. Digital twins serve as virtual replicas of physical assets (Grieves & Vickers, 2017), enabling operators to monitor, analyse, and predict asset states effectively. According to the Digital Twin consortium, the key capabilities required for digital twin use cases are data services, integration, user experience, intelligence, management and trustworthiness. This provides a framework for tailoring the capabilities of a digital twin for a particular industrial asset. The intelligence capability of a digital twin provides the requirements for enabling prognostic and health management applications. The analytics that drive intelligence in digital twins are constituted by either data-driven or knowledge-based models that provide insights for detection, diagnostics and prognostics for enhanced system reliability and support (Mihai, Yaqoob, Hung, Davis, Towakel, Raza, Karamanoglu, Barn, Shetve, Prasad, & Venkataraman, 2022).

However, developing the analytics that enable intelligence in digital twins (DT) for the full suite of PHM applications ─ detection, diagnostics and prognostics ─ is dogged with a lot of challenges which Compare, Baraldi and Zio (2019) describe in their work. One key challenge is the development of robust analytics for PHM applications, particularly with limited training data and in scenarios where assets are undergoing multi-component degradation (MCD) as part of a larger system. Bayesian approaches have been explored by Lin, Zakwan, and Jennions (2017) where the probability of two components in a fluid system was determined using a Bayesian probabilistic approach. However, there are limitations of this approach especially when compared with data-driven approaches in the MCD scenarios.

Another challenge in developing the analytics for PHM applications for Digital Twins is the evolution of the virtual replica of an asset throughout the asset's lifetime after commissioning and subsequent maintenance actions (Pires, Cachada, Barbosa, Moreira & Leitão, 2019), as various operating factors change the operating state of the asset, whether in a healthy or faulty condition. The complexity that the evolution of an asset throughout its lifecycle introduces in the DT development process presents model performance challenges for the PHM analytics embedded in the DT. Investigating how different DT model frameworks optimize analytics for PHM applications for an asset undergoing MCD scenarios will aid in identifying optimal DT model frameworks in the context of an evolving asset.

Lastly, the adoption of DTs has been increasing steadily in recent times, with data streaming and enhanced visualisation being some of the key selling points. However, the inadequate explainability in the outputs of the analytics capabilities limits the widespread adoption of DT analytics for critical assets (Presciuttini, Cantini, Costa & Portioli-Staudacher, 2024). In most DT applications, data-driven models that support the performance of DTs often train and perform as black boxes relying on the development of model weights which often become less intelligible (Kobayashi & Alam, 2024). Addressing the explainability of DT actions will facilitate the adoption of DTs for PHM applications, particularly for safety-critical systems.

2. EXPECTED CONTRIBUTIONS

This research aims to design a scalable online Hybrid-Digital Twin model architecture for IIoT-enabled PHM strategies for in-service support and maintenance applications. The expected contributions for this PhD research are presented below:

1. Development of physics-informed PHM analytics using limited training data for instantiating DT applications in Multi-Component Degradation scenarios.

2. Development of adaptive PHM analytics for evolving asset lifecycles in Digital Twin (DT) applications.

3. Development of interpretable DT model analytics for PHM applications in systems undergoing Multi-Component Degradation scenarios.

3. PROPOSED RESEARCH PLAN

The research plan seeks to advance the field of Hybrid-Digital Twins (H-DT) by defining an optimal physics-enabled model architecture for detecting and isolating Multiple Component Degradation (MCD) phenomena in complex systems. The research is based on a well-established testbed (see Appendix) to analyse the dynamic behaviour of a fuel system undergoing MCD scenarios. This hydraulic system comprises critical components, including a main supply tank, and an external gear pump driven by an induction motor. The rotational speed of the motor is regulated by a Variable Speed Drive (VSD). The system also features a solenoid shut-off valve (SHV) and five direct proportional valves (DPV1 to DPV5) for fluid flow control and fault emulation, respectively. Data collection is facilitated by pressure transmitters (P1, P2, P3, P4, and P5), turbine flow meters (F1 and F2), and a laser sensor to measure the pump's speed.

System components are connected using PVC tubing, and a finger valve is used for tank isolation when needed. In the context of fault simulation, specific control valves were manipulated to emulate fault conditions. For instance, DPV1 represented a clogged suction filter, fully open at 0% fault severity, while DPV2 simulated pump discharge side leakage and was fully closed at 0% fault severity. The SHV solenoid valve remained open, and DPV3, emulating a blocked or degraded shut-off valve, was fully open at 0% fault severity. DPV4 represented a clogged fuel nozzle, also fully open at 0% fault severity, while DPV5, simulating downstream pipe leakage, was fully closed with 0% fault severity. The healthy condition operating state of the system's control valves and their associated fault codes, as well as the test degradation scenarios for FDI Model Testing, are shown in the appendix.

The research will address several key objectives and research questions across four main areas:

1. Definition of a Hybrid-Digital Twin (H-DT): The research seeks to define an optimal architecture for H-DT models that meet diverse industry requirements and address MCD phenomena. This involves examining current trends and insights from literature via a systemic literature review.

2. Hybrid-Digital Twin Model Development: This phase involves the development of an online H-DT model tailored for MCD detection in complex systems. Key focus areas include data quality assessment, AI-enabled Fault Detection & Isolation (FDI), selection of hybrid model frameworks, and practical implementation considerations within Industrial Internet of Things (IIoT) systems.

3. System Reliability & Maintenance: The research will investigate the impact of employing an H-DT model architecture on different maintenance approaches, considering various technical, operational, and platform-specific requirements. The economic benefits of using H-DT models for different maintenance strategies will be analyzed.

4. Business Development: Finally, the research will focus on developing API-enabled services using a DevOps approach for the end-to-end implementation of the H-DT model architecture on IIoT platforms. It will explore the technical and business services enabled by an H-DT model architecture for cross-platform applications.

4. PROPOSED METHODOLOGY

The project will use the agile framework to plan various aspects of the digital twin development. A DevOps methodology will be adopted to facilitate the seamless integration and continuous deployment of physics-informed Prognostics and Health Management (PHM) analytics for the hybrid Digital Twin, focusing on components within the designated testbed. The industrial Internet of Things (IoT) platform Thingworx™ will be utilized to craft a user-centric experience (UX) for the digital twin, integrating the physics-informed PHM analytics for each asset through an Application Programming Interface (API) hosted on a remote server. Different physics-informed PHM analytics approaches will then be benchmarked on their performance in predicting multi-component degradation (MCD) scenarios in the context of challenges presented in the background of this report. Bayesian approaches will then be used to develop a trustworthiness framework to address the physics-informed PHM model uncertainty in predicting MCD phenomena. The Hybrid DT model testing and validation will be done using real-time data from the existing testbed and another testbed (proposed) which contains the same assets but in a different configuration. This will help in determining the scalability of the intelligence that underpins the predictive capabilities of the hybrid digital twin.

5. Research Work Done And Preliminary Results

5.1. Data Quality and FDI Model Performance

The relationship between data and predictive analytics was investigated in a recently published paper by Barimah, Niculita, McGlinchey and Cowell (2023). The analysis in this paper used data generated on the testbed described above as well as synthetic data to demonstrate high repeatability by the measurement system of the testbed. In the development of analytics for PHM applications, a lot of emphasis has been placed on data transformation for optimal model development without enough consideration for the repeatability of the measurement systems producing the data. This paper explored the relationship between data quality, defined as the measurement system analysis (MSA) process, and the performance of fault detection and isolation (FDI) algorithms within smart infrastructure systems using components of the testbed described above. The methodology employed starts with an MSA process for data quality evaluation and leads to the development and evaluation of fault detection and isolation (FDI) algorithms.

During the MSA phase, the repeatability of a water distribution system's measurement system was examined to characterize variations within the system. A data-quality process was defined to gauge data quality from the measurement system of the water distribution system. Synthetic data with varying data levels of quality levels was also used to investigate their impact on FDI algorithm development. Key findings reveal the complex relationship between data quality and FDI algorithm performance. The work carried out showed that synthetic data, even with lower quality, can improve the performance of a statistical process control (SPC) model, whereas data-driven approaches benefit from high-quality datasets. The study underscored the importance of customizing FDI algorithms based on data quality and a framework for instantiating the MSA process for IIoT applications, was also proposed for edge analytics which would be considered as part of future work.

5.2. Physics-Informed PHM for MCD scenarios

Optimizing PHM analytics for a system undergoing MCD scenarios using limited data was also investigated in the paper by (Barimah, Niculita, McGlinchey, Cowell and Milligan) and submitted to the PHME2024 conference which is currently under review. This study addresses the challenge of limited degradation data in developing Fault Detection and Isolation (FDI) models for multi-component degradation (MCD) scenarios. Utilizing a small fraction (1%) of the water distribution testbed dataset analyzed in the previous publication, a weighted ensemble hybrid approach was proposed and evaluated against more established modelling approaches. The proposed approach combines heuristic approximation and Physics-Informed Neural Network (Cai, Mao, Wang, Yin & Karniadakis, 2021) methods with a neural network model to enhance diagnostic performance.

The hybrid model generally outperforms other algorithms when tested on an MCD dataset, demonstrating improved diagnostic accuracy in such scenarios. This study contributes to the application of physics-informed FDI models for PHM applications in MCD scenarios, ultimately advancing asset health management. The paper also presents an ensemble FDI approach with the capability of addressing the limitations of integrating both data-driven and physics-based FDI models in multi-component degradation scenarios. Additional research will focus on dynamically optimizing ensemble hybrid model weights, leveraging prediction and model uncertainty to further enhance model performance for PHM applications.

6. Conclusion

In conclusion, this research endeavours to push the boundaries of Hybrid-Digital Twin (H-DT) technology, specifically targeting the challenges posed by Multiple Component Degradation (MCD) phenomena within complex systems. By researching issues of data quality assessment, fault detection and isolation (FDI) algorithm development, and the optimization of Predictive Health Management (PHM) analytics, some strides have been made. By studying data-driven and physics-based models, this research aims to propose a hybrid approach that optimizes diagnostic accuracy in MCD scenarios for PHM applications. The physics-informed PHM analytics developed from this research will improve on the current status quo by developing DT analytics models for PHM applications based on limited degradation data, adaptable in evolving asset lifecycles and intelligible. This will provide a new approach for addressing MCD scenarios aside from the use of classic Bayesian approaches for MCD prediction in the context of limited degradation data. This project will be relevant to industry because it will reduce the requirement for acquiring a lot of degradation data to train their degradation models ultimately reducing the cost of the FDI model development process for complex cases such as MCD scenario.

ABSTRACT

Since their introduction more than 20 years ago, PHM strategies for aerospace equipment have gone a long way, enabling operators and Original Equipment Manufacturers (OEM) to monitor their assets, track down abnormal behaviors and plan maintenance action in advance. On the other hand, the transition from PHM strategies using simulated data to solutions utilizing real-life operational data is consistently prone to significant challenges and demands. This doctoral thesis aims to develop a PHM/CBM framework applied to a Electro-Hydraulic Actuators (EHAs) leveraging real in-service fleet data. In this paper, the first steps of the research project are presented.

1. INTRODUCTION

In the end of the 90s, the Joint Strike Fighter (JSF) Autonomic Logistics (AL) system began to take shape in the minds of forward-looking analysts and engineers with one mission: conceiving a revolutionary way to assist assets along their life cycle, hence enabling enlightened operational processes, innovative maintenance strategies and progressive logistic solutions (Smith, Schroeder, Navarro, & Haldeman, 1997; Hess & Fila, 2002). The AL framework core is encapsulated within Prognostic and Health Management (PHM) solutions which, as a consequence, have been defined as key enabling technologies for the development of reliable Performance Based Logistics (PBL) frameworks.
The creation of more available, dependable and resilient assets is especially important in the military aircraft sector, where the availability and reliability of assets are crucial for defense administrations to foster trust and guarantee mission readiness. Since the introduction of PHM strategies in the industrial and aerospace sector, in fact, many systems have been the scope of research in order to develop tailored prognostic strategies. It may then seem trivial that, along with other pivotal subsystems, the Flight Control System (FCS) is being gradually more covered by these approaches. However, this is only true to some extents.
While the constantly growing interest buildup involving the More Electric Aircraft (MEA) concept has led many prognostic research activities related to Electro-Mechanical Actuators (EMAs), applications on the widespread hydraulic actuators have somewhat lagged behind in terms of PHM. The challenges linked to the lack of precise and extensive data as well as the major difficulties in understanding and modeling failure mechanisms add one more difficulty layer to an already demanding task, which however deserves attention and can prove to generate extensive savings (Rodrigues, Yoneyama, & Nascimento Jr, 2012).

2. NOVELTY AND SIGNIFICANCE

The sharp contrast between the popularity of EHAs in both commercial and military aircraft and the scarcity of PHM related published studies focused on these actuators highlight a significant research gap - a gap that deserves attention.
The development of PHM solutions and strategies for such pivotal widespread systems holds substantial operational and economic potential for every stakeholder in the MRO sector. With the military MRO sector valued at around 37 billion USD in 2024, the demand for digital transformation initiatives and advanced MRO services is expected to undergo a substantial growth in the coming years, motivated by the necessity to maintain aging fleets and incorporate technological advancements for legacy equipment.
One way to address these performance requirements is focusing on the operations. The adoption of condition-based maintenance (CBM) and predictive maintenance (PDM) strategies falls within this enlightened vision which, thanks to the benefits offered by PHM analyses, provides decision makers with extended situational awareness of fleet operations. Some of the main components of a FCS are the actuators, which control the aerodynamic surfaces. Primary flight controls actuators are extremely safety critical elements within aircraft FCS

and, at the current state, they exploit mostly EHAs or Electro-Hydro-Static Actuators (EHSAs). Sure enough, found in most commercial and military aircraft, EHAs represent to date the backbone of actuation mechanisms for flight controls.

3. State of the Art

A solid literature base exists for individual actuator components. These studies have developed a wide range of solutions related to component-level fault detection and isolation (FDI), degradation models, and comprehensive PHM routines for individual parts: (Mi & Huang, 2023; Byington, Watson, & Edwards, 2004; Zhong et al., 2023) for servo valves, (Shanbhag, Meyer, Caspers, & Schlanbusch, 2021) for cylinders, (Vianna & Malere, 2014; Bertolino, Gentile, Jacazio, Marino, & Sorli, 2018) for leakages, (Chao, Shao, Liu, & Yang, 2023) for piston pumps. Additionally, some works have concentrated on the construction of custom test benches (Chiavaroli, De Martin, Evangelista, Jacazio, & Sorli, 2018) and the development of models (Iyaghigba, Petrunin, & Avdelidis, 2024), aiming at the generation of custom datasets. Moreover, some PHM strategies at the FCS level have been envisioned (Kosova & Unver, 2023; Shen & Zhao, 2023). Finally, most of the EHA level approaches found in literature primarily focus on the sole diagnostics (Iyaghigba, Ali, & Jennions, 2023). Notably, these approaches leave a consistent gap for EHA level PHM, which, to the best of the author knowledge, is approached with a limited number of strategies. In (Liu, Zhang, & Lu, 2015), the author developed EHA performance degradation predictions leveraging Elman neural network observer, support vector regression (SVR) and Gaussian Mixture Model (GMM). The research carried out in (Soudbakhsh & Annaswamy, 2017) and (Lu, Yuan, & Ma, 2018) shows the development of both a fault detection technique and a health monitoring approach. (Guo & Sui, 2020) presented an application of the Minimum Hellinger Distance on top of a Particle Filtering (PF). This PF-based solution is adopted by another PHM framework which combines also high-fidelity models (Autin, De Martin, Jacazio, Socheleau, & Vachtsevanos, 2021; De Martin, Jacazio, & Sorli, 2022). A modular hybrid fault prognosis method is developed in (Kordestani, Samadi, & Saif, 2020), where the author leveraged distributed neural networks and recursive Bayesian algorithm. In (Cui, Jing, Jiao, Huang, & Wang, 2023) the author approached a hybrid method: the nonlinear Wiener process (NWP) algorithm is used for the physics based section while the data-driven echo-state-network (ESN) is employed for the data driven one. In summary, the exhaustive yet limited number of studies mentioned above lay its roots on detailed actuator level data obtained from test benches and laboratory tests. Although highly valuable, the results of such studies hardly transfer to actual in-service legacy systems as detailed monitoring of low-level subsystem data is often not carried out and the control signals remain inside the FCC control loop without being saved or logged. On the other hand, the approaches that leverage operational data collected from real-world operational scenario are scarce and the few published studies provide constrained findings (Schoenmakers, 2020; Kannemans & Jentink, 2002).

In conclusion, if creating these frameworks was not an already challenging task, designing them for legacy and already operational platforms, definitely does not make the process easier. In this scenario, PHM engineers face obstacles related to working with pre-existing systems that were not originally designed for PHM applications (e.g low and/or variable sampling rates, limited built-in sensing/testing capability, no subsystem level sensors, hand written records, siloed databases, etc) as well as a vertical functional organization in the industry (Vogl, Weiss, & Donmez, 2014; Esperon-Miguez, John, & Jennions, 2013).

4. Approach and Work in Progress

This paper presents the initial steps towards implementing a comprehensive CBM framework for a specific aircraft subsystem. Precisely, the horizontal tail (HT) flight control Primary Actuation System (PAS) of an Advanced Jet Trainer (AJT), a twin-engine lead-in fighter training platform equipped with fully digital flight controls and avionics, is considered as a proof of concept (Baldo, De Martin, Sorli, & Terner, 2023). Through an in-depth analysis of design documents and operational procedures, relevant data have been identified and categorized. The AJT HT flight control PAS can be categorized as an EHA controlled by a tandem configuration Direct-Drive-Valve (DDV). The HT assembly is configured as an all-moving tail, a very popular solution when a good trade-off between control effectiveness, aerodynamic efficiency and operational complexity is desired. This solution has been adopted in various high-performance platforms (e.g. F16 Fighting Falcon, F22 Raptor) providing excellent maneuvering and flying qualities. On the other hand, DDVs are established solutions for flight controls and the adopted crank-connecting rod mechanism is widely accepted among mechanical solutions for longitudinal control.

The workflow employed for this research is reported in Figure 1. The most time demanding step so far has been represented by the domain understanding phase where the platform and data knowledge acquisition has been carried out. During this phase, significant effort has been devoted to acquiring comprehensive knowledge about the platform and gathering data. Leveraging the research group experience and expertise, both from the OEM and the University, the author created a data organization overview with the requested data for the first steps along with importance and priority indications. In this way, the author managed to reconstruct the data lineage and the data flow from the operative base to the info logistic systems and to the project data repository (DR). This first phase has been pivotal to plan ahead and understand which possible

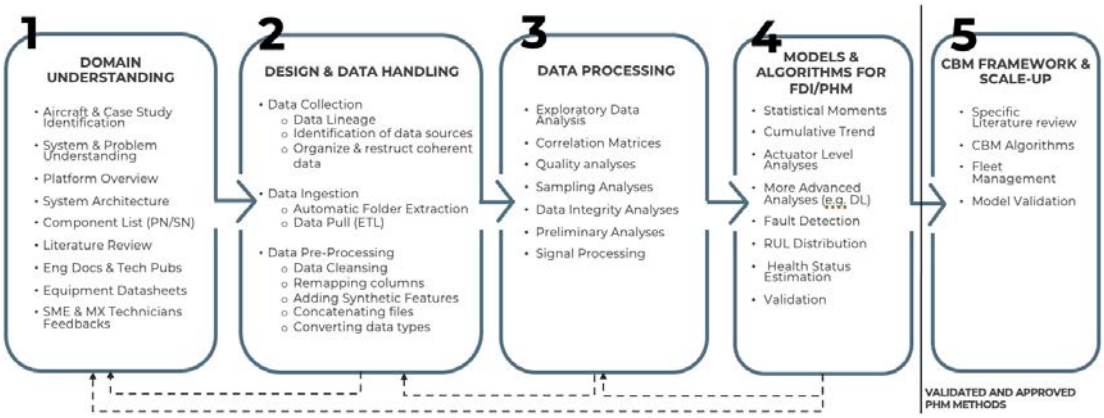

Figure 1. Research project workflow. Note the loopbacks to enhance the data processing with various iterations if necessary.

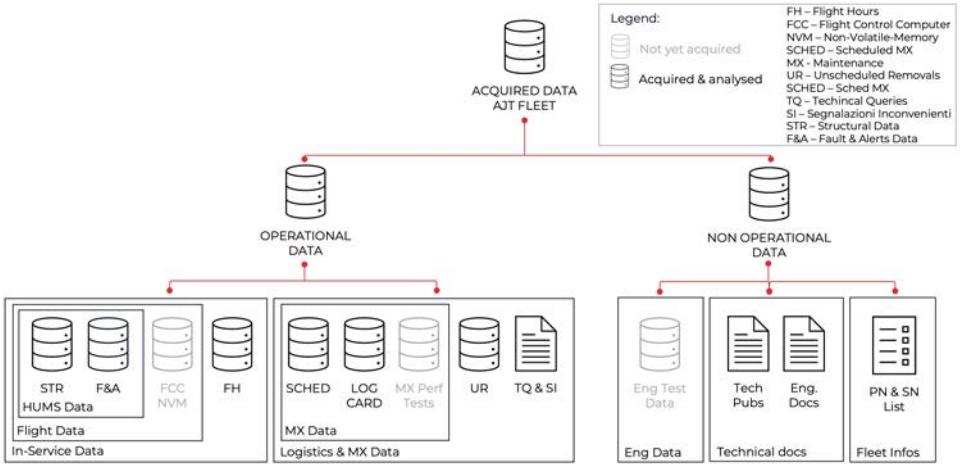

Figure 2. Data repository divided in categories.

strategic and methodological options could be approached, based on the available data. The current DR, encompassing more than 25000 Flight Hours (FH), is illustrated in Figure 2 where a clear distinction between operational (OD) and non-operational data (NOD) has been carried out to streamline the data classification process. LMX include Scheduled MX, unscheduled removals, log cards, technical queries, inconvenience reports and MX performance tests.

OD can be divided into In-Service Data (ISD) and Logistics & Maintenance Data (LMX). ISD includes all the data obtained from the aircraft itself after the sorties (FH register, Health Usage Monitoring System (HUMS) data and the Non-Volatile Memory of the FCC). In particular, HUMS data downloaded from the aircraft (S5000F, 2023) is divided in structural related data (STR) and Faults & Alerts (F&A).

Other potential operational data sources, which are often employed in the development of PHM strategies for legacy equipment, could include the Crash Survival Memory Unit (CSMU) or the Digital Video and Data Recorder. However, these latter sources were excluded from the study due to unreliable data download processes that occur only on an occurrence basis rather than consistently.

On the other hand, NOD encompass all technical information involving design, performance, process and configuration of aircraft components and subsystems (e.g. PAS PN and SN).

Following the domain understanding, the design and data handling and the data processing steps, the research is currently approaching the models and algorithm phase. This first steps focused on data derived from STR HUMS, Log Cards and UR. A total of 54 flight parameters (FP) has been selected through physical reasoning from the STR file. Given the lack of component-level signals that can accurately describe actuator health, relevant indicators were selected based on their potential to represent mechanical wear processes or possible flight anomalies (e.g. mechanical work). The selected FPs include:

- load components (forces and moments) acting on the HT and fuselage
- yaw, pitch and roll rates and accelerations
- body angles

- north, east, up speed components
- mobile surfaces deflections
- stick, pedals and throttle commands
- true air speed, Mach
- timestamps and complementary data
- 4 additional indirect signals (difference between two consecutive HT positions and the mechanical work carried out by the actuator obtained multiplying the position difference with the moment acting on the HT)

It is important to underscore once again that, by design, no actuator level data is recorded, including the actuator command produced by the FCC which would greatly benefit usage monitoring. FPs are saved in the form of time-series data with variable frequency. HUMS was not designed for PHM applications, thereby only a few irregular and sparse batches of high frequency data can be found in data records while most of the samplings are acquired at frequencies below 5 Hz. At the current state, this irregular low frequency sampling does not enable low level dynamic analyses of the actuator (whose dynamics is characterised by much higher frequencies) or the adoption of literature strategies based on high frequency actuator signals.

Following data quality and sampling analyses, the author thus decided to adopt a statistical approach based on cumulative features (CF). This approach has been chosen to determine if the data at hand demonstrates prognostic value in relation to the selected subsystem. CFs are currently being obtained from the merging of operational data sources and are the scope of current activities as reported in Figure 3. The four main statistical moments (SM) are calculated from the time series data of each flight for each FP. Then, CF are created by integrating these SMs in time (multiplying the FP SMs by the flight time) to replicate a time degradation tailored to the effective aircraft usage. Subsequently, the CF variations between two unscheduled removals are calculated and visualized using histograms representations. Histograms are then analysed and a signal-to-noise ratio ranking is performed to discern the most informative CF for further analyses and model development.

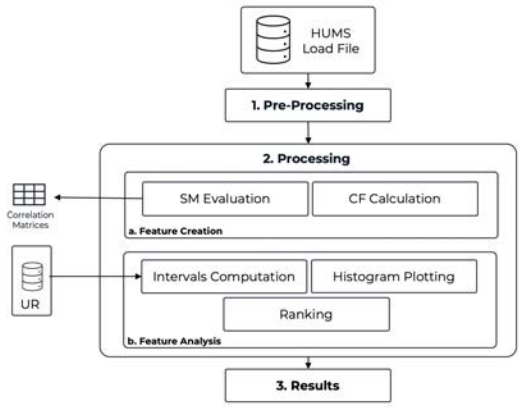

Figure 3. Statistical methodology overview.

The model and algorithm phase for diagnosis and PHM is currently being investigated and the calculations are currently being carried out. These results, if positive, would allow the author to statistically allocate a failure probability distribution in time leading to the next steps of the research project: conceiving a maintenance framework for fleet management leveraging a selected PHM strategy to support CBM. Otherwise, a custom actuator model will be needed to integrate in-service time series signals.

ACKNOWLEDGMENT

This publication is part of the project PNRR-NGEU which has received funding from the MUR – DM 352/2022. This research is cofunded by Leonardo SpA.

himanshu.gupta@kuleuven.be
Pradeep.kundu@kuleuven.be

ABSTRACT

Current Prognosis and health management (PHM) technology suffers from challenges such as data availability, system interoperability, scalability, and transferability. In previous years, the PHM field has advanced a lot, but very few studies have been presented in which these challenges are addressed, and hence, PHM solutions are still confined to the lab environment. Digital Twin technology has the potential to address these challenges altogether and can add significant value to the PHM field. This thesis aims to develop an implementable Digital Twin framework for feed drive systems' condition monitoring and maintenance optimization, targeting these prevalent PHM challenges. The proposed framework will employ multiple physics-based models to generate synthetic data for different system states, configurations, and applications, and utilize this data with the help of machine learning to overcome the PHM challenges. The successful address of these challenges will pave the foundation in the direction of generalization of PHM solutions and also enhance the trustworthiness and reliability of PHM solutions.

Keywords-Digital Twin; Feed drive; Artificial intelligence

1. MOTIVATION

The feed drive systems primarily ball screw systems are used to convert rotary motion to linear motion and are employed in the field of manufacturing, machine tools, and robotics due to its high precision, and are used as electromechanical actuators for the aerospace and aviation components such as landing gear systems, flight control, engine actuation systems, etc.,(Qiao et al. 2018) where seamless and reliable operation is required. These systems have been employed due to high positioning accuracy and rigidity, which has been achieved by introducing preload between the screw and nut. Due to continuous operation, fatigue, and wear, these systems accumulate defects and lose preload over time, which leads to a loss in required precision and creates a backlash. Along with preload loss, the common fault modes for these systems are jam, spall, binding, and shaft bent (Yin et al. 2023). The mechanism failure of the feed drive is responsible for 18.72% of downtime in machine tools (Jia, Rong, and Huang 2019). As per the ASM handbook (Anon 1989) feed drive condition monitoring can decrease the production cost by up to 40% and increase the total productivity by 140% for machine tools.

For PHM of the feed drive, primarily physics-based or data-centric approaches are used (Butler et al. 2022). The physics-based approaches provide enhanced interpretability, but they are very sensitive to system parameters and fail to accommodate the uncertainties involved in the system. Data-centric approaches utilize the potential of machine learning. These approaches tend to be more accurate, but their accuracy depends on the amount of available historical data of the asset, which is not readily available in the field, making these approaches difficult to implement. Additionally, issues such as model interpretability may arise, hindering the understanding of how the model arrives at its conclusions.

Alternatively, digital twin (DT) technology offers a promising solution, which utilizes the concept of both physics-based and data-centric modeling strategies in synchronization and mitigates the shortcomings of both (K. Liu et al. 2022). Advancements in developing Digital Twins for feed drive systems have been relatively limited. W. Zhang et al. (2022) developed a DT framework for identifying rolling joints' dynamic parameters (stiffness and damping) for an FEA model. This involved conducting model tests on hardware and utilizing a DNN model in conjunction with the PSO algorithm to ascertain the parameter value. (D. Liu et al. 2022) developed a Digital Twin lumped mass dynamic model of a feed drive servo actuator system that maps the command and load information of the actuator to identify its vibration mode for the purpose of its health monitoring. (K. Liu et al. 2022) presented a multi-layer DT framework to predict and

compensate for time-varying positioning errors for a CNC machine. These existing DT frameworks focus on only one aspect of DT, i.e., developing virtual models, and fail to provide an implementable DT for a complete PHM solution with the capability of anomaly detection, diagnosis, and prognosis of the asset.

Additionally, existing PHM solutions face challenges like transferability, scalability, interoperability, and historical data availability. Transferability refers to the capability of employing a single PHM solution across various designs, materials, and configurations of the same asset. Scalability involves the adaptability of the PHM solution to the system used in diverse applications. Interoperability denotes the ability to apply the same PHM solution across different operating conditions of the asset. Lastly, historical data availability pertains to the accessibility and adequacy of data related to different fault severities and failures.

There have been progress in DT development for other applications which tries to tackle these challenges, such as (Feng et al. 2023) developed a DT framework for gear surface degradation monitoring. They utilized physics-based models to virtually represent the gear dynamics and employed optimization algorithms to fine-tune their dynamic parameters. These models were used to generate a data library for various degradation states, enabling transfer learning models to provide meaningful predictions by utilizing the vibration signal from the target asset. The framework is capable of adapting to uncertainties and demonstrates interoperability for different operating conditions. However, it focuses solely on monitoring specific defects, lacking a complete comprehensive solution. (Qi et al. 2024) Developed a DT-based monitoring system for the machining process of complex workpieces. The framework contains multiple layers and digital representation includes multiple models such as geometric, physics, behavior, and rule models. Real-time dynamic data is used for interaction mapping between the virtual models and the physical process. These tuned virtual models provide the state of the process. The framework applies to different operating conditions but fails to adapt to different applications and configurations.

This thesis aims to provide an approach for the development and implementation of a DT framework aimed at PHM of a feed drive system. The proposed framework aims to tackle the above defined PHM challenges.

2. PROPOSED METHODOLOGY

Figure 1. shows the proposed conceptual DT framework for condition monitoring and maintenance optimization, which has four distinct layers.

- Physical layer

The physical layer includes the monitored asset, with sensors for acquiring dynamic signals and necessary data acquisition devices. The layer provides the DT framework with the essential data for tuning the virtual model and for continuous monitoring of the asset.

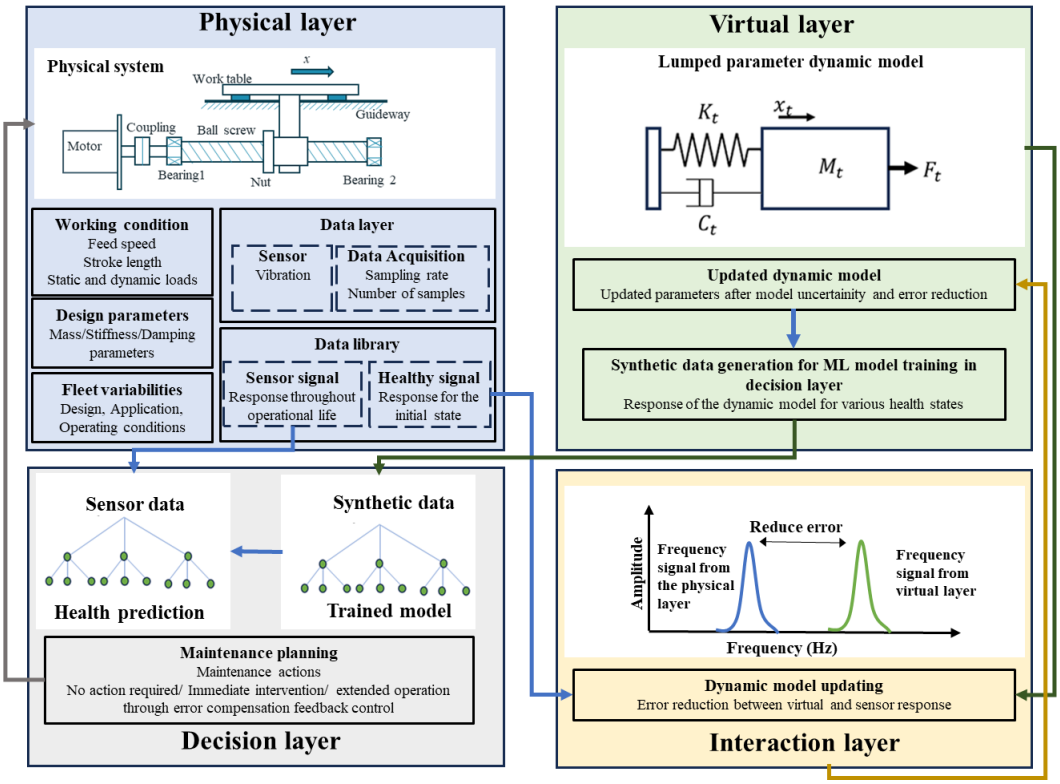

Figure 1. Proposed Digital Twin framework

- Virtual layer

The virtual layer mirrors the physical layer and simulates the dynamic behavior of the asset through either a lumped parameter dynamic model or an FEA model. The model employed is developed with adjustable parameters, which are adjusted as per the design configuration of the asset with the help of the interaction layer. This adaptability ensures that the virtual model correctly represents the physical asset.

- Interaction layer

This layer plays a crucial role in maintaining the virtual model's precise correspondence with the physical system. It accomplishes this by observing and modifying the virtual model's parameters to reduce any differences noted during comparisons of the model's behavior with the real-world responses of the physical system. The parameters will be tuned only once with the help of data for the healthy condition of the asset when the condition of the asset is known with relative certainty. This will help in overcoming the need for historical failure data.

- Decision layer

The tuned virtual model is utilized to create data repositories for various operational scenarios and fault severity stages of the physical asset. The decision layer utilizes this compiled data to train the machine learning (ML) models. After its training phase, the ML models employ the physical asset's responses as inputs to monitor the condition of the asset in real time. Further, the output from this health prediction model will be used for maintenance planning of the feed drive.

3. OBJECTIVES AND RESEARCH PLAN

The DT framework will be developed by focusing on each layer discussed in the previous section as a full objective. The proposed thesis has four objectives:

1. Configure a test rig with sensors and data acquisition hardware to gather data essential for the development and validation of the proposed framework.
2. Develop lumped parameter models for the test rig, enabling simulation of various faults, operating conditions, and applications of the feed drive. Additionally, create parametric and ML models to assess discrepancies between physical and virtual responses, facilitating adjustments to model parameters.
3. Develop ML models with the help of data from models created in objective 2 for health predictions.
4. Based on the output of the models from objective 3, develop maintenance planning strategies for the asset.

These objectives will be achieved by the following plan:

In objective 1, a test rig for the feed drive system will be configured. This rig would be used for multiple experiments related to different operating conditions and faults to closely emulate the environmental and operational variables encountered in an industrial setting. A triaxial accelerometer along with required data acquisition hardware will be used to gather vibration data from the rig. The vibration data will be further processed using advanced signal processing techniques such as wavelet transform and empirical mode decomposition to remove random noise components and extract the signal relevant to feed drive system dynamics only. The rig would be used to gather vibration data for three different nuts with different preloads to understand the effect of preload loss on the system's dynamics. The rig would later be used to collect data for the insinuated faults such as wear, nut and screw spalling, and backlash creating at least three datasets related to each fault. At last two run-to-failure experiments will be performed on the rig to understand the natural degradation of the feed drive. Based on the collected data health indicators will be selected for anomaly detection and diagnosis.

In objective 2, based on the configured test rig a lumped parameter model will be developed for the multiple rotational and translational degrees of freedom (DOF) of the feed drive. The model will incorporate the Hertzian contact theory to simulate the rolling elements and the Archard wear theory to simulate defects like wear. The model will be capable of simulating the experiment conditions planned with the rig. The models representing the interaction layer will be developed by using lumped models related to specific DOF and by using ML models that can provide a nonlinear mapping between the response of the physical asset and virtual model parameters such as stiffness and damping parameters. These parameters will be updated by comparing the difference in various features between the collected signal from the test rig and the synthetic signal generated through the virtual layer.

In objective 3, using the data gathered from objective 2 different explainable regression and classification ML models such as random forest, linear regression and decision tree models (Kundu, Darpe, and Kulkarni 2020) will be used for health assessment and damage quantification of the asset under the natural fault progression. These models will utilize the real-time vibration signal from the physical asset to predict its health state using features like natural frequency and ball pass frequency extracted from the signal. The predicted health state will further be utilized to estimate the stochastic positioning error. The initial concept of the proposed DT framework based on a single DOF model was developed and demonstrated in (Gupta and Kundu 2024).

In objective 4, the results obtained from objective 3 will serve as the basis for devising maintenance planning strategies for the asset based on the life cycle cost analysis. Further, the error compensation feedback control strategy will be formulated by utilizing an ML model to estimate required compensation based on location-specific positioning errors

estimated in objective 3. This is very important to utilize the maximum life of the feed drive.

Once all the objectives are fulfilled the DT framework will be ready to implement on any feed drive system. The framework designed will possess the flexibility to adjust parameters based on the specific asset and application, thus ensuring high transferability and scalability. Also, DT will be trained for different operating conditions and fault severities addressing interoperability and data availability issues. The current objectives of this thesis will focus on detection, diagnosis, and health management aspects.

Future work for this thesis could involve integrating the prognosis module and exploring the implementation of the framework on edge devices. Additionally, investigating order reduction techniques for both machine learning and physics-based models could help alleviate computing load and further improve the implementability of the framework.

4. CONCLUSION

This thesis aims to develop a digital twin framework for PHM applications that can provide better accuracy and versatility than physics-based and data-centric approaches. The proposed framework would be adaptable to different design configurations and also compensate for any system variations such as changes in operating conditions and applications. The research will contribute to tackling key PHM challenges such as transferability, scalability, interoperability, and historical data availability.

ABSTRACT

Absence of failure data is a common challenge for data-driven predictive maintenance, particularly in the context of new or highly reliable systems. This is especially problematic for system level failure prediction of analog electronics since failure characteristics depend on the actual system layout and thus might change with system upgrades. To address this challenge, this work pursues a novel simulation-assisted failure analysis methodology enabling automated and comprehensive evaluation of system level failure effects and failure detectability. While results obtained from simulations are suitable for comparative studies, they are confined to the simulation environment. To overcome this limitation, failure simulations are combined with generative models to generate realistic representations of missing failure data. Preliminary results demonstrate the capability of conditional generative adversarial networks (cGANs) to generate operational data of healthy systems, which accurately reflects correlations present in the source dataset. The proposed approach, using simulations as an additional source for generative models, not only targets the scarcity of failure data for highly reliable electronic systems but also ensures the adaptability of predictive maintenance algorithms to accommodate future system modifications and upgrades.

1. INTRODUCTION

Data-driven predictive maintenance of analog electronics requires algorithm-based detection of failure precursors in operational datasets containing voltage and/or current signals. However, obtaining sufficient historical failure data to train the algorithms, particularly for high-reliability or novel systems like safety instrumentation, is often a challenge. While manual studies of failure trajectories are feasible at the component level - such as examining discharge curves for capacitors - similar analyses at the system level involve studying numerous failure conditions, since failure characteristics not only depend on the components themselves, but also on their configuration in the system's layout. As a result, common failure trajectories may evolve with system upgrades or new generations, which would require validation or repetition of manual analyses. Hence, overcoming missing failure data requires a more automated approach, allowing exhaustive studies of failure characteristics while being adaptable to system upgrades.

The focus of this work is on developing a comprehensive simulation-assisted framework to establish a predictive maintenance algorithm for analog electronic systems in the absence of failure data. To illustrate this framework, a radiation monitoring electronics system, designed primarily for personnel safety, serves as demonstrator. It continuously monitors ambient dose rates and activates machine interlocks if defined radiation thresholds are exceeded. Given the system's critical role in ensuring safety, it is engineered to transition into a fail-safe mode upon detection of internal faults, initiating interlocks to mitigate risks. Thus, unforeseen failures triggering such interlocks can significantly impair the operational availability of downstream equipment. To address this conflict between safety and availability, the implementation of predictive maintenance based on data-driven failure prediction is proposed.

2. LITERATURE REVIEW AND RESEARCH CONTRIBUTIONS

Limited availability of failure data poses a challenge for failure prediction in industrial equipment, especially in systems

with high reliability and preventive maintenance (Rombach, Michau, & Fink, 2023), making failures observed during operation rare. Common approaches to overcome the scarcity of failure data include laboratory experiments to reveal failure modes (Janeliukstis, Ručevskis, & Kaewunruen, 2019), physics-based models incorporating relevant failure processes (Sun, Fan, Qian, & Zhang, 2016), or simulations to evaluate the system's response to failures (Mosleh, Montenegro, Alves Costa, & Calçada, 2021). In contrast, data-driven approaches, typically employing generative methods, eliminate the need for intricate system modeling. (Xiong, Fink, Zhou, & Ma, 2023) use generative adversarial networks (GANs) to extend already available failure data to new, unseen operating conditions based on a physics-informed loss function. While simulations of analog circuits are commonly employed for studies of failure effects (Zhang, Hong, Gao, & Yin, 2021), using simulations as a data source for generative models is currently limited to mechanical systems. (Gao, Liu, & Xiang, 2020) exemplify simulation-assisted data generation in the field of roller bearings, using FEM simulations to generate missing failure data via GANs.

This work explores the potential benefits of incorporating simulation-assisted failure analysis and data generation into predictive maintenance algorithms for analog electronics in the absence of failure data. The key contributions are:

- Utilization of synthetic datasets obtained from simulations to inform decision-making in the development of predictive maintenance algorithms at an early stage
- Generation of missing failure data using simulation-assisted generative methods bridging the gap between the healthy and the faulty domain
- Automated and resource-efficient framework for system level failure prediction in the absence of real failure data

3. Methodology and Preliminary Findings

In the frame of a feasibility study (Waldhauser, Boukabache, Perrin, & Dazer, 2022), unsupervised anomaly detection algorithms were applied to operational datasets of the radiation monitoring electronics system. The study demonstrated the capability of these algorithms to detect unusual data events, such as rare spikes of the dose rate measurement. Although the detected data events are technically anomalies, they are not necessarily related to hardware degradation or faulty behavior. Instead, they may represent atypical yet normal operational behavior. This results in the requirement of introducing knowledge on the system's failure behavior to establish the link between detected anomalies and the system's condition.

Since manual studies of the failure behavior are costly and not adaptable to design changes, alternative, more automated possibilities for acquiring comprehensive failure knowledge need to be explored. Here, simulations of the analog electronics using the SPICE simulation engine can be used to increase the understanding of the failure behavior. Specific failure scenarios are simulated by altering component characteristics, such as gradually reducing the capacitance of electrolytic capacitors. Hence, the impact of these failures on system-level outputs can be observed, facilitating the identification of failure patterns and assessing the detectability of component failures.

Additionally, simulation-derived datasets were used to identify the optimal source of failure knowledge for hybrid anomaly detection algorithms, which incorporate labeled failure data (Waldhauser, Boukabache, Dazer, Perrin, & Roesler, 2023). The results indicated that failure data derived from hardware tests, such as accelerated life tests, proved most beneficial in improving algorithm performance within this synthetic environment. Hence, the findings suggest prioritizing resources towards conducting hardware tests to gather failure data, as opposed to analysis of anomalous data events for failure identification by system experts.

4. Future Work and Research Strategy

The above mentioned studies emphasize the crucial need of understanding the system's failure behavior to refine failure prediction algorithms for identifying patterns indicative of hardware degradation. Failure simulations of analog electronics allowed detailed studies of failure detectability, common failure characteristics, and the generation of synthetic datasets. Although these simulations were suitable for comparative analyses, their utility is inherently limited to the simulation environment. Hence, future research endeavors will focus on bridging this gap between simulated and real datasets to ultimately compensate the missing failure data.

The subsequent phase of research therefore aims at manipulating operational datasets based on simulations to generate synthetic failure data. Here, one possible solution relies on generative artificial intelligence. Initially, a generative model is trained on data representing healthy system states with the objective of reproducing this baseline data. This methodology is then extended to address the generation of realistic failure data by fine-tuning the generative model with simulated failure scenarios without relying on real failure samples.

Preliminary studies with data of healthy states from radiation monitoring electronics containing measurements of internal voltages have demonstrated the capability of Wasserstein conditional generative adversarial networks (WCGANs) to generate synthetic data while preserving the correlations present in the training dataset. For example, WCGANs can accurately capture the relationship between temperature fluctuations and specific voltage signal characteristics. Figure 1 shows the comparison of real and WCGAN generated data for the kurtosis values of the 5 V signal.

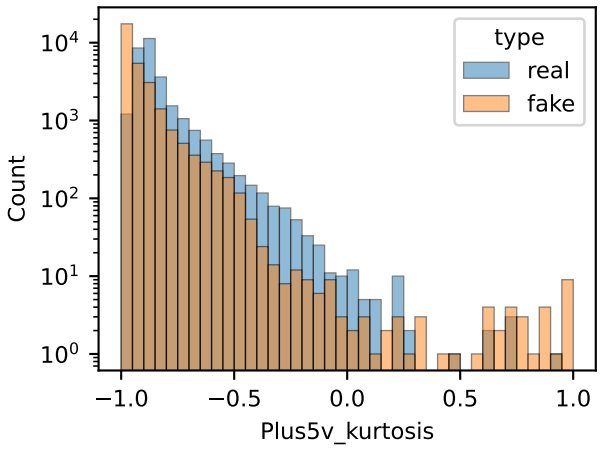

Figure 1. Histogram comparing the distributions of real and WCGAN generated (fake) data for the healthy system state on the basis of 30,000 samples per type. Plus5v_kurtosis is the kurtosis of the 5 V signal, with data normalized.

Ultimately, hardware tests of representative failure states will be required to validate the authenticity of the generated synthetic data. However, this necessitates accurate information regarding the health status of each component. Various options are being considered, including replacing components to replicate changes in their characteristics or inducing localized heat exposure to accelerate aging and confine failures to specific components.

5. Conclusion

The proposed methodology demonstrates a novel approach for developing predictive maintenance algorithms without relying on historical failure data. Simulations serve as additional knowledge source along the development process. This includes identifying detectable failures and generating synthetic failure data that is instrumental for training robust failure prediction algorithms. While hardware-based studies are still relevant, they are complemented by simulation results and limited to representative examples for validation purposes. Besides assisting the generation of missing failure data, comprehensive simulations of failure effects hold significant potential in automating analytical reliability assessments.

Abstract

Manufacturing industries are expanding rapidly, making it essential to detect early signs of machine faults for safety and productivity. With the extension of machines' runtime due to industrial automation, breakdown risks have increased, leading to economic and productivity consequences and sometimes even causalities. The surge in industrial big data from low-cost sensing technologies has enabled the development of intelligent data-driven Machinery Fault Detection (MFD) systems based on machine learning techniques in recent years. However, most existing methods are based on supervised pattern classification techniques to detect previously known fault types, which have limitations such as lack of generalization across different operational settings, focusing only on specific machinery and/or data types, and considering the identical and independent distribution of training and testing data. Therefore, my PhD research aims to develop a robust MFD framework for practical use by addressing these limitations.I will explore the potential of ensemble learning, unsupervised and semi-supervised anomaly detection, reinforcement learning, transfer learning, and cross-domain adaptation approaches in MFD. My PhD research will contribute to the field of data-driven MFD by proposing novel, effective solutions that can be applied across various manufacturing applications.

1. Background

Rotating machinery holds significant importance in modern industries. These machines often operate longer and under adverse conditions, making them prone to failure. Machine failures result in substantial maintenance costs, production inefficiencies, financial losses, and even risks to human life. Common electric motor failures involve bearings, stators, rotors, and gearboxes. The continuous operation of these machines can lead to wear, cracks, and other defects, emphasizing the need for accurate and timely fault detection and diagnosis to mitigate financial and safety risks (Neupane & Seok, 2020).

2. A Brief Discussion on the State-Of-The-Art

Recent developments (Neupane, Kim, & Seok, 2021; Zhong, Zhang, & Ban, 2023) in MFD have mainly focused on classifying the health states of machinery through extensive analysis of samples under normal and faulty conditions. While these studies have contributed to the creation of robust fault diagnosis systems, there is a limited exploration in examining semi-supervised learning (SSL) methods (see Figure 1). Moreover, the prior SSL applications primarily focus on fault classification (Zong et al., 2022; Zhang, Ye, Wang, & Habetler, 2020). Reinforcement Learning (RL) is increasingly being employed in various domains of MFD, such as transmission lines, hydraulic presses, and industrial process controls (Teimourzadeh, Moradzadeh, Shoaran, Mohammadi-Ivatloo, & Razzaghi, 2021; Junhuai, Yunwen, Huaijun, & Jiang, 2023). Although most RL applications treat fault diagnosis as a simple classification task, there are also some innovative approaches that extend its use to complex system management. For instance, (Vos, Peng, & Wang, 2023) employ an RL framework to optimize fleet management in the aviation sector, demonstrating how RL can effectively handle the dynamic decision-making required to maintain high fleet availability and minimize maintenance costs across aircraft with varying ages and degradation paths. Furthermore, data fusion methods play a critical role in enhancing the accuracy of fault detection systems. Techniques range from data-level fusion, such as weighted averaging and Kalman filters, to more complex feature and decision-level fusions that utilize statistical and machine learning methods, such as principal component analysis and Bayesian decision theory (Kibrete, Woldemichael, & Gebremedhen, 2024). Despite these advancements, the integration of multi-level fusion and cross-domain adaptation remains limited, highlighting a significant area for future research.

3. Motivations

First, the existing studies on MFD primarily employ supervised learning approaches (over 80%, see Figure 1), which can accurately identify known faults but struggle to detect

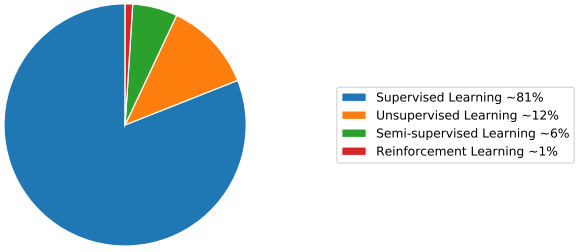

Figure 1. Machine learning techniques used for MFD

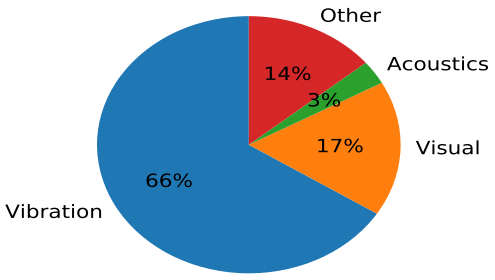

Figure 2. Data types used for MFD

novel or unseen ones (Das, Das, & Birant, 2023). This limitation is problematic in complex industrial settings where modern machines operate, as new fault types can emerge over time. Also, accurately identifying various fault types necessitates a substantial quantity of labelled data, which is a difficult challenge in real-world industrial settings because annotating takes time, expertise, and resources. Moreover, the labelled data may not cover all possible faults, restricting the diversity of the training dataset and hindering the model's ability to generalize to unseen faults.

In supervised learning, the effectiveness of the algorithms heavily relies on the accuracy of the data labels, which are typically derived from expert interpretations of sensor readings or from known operating conditions. This dependency on labeled data also extends to SSL, where limited labeled data can constrain the learning process to the inherent accuracy of these labels, a limitation referred to as the Bayes rate (Nian, Liu, & Huang, 2020). To address this challenge, RL can be used, which is a promising ML framework that learns from trial-and-error interactions using rewards rather than explicit instructions (Wang, Jiang, Li, & Liu, 2020). RL has demonstrated success in various fields, including manufacturing, but its application in MFD is limited. Existing fault detection systems have not thoroughly exploited the potential of RL in optimizing maintenance decisions and fault detection strategies. Current RL algorithms for MFD often treat fault diagnosis as a simple classification task, which may not fully utilize the capabilities of the RL framework. RL can learn the sequence of events leading up to a fault, which can be used to predict when a fault is likely to occur. Moreover, the use of RL algorithms is currently limited to a single machinery or environmental setting. This research aims to explore the application of RL algorithms in MFD and develop specialized RL algorithms that can effectively handle the dynamic nature of fault patterns and machine operational conditions.

Additionally, most existing (about two-thirds, see Figure 2) ML-based MFD techniques use vibration data to predict faults (Das et al., 2023). Vibration signals, however, can be problematic in harsh environments or areas with high background noise, which can decrease the accuracy of collected data. Moreover, traditional vibration sensors may not always be practical for installation in locations that are difficult to access or on specific types of equipment. For example, placing these sensors on ball bearings within centrifugal pumps or on equipment operating under extreme conditions such as low-temperature vacuum pumps can pose significant challenges (Hoang & Kang, 2019). Furthermore, an exclusive reliance on vibration data could potentially limit the performance of ML models. Thus, the incorporation of other data types could offer a richer understanding of the problem and yield improved results. Utilizing diverse data types, such as temperature, current, acoustic, and visual information, into fault diagnosis algorithms can offer a more comprehensive and accurate understanding of machinery health. Combining data from multiple sources not only improves the detection of subtle faults, reducing diagnostic errors but also compensates for potential sensor failures or data inaccuracies due to environmental interference.

Moreover, most existing work on MFD focused on specific machine types and operational environments. Usually, models are trained on data from one type of machine in a particular environment and are expected to perform effectively on similar machines or the same machine under different conditions. This expectation is based on the assumption that the source (training) and target (test) data are independent and identically distributed (*iid*) (Li et al., 2022). However, achieving this *iid* condition in industrial applications is challenging due to several factors: (a) machines can exhibit different behaviors and degradation patterns over time or when operated in varying conditions; (b) differences in machine manufacturing, wear-and-tear, and operational settings can introduce significant variability in the data. These factors contribute to the 'domain-shift' problem, where the training data no longer represents the new conditions under which the model is tested. This domain shift can significantly reduce the effectiveness of fault detection models, as they fail to generalize across different operational scenarios. Thus, addressing this issue is crucial for affecting machine health monitoring and fault diagnosis in diverse environments.

4. Research Aim and Objectives

This PhD project aims to develop a robust framework for MFD by addressing identified limitations and research gaps. Defined as 'robust', our framework ensures that various algorithms—including unsupervised, semi-supervised, and reinforcement learning techniques—-perform effectively in real-world industrial settings. These environments are often complex and noisy, with heterogeneous data. By utilizing diverse data types, our framework anticipates supporting effective applications across different domains. This aim will be achieved through the following objectives:

1. To investigate the potential of unsupervised and semi-supervised anomaly detection (AD) methods for identifying anomalous patterns in MFD. This approach eliminates the need for labeled data and addresses the challenges of class imbalance.
2. Additionally, there is a goal to fully utilize the capabilities of RL for MFD by creating specialized algorithms that can optimize maintenance and fault detection strategies. Apart from fault classification, RL has potential in AD (Arshad et al., 2022), optimizing maintenance strategies (Marugán, 2023) or prediction (Siraskar, Kumar, Patil, Bongale, & Kotecha, 2023). This will help overcome the limitations of treating fault diagnosis as a guessing game and improve performance in diverse operating conditions.
3. Another objective is to explore the potential of using diverse data types for developing MFD algorithms, which can enhance diagnostic efficiency and provide a comprehensive understanding of machinery health status. The study will also investigate the use of ensemble models to improve accuracy and efficiency.
4. Lastly, the aspiration is to bridge the gap between different data types and operational settings using domain adaptation and transfer learning techniques, which can enhance the model's ability to generalize across diverse settings.

5. Research Methodology and Timeline

To create an integrated framework for MFD that makes use of robust semi and unsupervised learning-based AD algorithms, our approach encompasses data preprocessing, algorithm selection, and model training, with the aim of generating anomaly scores for predicting faults. We will evaluate the performance of our models using metrics such as precision, recall, F1 score, etc., and compare them with supervised methods. Our work on this project is ongoing, and we submitted an article to "the 8th European Conference of the PHM Society (PHMe2024), presenting the results of our experiments with various AD algorithms on the Case Western Reserve University (CWRU) bearing dataset, Paderborn University (PU) bearing dataset, and Health and Usage Monitoring System (HUMS) datasets. The outcomes of our study so far have been encouraging, demonstrating the efficacy of AD methods.

To achieve our second objective in employing RL in MFD, the formulation of problems, the development of algorithms (including state representation, action space definition, reward function design, and RL algorithm selection), data collection and preprocessing, training and testing, and continuous refinement of the RL algorithm based on evaluation metrics such as performance against baseline models, rewards evaluation, fault detection accuracy, and training convergence progress will be done. Since real-time data collection is limited in our setup, we will focus on employing offline RL techniques (Deng, Sierla, Sun, & Vyatkin, 2023). Offline RL is ideal for situations where learning must be derived from pre-existing datasets rather than from interactions with the environment in real-time. For implementing these techniques, we can utilize well-established libraries, which provide the necessary tools to effectively apply offline RL algorithms to our data.

To accomplish our third objective, we aim to develop a comprehensive MFD algorithm by integrating various data types. Our aim is to improve adaptability, generalization, accuracy, and fault detection capabilities under different machinery conditions. We employ flexible models that can handle heterogeneous data, which are preprocessed for noise and normalization, and utilize ensemble techniques like data, feature, or decision fusion. Evaluation will be based on accuracy, precision, recall, and F1 score metrics. We have made progress by using the PU dataset to fuse vibration and current data, which will gradually advance to the integration of X and Y-axis vibration data, two phases current data, and torque data, ensuring comprehensive feature integration and decision-making.

To effectively enhance MFD in diverse operating conditions and overcome the challenges of limited data by employing domain adaptation and transfer learning techniques, we will apply domain adaptation methods like discrepancy, adversarial, or reconstruction-based approaches (Zhang et al., 2023). Moreover, multi-source domain adaptation is also being explored. The effectiveness of the approach is evaluated using classification and domain discrepancy metrics.

5.1. Expected Outcomes and Publications

This project aims to develop a novel, robust, and flexible MFD system for real-world applications. The framework will implement an unsupervised or semi-supervised learning-based fault detection framework, utilizing diverse data types and incorporating RL for fault prediction and cross-domain platforms as well. Apart from these, we have expected to publish a review paper, which is almost ready to submit. Also, a few conference articles and collaboratory publications are also expected.

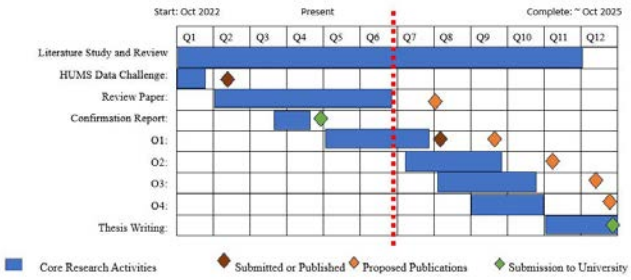

Figure 3. Proposed Timeline for this PhD

5.2. Works Done So Far and Timeline

During the course of this research project, significant progress has been made across various aspects of the study.

Literature Review and Draft Article: Our initial phase included a comprehensive literature review and a draft of a detailed review paper on significant MFD developments. The paper covers multiple topics and is almost ready for submission.

Participation in HUMS Data Challenge and Conference Presentation: We participated in the HUMS Data Challenge and presented our research at the HUMS conference, where our findings were published. Our work involved using signal processing and statistical-based approaches to detect cracks in the provided dataset and the auto-regressive integrated moving average method for predicting fault progression.

Manuscript Submission in PHMe2024: We also submitted an abstract and full manuscript for the upcoming conference PHMe2024, going to be held on July 3- 5, in Prague, CZ. The article is related to the use of semi-supervised-based techniques for machinery fault detection, which is objective 1 of this project.

Objective 1 continued: The work being carried out for objective 1 is being extended. We are actively engaged in the incorporation of a new dataset and in the application of semi-supervised techniques for anomaly detection. Furthermore, we are exploring various data transformation methods and combinations of features to enhance our results.

This PhD program commenced in October 2022 and is expected to be completed by 2025, within a three-year timeframe. In addition to core research and publication activities, administrative tasks must be carried out throughout the program, as per university and faculty regulations. To facilitate effective planning, the entire three-year period has been divided into twelve three-month periods and is shown in figure 3.

6. Conclusion

Implementing a robust machinery fault detection system in real-world settings presents several challenges, such as adaptability to a variety of machines, compatibility with existing infrastructure, and scalability across diverse industrial environments. To tackle these challenges, we aim to develop adaptive algorithms, enhancing system compatibility with current technologies, and ensuring scalability for broad industrial applications. Moving forward, our vision for MFD research encompasses the integration with predictive analytics, aiming to transform MFD systems into comprehensive diagnostic tools that not only detect but also predict faults, significantly reducing downtime and maintenance costs. This future-oriented approach aims to solidify the role of MFD in advancing predictive maintenance strategies and thereby contribute a sustained impact to the field.

jean.meunier-pion@centralesupelec.fr

ABSTRACT

Natural Language Processing (NLP) has seen a surge in recent years, especially with the introduction of transformer architectures, relying on the now famous self-attention mechanism. Especially, with the rise of Large Language Models (LLM), propelled by the appearance of ChatGPT in 2022, a new hope of extracting relevant information from text has emerged. In the meantime, natural language data have not often been used in risk, resilience, and reliability tasks. However, text data containing reliability-related information, that can be used to monitor health information regarding complex systems, are available in several and diverse shapes. Indeed, text data can either contain theoretical expert knowledge (technical reports, documentation, Failure Modes and Effects Analysis (FMEA)), or in-practice expert knowledge (incident reports, maintenance work orders), or in-practice non-expert knowledge (customer feedback, news articles). Critical infrastructures, such as nuclear powerplants, railway networks, or electrical power grids, are complex systems for which any failure would induce severe consequences affecting many people. Such systems have the advantage of serving many users, thus having many possible text sources from which technical information and past incident data can be mined for anticipating future failures and generating responses to catastrophic scenarios. The goal of this work is to develop methods and apply state-of-the-art NLP techniques to text data relating to critical infrastructures and failures, to (1) mine information from unstructured language data, and (2) structure the extracted information. Preliminary experiments were conducted on customer review data and incident reports, and show promising performance for failure detection from text data with transformers, as well as incident-related information extraction using LLMs.

1. STATEMENT OF THE PROBLEM ADDRESSED

Risk, resilience, and reliability have seen some attempts to use Natural Language Processing (NLP) to make use of text data in systems health monitoring. NLP was applied to maintenance records data so as to filter maintenance records by types (Stenström et al., 2015). Sharp et al. (2017) also developed a framework on maintenance records, to classify such data based on expert tags and by supervised learning. Considering the specificity of technical terms used in maintenance work orders, Brundage et al. (2021) introduced the notion of Technical Language Processing (TLP) and discussed the need for models designed and trained specifically on technical language data. Other works (Li & Wu, 2018; Huang et al., 2021) have proposed a statistical approach to look at co-occurrences of terms and a graph visualization to quickly perceive how failures are characterized in diesel engines, based on Failure Modes and Analysis Effects (FMEA) data. Research in NLP for risk, resilience, and reliability covers multiple applications, with different datasets and tasks. However, it suffers from a lack of common shared open-source datasets and benchmarks, and with the rise of generative artificial intelligence, there is currently room for improving existing frameworks and developing new ones.

The research question addressed in this thesis is the following: how can one extract information from unstructured text data, and then structure the extracted information, to learn failure knowledge from text data?

The initial approach should involve using state-of-the-art NLP techniques, especially Large Language Models (LLMs) and transformers (Vaswani et al., 2017) in general, to extract information from text. The extracted information will then be organized in knowledge databases, according to ontologies, in order to structure the information relating to risk, resilience, and reliability. The goal is to use the large amount of available text data containing health information of complex systems so as to learn and structure knowledge on failures of critical infrastructures.

To that end, various forms of text can be used. Either documents containing theoretical expert knowledge, such as technical reports, technical documentation, or FMEA; or documents with in-practice expert knowledge, such as incident reports, or maintenance work orders; or documents with in-practice non-expert knowledge, such as customer feedback, or news articles. Such data can then be used in two complementary ways: either to directly mine information

from them, or to give context and knowledge while extracting information from other documents.

The expected benefits are the creation of tools in the form of specialized technical search engines and automated text assistants to support informed decision-making for the anticipation of incidents and the generation of response scenarios when encountering failures in critical infrastructures.

2. Expected Contributions to the Field

The main expected contributions to the field include (1) the development of open-source datasets to support NLP tasks applied to risk, resilience, and reliability, (2) the application of state-of-the-art NLP techniques, including LLMs to reliability data and the creation of associated benchmarks, (3) the design of an ontology for reliability engineering and the development of a method to automatically populate knowledge databases whose architecture would rely on this ontology.

3. Research Plan

The research plan currently includes the following parts: (1) detecting failures and assessing reliability from text data, (2) applying LLMs for information extraction, (3) focusing on failure mode extraction with the proposed framework for information extraction assisted by LLMs, (4) designing an ontology for reliability engineering, and (5) automatically populating knowledge databases for system reliability.

As a transversal task, the development of fine-tuned LLMs for risk, resilience, and reliability tasks, e.g., including code generation for reliability engineering, is a common thread.

3.1. Failure Detection and Reliability Assessment from Text Data

The simplest unit of information that can be extracted from text data regarding reliability is whether or not the document at hand states that a failure occurred.

Following previous research (Meunier-Pion et al., 2021), a set of customer review data for failure detection was developed for the task of detecting if customers report a failure in their review of a product. It is composed of 2,415 customer reviews labeled for binary classification. Additionally, labels include a level of granularity that enables the subtask of classifying failures severity as tolerable or intolerable.

Due to the ambiguity of customer reviews, several annotators were required to label the dataset and a human benchmark score was derived from the annotations to know what the best performance of a machine model could be. The human performance was estimated to 91.24% of balanced accuracy, while the best model involving a fine-tuned DeBERTa-v3 transformer (He et al., 2023) reached 88.50% balanced accuracy. This constitutes promising results for detecting failures in customer review data, and in natural language in general, in order to generate lifetime data from text corpora and assess reliability directly from natural language data.

The results from this research part suggest that reliability-related information can be extracted from text data. Building upon this preliminary work, the aim of this thesis is to gather more fine-grained information regarding systems health, such as failure causes, failure modes, degradation, maintenance actions, interdependencies between system components, and so on.

3.2. Application of LLMs to Information Extraction

With the rise of LLMs and their incredible capabilities for understanding natural language, it seems that NLP information extraction tasks can be addressed more effectively. However, one limitation of LLMs is that they are designed for generating text, in the form of long consecutive sentences, instead of returning only a specific word or set of words answering a short query.

In this research, LLMs were applied on nuclear powerplants incident reports data for extracting basic information such as the date of an incident and the place of an incident. Using a small LLM stored on less than 3 GB, an average accuracy of 94.5% could be reached for the extraction of date and place of incidents, over an initial dataset of 50 incident reports. Besides, one should note that if a LLM outputs “The date of the incident was 2023.”, then the output is considered invalid, as the expected queried information is only “2023”, making the task more challenging as conciseness matters.

The goal is to provide a framework for extracting information thanks to LLMs, that combines the ability of LLMs to understand text and generate high quality answers, with a methodology for extracting specific queried information. Here, in this part of the research, the goal is not necessarily to extract technical information, but rather to come up with an effective and performant framework for extracting pre-defined attributes when queried, as illustrated in Figure 1.

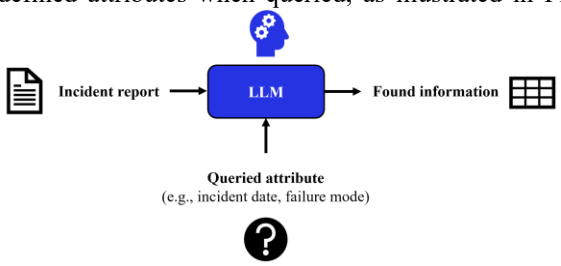

Figure 1. Information extraction using an LLM.

3.3. Failure Mode Extraction

By leveraging the framework developed for Section 3.2., one type of reliability-related information that can be queried

from text is the failure mode of a given system, i.e., how the system failed. As part of this research, methods are developed to extract failure mode information from text.

There are mainly two ways of extracting failure mode information from text: (1) classifying failure mode based on pre-defined failure mode labels, or (2) generating a failure mode label that fits the given description of an incident.

While the first way, involving multi-class classification may be convenient to assess performance and compare models, it requires the definition of class labels, which are not always available, especially when working with new unseen data. On the other hand, the second envisioned approach to extracting failure mode from text involves generating labels, which requires a more sophisticated evaluation framework. This approach is intended in this research, in order to leverage LLMs for information extraction. Additionally, one modern technique that will be investigated in this research is Retrieval-Augmented Generation (RAG), which consists of generating an answer to a query, with the addition of a context from a vector database and similar to the input query.

In the meantime, the first way of extracting failure mode information is currently under study and preliminary results on the National Highway Traffic Safety Administration (NHTSA) complaints dataset show that it is possible to reach 86% balanced accuracy on multi-class classification of failure modes on text data, using only standard NLP techniques, without even the use of transformers.

3.4. Definition of an Ontology for Reliability

The objective of this research being to learn failure knowledge from text data, one important part of this work is to define an ontology for reliability. Previous works in maintenance have already applied ontology frameworks to define ontologies like an Ontology model for Maintenance Strategy Selection and Assessment (OMSSA) (Montero Jiménez et al., 2023).

The purpose of defining an ontology for reliability is to organize concepts relating to failures in order to structure failure knowledge. This should enable and facilitate the automatic instantiation of knowledge databases containing failure information extracted from text data.

3.5. Automatic Population of Knowledge Databases

Ultimately, the purpose of this research is to enable the automatic population of knowledge databases containing failure-related information extracted from text data.

In that respect, a challenge that will be addressed in this research is grouping fields of the same data record. Indeed, multiple data records can have their information in the same document and an additional challenge thus is: how to distinguish between different data records? How can one group fields together to create the correct instance, and not mix fields from different records together?

More specifically, fields that can be extracted from text data include, for example, the date of an incident, the failure mode, and the root cause of the failure. The challenge is to correctly map the date of incident A with the failure mode and root cause of A, and not map it with the failure mode and root cause of B, whenever A and B co-occur in a document.

3.6. Fine-Tuning LLMs for Reliability Engineering

As part of this research, a transversal component will be the development of fine-tuned LLMs specialized on technical data in order to efficiently use technical engineering data and to address tasks relating to system health monitoring.

In that respect, a first attempt of benchmarking LLMs on the fields of risk, resilience, and reliability, is under study and involves the creation of a dataset for code generation containing more than 50 code generation questions. This dataset is inspired by the HumanEval dataset (Chen et al., 2021) and involves the usage of unit tests to guarantee the capability of the model to generate effective code. The goal is to evaluate current state-of-the-art LLMs, such as variations of Mistral or Llama models, on the vertical application of risk, resilience, and reliability, whereas traditional code generation benchmarks (Austin et al., 2021; Du et al., 2023) consist of general programming tasks.

Then, an LLM will be fine-tuned on specific data to compensate for the lack of expert knowledge from general LLMs, and enable the generation of more accurate technical scripts from an artificial intelligence code assistant. This approach will be generalized to fine-tune LLMs not only for code generation, but also for natural language in general, in order to acquire expert knowledge on complex systems.

4. CONCLUSION

The current research aims at developing open-source datasets and benchmarks for NLP for risk, resilience, and reliability, while leveraging state-of-the-art techniques like LLMs. The main focus here is the development of methods for information extraction and structuring knowledge.

Preliminary results show encouraging evidence that state-of-the-art NLP techniques are able to mine failure-related information from text data. Nonetheless, the methods developed in this thesis are intended to be applied to critical infrastructures, thus confidence indicators are necessary to measure the trustworthiness of the developed models.

As a common thread, an objective throughout this research is to create NLP-related materials, including datasets and code, that will be shared to encourage research in this field and ensure access to trustful and reproducible results.

ABSTRACT

Maintenance plays an important role in fulfilling the goals of the Prognostics and Health Management (PHM) field. As of now, no publication has addressed the impact of imperfect repair actions from the prognostics perspective. Imperfect repairs introduce complexities, altering system degradation processes and increasing prediction uncertainties, thereby impacting the accuracy of Remaining Useful Life (RUL) predictions. To fill this gap in the literature, the study proposes developing a robust prognostic model adaptable to post-repair operations. The prognostic model that will be developed is stochastic since stochastic models have already proven their adaptability to unseen test data. However, further development of such models is needed to deal with data on repaired systems. In addition to that, the implementation of a Bayesian Extension allows uncertainty interpretability to be considered to account for the uncertainty coming from the repair action itself but also from the different sources of uncertainties that have not been studied in the field of prognostics.

1. PROBLEM STATEMENT AND STATE-OF-THE-ART

Prognostics and Health Management (PHM) is a field that provides users with a thorough analysis of the health condition of a system which allows users to maximize the operational availability, reduce maintenance costs, and improve the system's reliability and safety (Tsui et al., 2015). PHM includes the following modules: data acquisition, diagnosis, prognosis, and decision-making (Moradi & Groth, 2020). Prognosis takes the information of the data coming from data acquisition alone or both the information of diagnosis and data acquisition. The output of prognosis is then the prediction of the Remaining Useful Life (RUL) of the system, which is the time left before the system reaches failure.

Prognostics plays a vital role in decision-making processes, guiding actions like system retirement or maintenance scheduling. Maintenance strategies vary from perfect maintenance (replacement) to imperfect maintenance (repair), with the latter being favored for its cost-effectiveness (Do Van et al., 2013). (Bougacha et al., 2020) conducted a review on post-prognostic decision-making, particularly focusing on aerospace applications. Existing approaches in this review typically consider current degradation levels or use prognostics assuming the system is as good as new to inform maintenance decisions. (Nguyen & Medjaher, 2019) developed a Deep Learning-based framework that covers the entire process from data-driven prognostics to maintenance decisions. However, the framework's limitation lies in its consideration of only perfect maintenance. To the best of the author's knowledge, (Welz et al., 2017) is the only work that has addressed repair actions in prognostics, emphasizing the importance of including data from repaired systems to enhance prediction accuracy. Yet, this study lacks reporting on RUL prediction and corresponding confidence intervals, providing only an average error of failure time.

Therefore, a significant research gap exists in the current literature regarding how to perform prognostic when the engineering system has been subjected to imperfect maintenance. In other words, there is a need to develop prognostic models that perform accurately when trained on data from systems with no repair but tested on systems repaired one or more times. This gap is notable given PHM's predictive maintenance and cost reduction goal.

Understanding the effects of repair actions on prognostic

models is crucial, as repairs can alter the degradation process of a system. As a consequence, it will negatively affect the performance of the prognostic model by the decrease in the accuracy of RUL predictions, and an increase in the uncertainty of the predictions. Thus, it will reduce the reliability and robustness of prognostics, which will raise concerns about the eligibility of prognostics for decision-making. Therefore, many questions arise to deal with such a scenario. Should prognostic models consider dependencies between pre and post-repair operations? How can the prognostic model acknowledge the health recovery of the system? And how can uncertainty arising from repair actions be managed effectively?

To address the consideration of imperfect repairs in prognostics, it is necessary to develop a robust prognostic model that allows for interpretable uncertainty given the increased uncertainty expected from the repair actions. Understanding the concepts of robustness and uncertainty management, along with the challenges they present, is essential.

Robustness, defined as a system's ability to perform acceptably across various conditions, poses a challenge in prognostics due to the lack of adaptation mechanisms in existing models. Attempts have been made to improve robustness, such as using adaptive batch normalization or domain adversarial neural networks. Still, challenges persist, with high errors in terms of accuracy, along with instability and noise in the predictions

Exceptionally, the Adaptive Non-Homogeneous Hidden Semi-Markov Model (ANHHSMM) demonstrated adaptable capabilities (Eleftheroglou et al., 2020). This stochastic model was trained with 8 composite specimens under fatigue loading, and later on, tested with 3 specimens, also under fatigue loading, and suddenly experienced an unexpected phenomenon. The model provided good results, however, it has not been validated for a case study involving repairs.

Uncertainty management is the second challenge when performing prognostics with data from repaired specimens in the test set. Uncertainty management is defined as the identification of sources of uncertainty and the reduction of uncertainty by leveraging data to better characterize the inherent prognostic uncertainties, thereby reducing their impact on RUL predictions (Sankararaman, 2015).

However, to identify uncertainty it is first necessary to quantify it. Uncertainty quantification (UQ) is already a challenge in data-driven prognostics when using ML models that are deterministic by nature. Such models usually do not report UQ in their RUL predictions, as seen in (Zhu et al., 2020; Ma & Mao, 2020; Ren et al., 2020; Zhang et al., 2023; Cheng et al., 2022). In contrast, some publications address uncertainty quantification when using stochastic models or particle filters, but they provide broad confidence intervals, which results in a lack of valuable information for decision-making (Huang et al., 2017; Cadini, Sbarufatti, Cancelliere, & Giglio, 2019; Cadini, Sbarufatti, Corbetta, et al., 2019; Moghaddass & Zuo, 2014; Liu et al., 2018).

To handle broad ranges of confidence intervals is then necessary to perform uncertainty management. But even though some data-driven prognostic models allow UQ, then it is necessary to identify the sources of uncertainty. The classical categorization divides uncertainty into aleatory and epistemic (Der Kiureghian & Ditlevsen, 2009). However, as the authors themselves have mentioned, such categorization is artificial and it depends mostly on the modeler's choice and the application, which is why it is common to see disagreement on how to disentangle uncertainty by using this categorization.

In (Eleftheroglou et al., 2020), a more relevant categorization for prognostics is proposed, identifying five sources of uncertainty: past uncertainties from manufacturing processes, present uncertainty about the system's health, future uncertainty, model uncertainty, and prediction method uncertainty. This new framework has not been applied to real-life scenarios yet, with existing literature still relying on the classical categorization.

2. Expected Contributions

There is no relevant literature addressing imperfect repair actions from the perspective of prognostics. Therefore, this research will serve as a first attempt to address this issue by developing a robust prognostic model that can be trained with degradation histories of systems that have not been repaired and then tested on degradation histories of repaired systems. Thus, the contribution to the field is a prognostic model that has an adaptation mechanism and can take into account the dependencies between pre and post-repair operation, as well as include the recovery of the system after repair.

Additionally, a Bayesian extension is considered because it allows the estimation of a subjective probability. Unlike the frequentist approach, where the statistics are calculated based on the entire population. This is undesirable since calculating the uncertainty based on the statistics of the entire population when they have been subjected to different conditions has no purpose. Instead, the Bayesian approach works under prior knowledge and available data (Bayarri & Berger, 2004). Even more, the model should include the uncertainty coming from the repair. Identifying this and calculating this source of uncertainty allows for more interpretability in UQ that allows future uncertainty management to have more valuable information for the decision-making process. As mentioned earlier, the classical categorization of uncertainty is not suitable for prognostics. Thus, this research attempts to tackle uncertainty quantification from another perspective that has not been implemented in the literature to date.

3. RESEARCH PLAN

The research plan is divided into three main parts:

- **Experimental Campaign**: since there is no available dataset for prognostics that includes maintenance actions, the first step is to perform an experimental campaign. The experiments consider materials mostly used in aviation structures, such as metals and composites. This phase of the research also involves the analysis of the experimental data, in terms of the effects on the degradation process and a comparison study on how the performance of different prognostic models that are commonly used are affected when dealing with this data.
- **Development of the prognostic model**: As mentioned in Section 1, it is necessary to develop a prognostic model that has an adaptive mechanism. After a literature review, the most suitable model for this application is the ANHHSMM, however, the model needs the addition of variables to take into account the repair of the system as well as the relaxation of some assumptions. Therefore, in this part of the research, the work would consist of developing the mathematical model, including the programming implementation.
- **Bayesian Extension**: Finally, the last part of the research involves the Bayesian extension that allows more interpretable uncertainty in the prognostic model by identifying sources of uncertainty.

As of now, the work that has already been done corresponds to the experimental campaign. The research group performed experiments with open-hole aluminum specimens of material 7075-T6. Each specimen had dimensions $300x45x2$ [mm] and a central hole of 6 [mm] diameter. The aluminum specimens were subjected to constant amplitude fatigue, with a maximum stress of 100 [MPa], frequency of 5 [Hz], and ratio of 0.1. The training data consists of 5 degradation histories of specimens from run to failure. The testing data consists of 5 specimens, also from run to failure. However, the testing specimens were repaired at cycle 14000 with a composite patch to cover the fatigue crack.

Figure 1 shows health indicators derived from experimental data using a neural network developed by the research team. Training trajectories are depicted in blue shades while testing trajectories are in red shades. For visualization, only two trajectories per training and testing set are shown. Notably, a distinct shift in cluster values occurs around cycle 14000 in the testing trajectories, indicating specimen health recovery post-repair. From the plot, it is evident that testing specimens had a longer lifetime, in comparison with the training specimens, due to the repair.

By using this data, a preliminary comparison between prognostic models has been done by the use of SVR and MLP. The results show the poor performance of both of these models

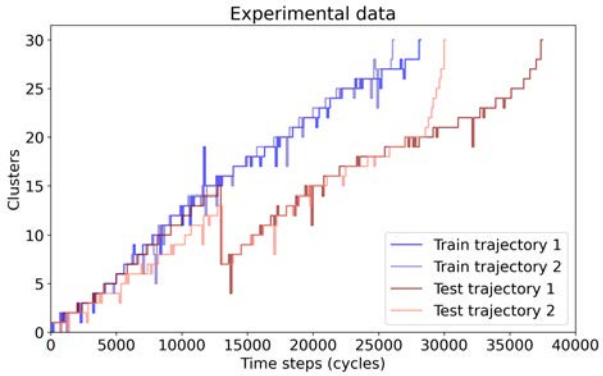

Figure 1. Experimental data of metal specimens for training and testing set.

with an average RMSE value for the test dataset of 131.0119 and 131.4693, respectively. This preliminary comparison shows the lack of adaptability of the models. Future work involves the comparison of more complex prognostic models such as Long Short-Term Memory (LSTM) and the ANHHSMM.

Part of the work in progress, is a literature review on uncertainty quantification in various prognostic models highlights the challenge in data-driven prognostics, particularly with ML models. Despite their high accuracy, ML models struggle with uncertainty quantification due to their deterministic nature. Another limitation is their reliance on the classical categorization of uncertainty into aleatory and epistemic types. The review compares methods for quantifying these uncertainties in ML models and implements a new prognostic measurement for Hidden Markov Models (HMMs) to assess stochastic models' ability to capture relevant uncertainties in prognostics, including past and future sources.

4. CONCLUSIONS

PHM is a field that assesses the health of an engineering system to perform predictive maintenance. Therefore, prognostics are key when predicting the health of the system and give valuable information for decision-making. However, within the prognostic field, a research gap exists when considering maintenance actions, such as repair. Repair is a common procedure that can have an impact on the degradation process of the system, and, therefore, it will negatively impact the performance of a prognostic model if this data is not part of the training set.

This research attempts to develop a robust prognostic model that can be trained with systems that have never been repaired and tested with systems that have been repaired one or several times. Even more, the research will also address UQ challenges such as the quantification of sources of uncertainty under the new categorization allowing more interpretability of uncertainty.

ABSTRACT

With the ever-growing capabilities of data acquisition and computational units in industry, development, and deployment of data-driven models (*e.g.*, predictive maintenance solutions) have become more abundant. However, if these models are not trained and maintained properly, they can be counterproductive as their predictions may be incorrect, unreliable, or difficult to interpret. In addition, unlike conventional software, the issues with such models often result in reduced productivity rather than traceable software errors. Therefore, we aim to use model performance evaluation measures introduced in trustworthy AI operations (TrustAIOps) to trigger re-evaluation of different parts of the data pipeline and the deployed data-driven model given machine learning operations (MLOps) requirements. We argue that by creating an ecosystem capable of monitoring different aspects of a data-driven solution by integrating and managing the implementation concepts in TrustAIOps and MLOps, it is possible to boost the performance of models given the constant changes induced by the specifications of Industry 4.0.

1. INTRODUCTION

Data acquisition and computational units improve daily which facilitate the development and deployment of data-driven approaches in Industry 4.0 settings. However, these data-driven models, when not trained and maintained properly, can be counterproductive as their predictions are not correct, reliable or interpretable. Unlike conventional software, the issues with model development manifest themselves in reduced productivity and not in other forms of traceable software error. In fact, when faced with during the run-time, they could be due to the errors from the data acquisition, data preprocessing, model training or model deployment submodels (Ashmore, Calinescu, & Paterson, 2021).

To ensure the acceptable performance of data-driven solutions, numerous implementation concepts have been introduced from the machine leaning operations (MLOps) society, which cover different aspects of preparing and deploying a data-driven solution. The following are some the most important characteristics of the models developed given MLOps requirements (Huyen, 2022):

1. **Reliability:** Correctness despite adversity
2. **Scalability:** Possibility of growth in complexity
3. **Adaptability:** Can cope with different data distribution shifts and business requirements
4. **Maintainability:** Documented and open to different tools

On the other hand, given the ever-growing application of machine learning solutions in different use cases, especially in safety-critical systems, performance criteria other than the accuracy have been promoted in research targeting trust worthy AI operations (TrustAIOps) which include but are not limited to (Li et al., 2023):

1. **Robustness:** Ability to deal with unseen data
2. **Generalization:** Distilling knowledge from limited training data for accurate predictions on unseen data
3. **Explainability:** Clarity on how a model makes decision
4. **Transparency:** Disclosing information about the model's lifecycle

As it can be seen in the above-mentioned characteristics, both MLOps and TrustAIOps put much emphasis on the performance of the deployed models given the possible changes in the data. These changes in Industry 4.0 settings are also relevant as there are many factors including production recipe, raw material vendor, product test unit fail/pass criteria, asset wear and tear, *etc.*, which can cause different types of data

distribution shifts. Predictive maintenance (PdM) as one of the important use cases of Industry 4.0 compliant solutions, is not an exception and requires tailored solutions for ensuring its effectiveness in an industrial setting.

1.1. Problem statement

How can the model performance evaluation measures introduced in TrustAIOps be used to trigger re-evaluation of different parts of the data pipeline and the deployed model given MLOps requirements? *(As a small remark; however, given the fact that the MLOps and TrustAIOps requirements cover numerous aspects of the PdM models, in the conducted studies, we consider only the characteristics listed above.)*

In the conducted research, we aim to introduce new implementation concepts which have proven to be useful for real industrial use cases in Europe and that are not properly addressed in the related work. In what follows pairs of MLOps and TrustAIOps, written as

$$TrustAIOps\ trigger \rightarrow MLOps\ requirement$$

are introduced with a specific implementation challenge for industrial PdM solutions:

1. **Robustness → Reliability:** Detecting previously unseen failures in the system
2. **Explainability → Scalability:** Interpretable model stacking
3. **Generalization → Adaptability:** Classifying different working conditions of an asset - Generation of run-to-failure data via simulation models
4. **Transparency → Maintainability:** Human-readable reports from different parts of the PdM solution

1.2. Research questions (RQs) and expected contributions

To elucidate further, given the complexity and high dimensionality of industrial data from different assets, how can

RQ 1. The model prediction certainty be correctly interpreted for out-of-training-distribution datapoints which represent previously unidentified failures of an asset? (see red blocks in Fig. 1). For inspecting the data-distribution shifts caused by changes in the working conditions refer to **RQ 3**.

RQ 2. The impact of different sources of uncertainty be minimized during model training using interpretable AI? (see grey blocks in Fig. 1)

RQ 3. Domain knowledge about different working conditions be included in data preprocessing and model training for enhanced data aggregation across different instances of the same production assets? (see green blocks in Fig. 1)

RQ 4. Lack of annotated data, *e.g.*, continuous data such as run-to-failure samples, be compensated using domain adaptation and simulation models? (see blue blocks in Fig. 1)

RQ 5. Human-readable reports be generated for increasing the transparency, *e.g.*, about how predictions are made and what data was used to train the model, of different submodels of the PdM solution, *esp.* for safety-critical system?

2. Conducted studies

In this section, a summary of the implemented solutions targeting parts of the first four **RQs**, specifically developed for the industry are presented. The solutions provided in this section adhere to the identical sequence as outlined in the **RQs**.

2.1. Detecting previously unidentified failures of an asset (Industry supported academic project)

It has been shown that the available data from different assets, even in case that they are abundant, normally do not cover different failure types that could occur in a system. Therefore, it is inevitable to monitor a PdM model in case data from a new working condition and/or failure type are exposed to it (Fig. 2). Despite numerous model calibration solutions, it has been observed that even models which are calibrated cannot demonstrate their certainty correctly when out-of-training-distribution data are fed into them. For PdM solutions, it is of utmost importance to inform the maintenance crew when a novel in the system has occurred as, otherwise, an exhaustive search is require for fault localization and diagnostics. In the conducted study, we have developed a post-hoc sample-based classification model built on top of the initial PdM solution that can detect previously unidentified failures in the system. The proposed method inspect the behavior of the PdM model, defined as the sequence of the PdM model certainty, and flags datapoints which indicate an anomaly in the PdM model behavior. The proposed method is tested on a demonstrator build by a company producing pneumatic components and has a mean accuracy of 94.35% (Fathi, Ristin, Sadurski, Kleinert, & van de Venn, 2024).

2.2. Reducing model uncertainty by interpretable model stacking (Industrial project)

Various changes in the production, *e.g.*, recipe updates, raw material vendor changes, improvements in quality test unit fail/pass criteria, *etc.*, impact the performance of the trained models given the potential data distribution shifts. If fact, with the adaptability in production as one of the main focuses of Industry 4.0, these changes reflect themselves in the data gathered from different assets which directly can impact the quality of the production. It is possible to counteract these changes in the gathered data by using different ensembling and model stacking techniques. In the conducted study we propose a novel approach for stacking the formerly trained

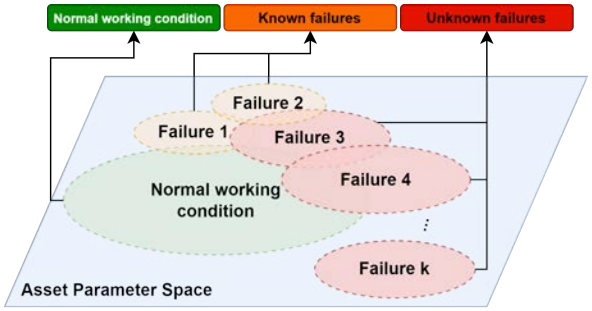

Figure 2. Asset parameter space and different known and unknown data modalities of the system

base learners. To avoid information loss due to prediction quantization of the base learners, in the proposed method we directly use the predicted probability values from the base learners and stack them using a linear regression model. The results demonstrate a 19.49% reduction in the binary estimated calibration error compared to convectional models which indicates the increased reliability of the final solution (Fathi, Stramaglia, et al., 2024).

2.3. Boosting model accuracy for different data modalities of an asset (Industrial project)

The constant changes in the production introduced in Subsection 2.2, can also lead to different dominant working condition of an asset which is also refereed to as data modality. In the conducted study, two instances of the same milling machine used for creating artificial bone joints of different sizes are examined to first detect and later to classify their different data modalities (see Fig. 3). Once different data modalities are distinguishable from one another, separate prediction models are trained for them which can increase the overall accuracy of the predictions up to 25.20%. In addition, for the data modality which forms the minority of the data from the asset, it is shown that by combining the corresponding data modalities from the two milling machines, it is possible to increase the accuracy for the aforementioned data modality up to 60.50%. In fact, by detecting corresponding data modalities, it is possible to address the problem of lack of annotated data for different instances of the same asset by simply sharing data from the same data modalities across the assets (Fathi, Sadurski, Kleinert, & van de Venn, 2023).

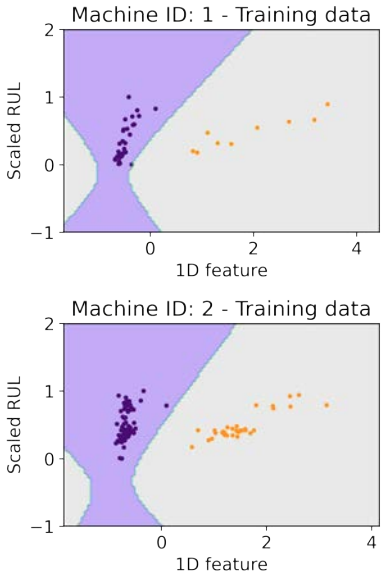

Figure 3. Decision boundaries of the trained model for classifying different data modalities of the asset

2.4. Data generation from simulation model for domain adaptation (Industrial project, paper under review)

Domain adaptation techniques developed for PdM normally focus on classification problem and neglect the regression problem of estimating the remaining useful life of an asset. In addition, they do not consider cases where the degradation of the asset is a random process itself either given the possibility of changes in the dominant failing component. Therefore, in the conducted study a novel approach for simulation data generation is introduced which is based on simulation parameter and data perturbation. It is shown how the proposed method can help cover different regions of the parameter space of the asset indicating different working conditions and parameterization of the asset (see Fig. 4). As a result, models trained with such data are more robust against signal reading manipulation and also demonstrate a more spread-out feature importance across a wider range of sensor readings while making predictions.

3. Future work and next steps

Given the conducted studies listed above, it is inevitable to create an ecosystem which is capable of monitoring different aspects of a PdM solution by **integrating** and **managing** the implementation concepts introduced in Section 2. In fact, this ecosystem will use the introduced TrustAIOps concepts to ensure the expected performance of the PdM solution given MLOps requirements. One of the most important features of this ecosystem as introduced in **RQ 5** (see Section 1.2), is providing human-readable reports from different submodels of the PdM solution to ease its maintenance and debugging. One feasible solution for the aforementioned ecosystem is to create a metadata-based management system which is capable of tracking changes in different submodels of the deployed PdM solution. These changes are the essentially the response of the PdM solution for adapting to the new working conditions and/or previously unseen failures of the system. When done correctly, the proposed solution can be used as a foundation for data-driven PdM solutions of different assets including safety-critical systems.
