Abstract

Industrial automation has extended machines' runtime, thereby raising breakdown risks. Machine breakdowns not only have economic and productivity consequences, but they can also be fatal. Thus, the early detection of fault signs is essential for the safe and uninterrupted operation of machinery and its maintenance. In the last few years, machine learning has been widely used in machine condition monitoring. Most existing approaches rely on supervised learning techniques, which face challenges in real-world scenarios due to the lack of enough labelled fault data. Additionally, models trained on historical fault data might struggle to detect new and unseen faults accurately in the future. Therefore, this research uses semi-supervised Anomaly Detection (AD) techniques to detect abnormal patterns in machines' vibration signals. As semi-supervised techniques are trained on normal data only, they do not require faulty samples and abnormal patterns are detected based on their deviations from the learned normal pattern. We compared the effectiveness of seven state-of-the-art AD methods, ranging from traditional approaches such as isolation forest and local outlier factor to more recent Deep Learning (DL) approaches based on autoencoders. We evaluated the effectiveness of different feature types extracted from the raw vibration signals, including simple statistical features like kurtosis, mean, peak-to-peak, and more complex representations like the scalogram images. Our study on three public datasets, with unique challenges, shows that the traditional methods based on simple statistical analysis have shown comparable and sometimes superior performance to more complex DL approaches. The use of traditional approaches offers simplicity and lower computational needs. Thus, our study recommends that future researchers start with the traditional approaches first and then jump to DL methods if necessary.

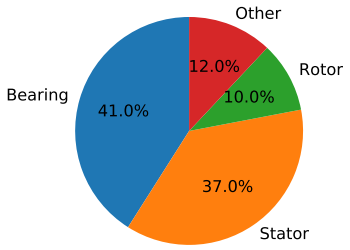

Figure 1. Proportion of machine components failure

1. Introduction

Rotating machinery is a fundamental component of modern industry and has a wide range of applications in practical engineering, including electric machines, trains, turbines, aero-engines, and so on (Jiao, Zhao, Lin, & Liang, 2019). The ubiquitous presence of these devices, from simple mechanical systems to complex nuclear power plants, reflects their critical role in modern industrial processes (Zhong, Zhang, & Ban, 2023). With the advancement of technology and productive growth in modern industry, there has been an increased reliance on machinery, making them frequently operated under adverse and challenging conditions and increased risks of failures. If unattended timely and accurately, these failures can have significant consequences, including decreased production efficiency, financial losses, and, in extreme cases, the potential loss of human lives (Neupane & Seok, 2020). Common failures in electric motors include bearings, stators, rotors, and gearboxes. Figure 1 shows the failure rates of these machinery components. These components are vital for efficient power transmission and operation of machinery. However, continuous use can result in wear, cracks, and defects of these components that can lead to machine breakdowns. Therefore, prompt and accurate fault detection and diagnosis are essential. Thus, timely maintenance of these components is critical to the machine's safe and reliable operation.

Fault diagnosis and maintenance are crucial for improving production efficiency and reducing accident rates in mechanical systems. Both the academic and industrial communities

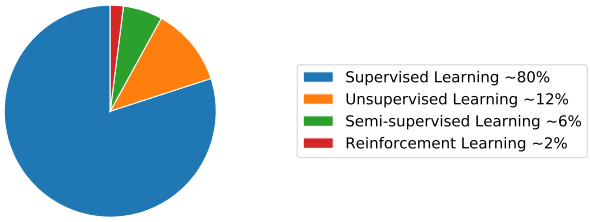

Figure 2. ML techniques used for MFD

have acknowledged the significance of Machinery Fault Diagnosis (MFD), leading to the development of various diagnostic methods for practical applications (Li, Zhang, Qin, & Estupinan, 2020). MFD has become an essential aspect of industrial development and engineering research, and numerous strategies have been developed by researchers, scientists, and engineers through years of innovative and diligent work.

Over the last decade, Machine Learning (ML) techniques have been widely used in MFD. A vast majority (over 80%, see figure 2) of those MFD methods have used supervised learning (SL) approaches (Das, Das, & Birant, 2023) to classify fault types. While such methods can detect faults previously seen, they are unable to detect new or unseen types of faults. Because many modern machines are operated in complex industrial environments, new types of faults can emerge over time. Also, to train a decent model to classify different types of faults, we need a sufficient amount of labelled data for each fault type. The scarcity of labelled data is a challenging problem in real-world industrial settings. Data labelling is an expensive and time-consuming process as it requires domain expertise to manually annotate different types of faults. Moreover, labelled data might not cover the entire spectrum of possible faults, leading to a lack of diversity in the training dataset and potentially limiting the model's ability to generalize to unseen faults.

To show the aforementioned limitations of SL in MFD, we evaluated the capability of the Decision Tree classifier using deep features from the pre-trained ResNet (ResNet-DT) (He, Zhang, Ren, & Sun, 2016) in detecting previously unseen faults. We trained the ResNet-DT model for binary classification (faulty vs. normal type) by excluding certain fault types from the training set, while including all fault types in the test set. The objective is to distinguish between normal operation and any fault condition, rather than identifying specific types of faults. We used 10 runs of a random 70-30 train-test split for each combination of omitting $i = \{0, 1, 2\}$ fault types from the training set. Our results, shown in figure 3, for the Case Western Reserve University (CWRU) datasets show that the ResNet-DT model's performance declines significantly when it encounters fault types that were not present during the training. In the x-axis of figure 3, labels C0, C1, and C2 represent the number of fault types intentionally omitted during the

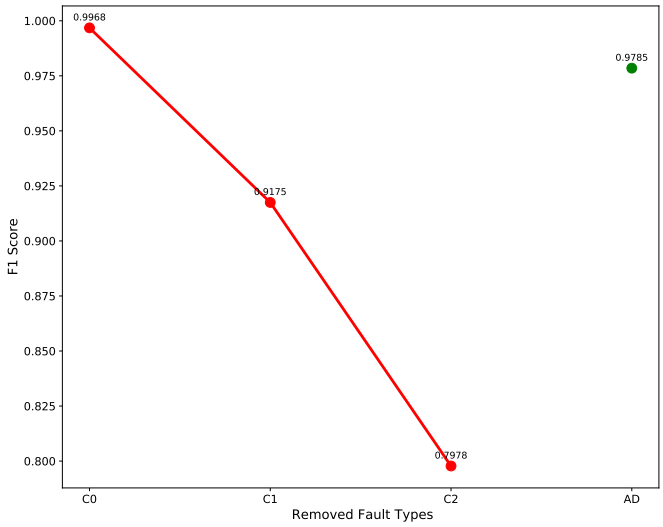

Figure 3. Average F1 score of the ResNet-DT classifier from scalogram images of vibration signals on the CWRU dataset.

model's training phase. C0 indicates that the model is trained with all fault types included. C1 represents the model being trained with one fault type excluded; this is done sequentially for each fault type (first excluding fault type 1, then including it while excluding fault type 2, and so on). Similarly, C2 denotes the exclusion of two fault types simultaneously. The y-axis shows the average F1-score for the classification of the fault condition, corresponding to the different combinations of omissions. Due to the numerous possible combinations of omitted fault types, we calculated and presented the average F1 score. The red dots in the figure denote the respective average F1 score for each fault type omission. In contrast, the green dot represents the F1 score of the Isolation Forest (iF) based semi-supervised Anomaly Detection (AD) method using the same ResNet deep features (ResNet-iF) trained on half of the normal dataset. The other half is concatenated with all fault types together. It is evident from figure 3 that the ResNet-DT model encounters challenges in detecting unknown faults. The trend shows a significant decrease in the F1-score as more fault types are excluded from the training set, underscoring the model's limitations in recognizing unseen machinery faults. In contrast, the ResNet-iF's average F1 score shows the effectiveness of AD methods in detecting unseen faults. The iF, trained on half the amount of the normal state machinery signals and tested on all the fault types along with the other remaining half of the normal data, performed nearly equal ($\tilde{1}.8\%$ lesser) to the ResNet-DT model (trained with 70% data as training) with no classes omitted in training.

Taking the supervised model's ineffectiveness in detecting unseen faults in real-world scenarios as the motivation for this project, we have explored the potential of semi-supervised learning (SSL) based AD algorithms that are trained on normal data only and aim to detect unseen fault types. These

algorithms model the profile of normal vibration signals to distinguish faulty (or abnormal) vibration signals from normal signals. In the real-world scenario, where the availability of normal/healthy machinery data is abundant, these algorithms are very useful and can detect anomalies or faults more easily and quickly than the SL classification models.

The use of SSL in MFD is relatively unexplored. Prior studies employing SSL techniques mostly focus on classifying the faults only. A recent study (Zong et al., 2022) on bearing fault diagnosis of CWRU and Xi'an Jiaotong University dataset focused on the use of SSL. The study utilized a short-time Fourier transform as a preprocessing step and employed SSL with domain adversarial neural network for fault classification and achieved an average accuracy of 96.77%. Another study by Zhang et al. (Zhang, Ye, Wang, & Habetler, 2021) also focused on SSL employing VAE for the classification of bearing faults for the CWRU and University of Cincinnati Intelligent Maintenance System dataset. With 16.67% of labelled data in each class, the accuracy of $\tilde{9}8\%$ was achieved. Moreover, a research (Zhang, Ye, Wang, & Habetler, 2020) addressed bearing AD challenges via few-shot learning based on model-agnostic meta-learning using CNN on the CWRU and Paderborn University (PU) dataset. The study also focused on classifying the bearing faults using a limited amount of data. Other than these two datasets, a study by Vos et al. (Vos et al., 2022) employed AD for vibration-based fault diagnosis. Experimented on Airbus and DST gearbox datasets, the study employed LSTM-SVM and simple OCSVM techniques.

For this research, we have used seven AD algorithms, including traditional approaches like iF (Liu, Ting, & Zhou, 2008), Local Outlier Factor (LOF) (Breunig, Kriegel, Ng, & Sander, 2000), one class support vector machine(OCSVM) (Schölkopf, Williamson, Smola, Shawe-Taylor, & Platt, 1999), and the Deep Learning (DL)-based techniques like Autoencoder (AE) (Ahmad, Styp-Rekowski, Nedelkoski, & Kao, 2020) and Variational AE (VAE) (Zhang, Ye, Wang, & Habetler, 2019), and the hybrid approaches like ResNet (He et al., 2016) and VGGNet (Simonyan & Zisserman, 2014)-based iF, LOF and OCSVM, which will be described in detail in later sections. The motive behind taking the traditional algorithms is that, for fault or anomaly detection, it is not necessarily true that DL architectures are always superior (Wang, Vos, et al., 2023; Audibert, Michiardi, Guyard, Marti, & Zuluaga, 2022). The traditional algorithms, with the simpler architectures, can sometimes outperform the complex and deeper networks.

The organization of this article is as follows. In Section 2, the dataset description is presented. Section 3 provides an overview of the methodology implemented in this research, and Section 4 presents the experimental results and analysis of this work. Finally, the article concludes in Section 5.

2. Dataset Description

We have used three datasets for this research, two of which are the most widely used benchmark datasets—the CWRU and PU bearing datasets— and the other is the Health and Usage Monitoring System (HUMS) planet gear rim crack dataset provided by the Defence Science and Technology Group (DSTG) in Melbourne, Australia.

2.1. CWRU Dataset

The CWRU bearing dataset is one of the most widely used fundamental bearing datasets for MFD research. It contains experimental data collected from a test rig with four different types of faults: inner race fault, outer race fault, ball fault, and normal (healthy) state. These faults are artificially induced with varying severities and load conditions. The dataset provides time-domain vibration signals, making it suitable for MFD methods such as feature extraction, classification, and model training (Chaleshtori & Aghaie, 2024). The dataset is publicly available on this website [1]. For this research, we have used all four types of faults with a fault diameter of 7 mils (1 mils=0.001 inches) with all available loads from 0 to 3 HP. A total of 413 instances were used for each class. The types of faults used are shown in Table 1.

2.2. PU Dataset

The PU dataset, provided by the KAT data center at Paderborn University, is a comprehensive resource for MFD and prognosis research. The PU bearing dataset comprises vibration data from experiments on six healthy bearings and 26 damaged bearing sets, of which 12 are artificial damages, and 14 are real damages. The dataset provides time-domain vibration signals, acoustic emission signals, and temperature measurements, covering various fault severities and load conditions (Lessmeier, Kimotho, Zimmer, & Sextro, 2016; Neupane, Bouadjenek, Dazeley, & Aryal, 2024). This dataset can be downloaded from this website [2]. For this research, we have taken five types of bearing vibration data, including two artificial fault types, two real fault types, and one normal state data. A total of 4967 instances from each class were used. Other information about the dataset is described in Table 1.

2.3. HUMS Dataset

The HUMS dataset originates from an extensive experimental study executed at the Helicopter Transmission Test Facility (HTTF) at the DSTG in Melbourne. This study was executed with the specific aim of investigating fatigue cracking in thin-rim helicopter planet gears, which are critical components of helicopter transmission systems. The dataset was released as a part of the HUMS 2023 Data Challenge. Further information about the experimental set, data processing, and acquisition

Grand Total	**808**	

technique for this dataset can be found on (Peeters, Wang, Blunt, Verstraeten, & Helsen, 2024), (Wang, Blunt, & Kappas, 2023), and (Sawalhi, Wang, & Blunt, 2024). A total of 808 four-channel planet-ring hunting-tooth average data files were provided in two sessions (526 files [*files from Day 21 to Day 27*] before the data challenge and 282 files [*from Day 17 to Day 20*] after the challenge). The whole dataset features 94 load cycles, out of which the last 60 cycles were released prior to the data challenge, and the first 34 load cycles were released later. Table 2 shows the number of records with respect to the days of testing. In this research, we used 282 data files from Day 17 to Day 20, which were taken as a training set, and the remaining 526 data files from Day 21 to Day 27 were taken as the test set. Our experiment encompassed data collected from all four sensors.

3. Methodology Implemented

The methodology implemented in this research is consistent across two benchmark datasets, CWRU and PU, with a minor difference in the pre-processing (PP) step for the HUMS dataset.

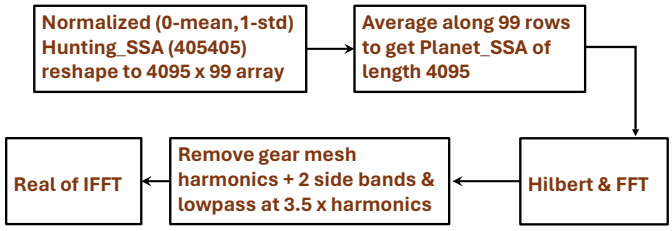

Figure 4. Preprocessing technique used for the HUMS dataset

3.1. Pre-processing

A. ***CWRU and PU datasets:*** The initial preprocessing step of standardizing the raw vibration signals was done to achieve a mean of zero and a standard deviation of one. Then, the signals of length, X (say), were segmented into N samples, each comprising 4096 data points. It is important to note that the value of N varies across datasets but remains constant for different fault types within a particular dataset.

B. ***HUMS dataset:*** The whole dataset consists of 808 files of Hunting tooth synchronous averaging (H-SSA) with 405405 data points per sample per channel, which was standardized to zero mean and unit standard deviation. This standardization of H-SSA mitigates variations in torque, speed, and temperature, enhancing sensitivity to fault-induced changes. Then, Planet Gear SSA (P-SSA) was derived by reshaping H-SSA into a matrix and averaging along specific rows corresponding to gear revolutions. Specifically, each 405405-data points sample was reshaped into a 4095×99 matrix array and was averaged along 99 rows to get the averaged sample of 4095 data points. The output 4095 data points sample was then transformed using Hilbert and then fast Fourier transform. The residual signals were generated by eliminating gear mesh harmonics and sidebands in the order domain. To detect rim cracks, an ideal low-pass filter at 3.5 times the gear mesh harmonics was applied, followed by an inverse fast Fourier transform (IFFT), and the real values of IFFT were taken as the data points for samples (Sawalhi et al., 2024), (Peeters et al., 2024). In this way, 808 planet-ring hunting-tooth average samples per channel, each of length 4095, were finally achieved. The preprocessing steps for the HUMS dataset can also be seen in figure 4.

3.2. Analyses Carried

After these prepossessing steps, two primary analyses were conducted for all three datasets:

A. ***Statistical analysis:*** For each segment generated, key statistical metrics including, Mean (M), Standard deviation (Std), Peak-to-Peak (P2P), Kurtosis (K), and Skewness (Sk) were computed and saved in a *CSV* format. Furthermore, labels were assigned to each of the samples of the

CWRU and PU datasets to indicate their condition, with '0' representing a normal state and '1' signifying a fault. Since the HUMS dataset does not contain distinctive normal and faulty signals, this labelling step was skipped for this particular dataset.

B. ***Wavelet transform analysis:*** Scalograms were generated from the pre-processed data files for each datasets, for further examination using the Continuous Wavelet Transform (CWT) (Zheng, Li, & Chen, 2002) technique, specifically employing the Morlet wavelet. Research (Neupane, Kim, & Seok, 2021), (Guo, Liu, Li, & Wang, 2020) indicate that vibration signals featuring periodic impulses correspond notably with the Morlet wavelet's properties. This alignment facilitates the utility of Morlet wavelets in identifying both anomalies and standard elements in machinery, which has made it a popular choice in this domain of study. Scalograms were labelled as '0' or '1' to indicate normal or faulty signals for the CWRU and PU datasets, and skipped for the HUMS dataset.

3.3. Anomaly Detection Approaches

Anomalies represent data instances that exhibit distinct characteristics from normal instances, and the detection of these abnormal patterns or instances is called anomaly detection (Liu et al., 2008). AD, also called outlier detection, is a widely used technique in data mining and ML to identify or detect instances or patterns that do not conform to the expected behavior within a dataset (Kumagai, Iwata, & Fujiwara, 2021). AD methods have been used in various applications, such as fraud detection (Pourhabibi, Ong, Kam, & Boo, 2020), intrusion detection (Aryal, Santosh, & Dazeley, 2021), and so on. The task of AD can be addressed through supervised, semi-supervised, or unsupervised learning strategies. However, a significant obstacle is the scarcity of high-quality training instances, particularly for anomalous behaviors, which pose challenges in various domains, including MFD. Given these challenges, it is imperative to address the task through semi-supervised approaches.

Semi-supervised AD techniques are designed to identify anomalies or outliers in data by combining labelled and unlabelled instances. The process begins by manually labeling a small subset of the data as either normal or anomalous, which serves as the training set. Using this labelled data, a model is trained to distinguish between these two categories. Subsequently, the trained model is applied to the unlabelled data, assigning scores or probabilities to each data point. Thresholds are then applied to these scores to classify instances as either normal or anomalous.

For this work, we have labelled only the normal data and trained the AD models on this subset of labelled data. We explored the efficacy of various AD algorithms like iF, LOF, OCSVM, AE, and VAE. The use of statistical features is primarily for traditional AD algorithms, like iF, LOF, and OCSVM only. In contrast, the scalogram images are fed as input to the DL architectures, like AE, and VAE. Additionally, DL architectures like ResNet50 and VGG16 are employed to extract the features from the scalograms, and traditional algorithms (iF, LOF, and OCSVM) are employed for the extracted features for detecting normal and anomalous instances. A brief overview of each of these algorithms is provided below:

- **iF:** Isolation forest (Liu et al., 2008) is an AD algorithm that operates on a tree-based approach to identify outliers in the dataset. This algorithm isolates anomalies by randomly selecting features and partitioning data points based on their values along those features. This process is repeated recursively until each data point is isolated in its own partition. Anomalies are identified as data points that require fewer partitions to isolate, as they stand out as unusual compared to normal instances.
- **LOF:** Local outlier factor (Breunig et al., 2000) is a density-based AD algorithm, that measures the local deviation of a data point in relation to its neighbors. It calculates the ratio of the local density of a point to the local densities of its neighbors, identifying outliers as data points with significantly lower densities compared to their neighbors.
- **OCSVM:** One class support vector machines (Schölkopf et al., 1999), an AD algorithm used for novelty detection, constructs a hyperplane that separates the normal data instances from the origin in a high-dimensional feature space. This method aims to maximize the margin between the hyperplane and the nearest normal data points, identifying anomalies as data points lying on the opposite side of the hyperplane from the normal class.
- **AE:** Autoencoders (Torabi, Mirtaheri, & Greco, 2023), a type of neural network architecture, can also be used for AD tasks. When trained on normal data points, AE aims to reconstruct input data with minimal error; however, anomalies generally result in higher reconstruction errors. By setting a predefined threshold, instances with reconstruction errors surpassing this threshold are flagged as anomalies or outliers.
- **VAE:** Variational AEs (Xie, Xu, Jiang, Gao, & Wang, 2024), a variation of AE, are capable of learning complex data distributions and generating new data samples similar to the training data. VAEs, trained on normal data points, aim to reconstruct input data with minimal error. However, anomalies typically result in higher reconstruction errors, as they deviate significantly from the learned data distribution. By comparing the reconstructed data with the original input, anomalies can be identified based on higher reconstruction errors.

Moreover, we have also used ResNet50 (He et al., 2016), and VGG16 (Simonyan & Zisserman, 2014) neural architectures for feature extraction from the scalogram images. These

are pre-trained architectures, which utilize a series of convolutional and pooling layers to extract hierarchical features from input images. ResNet50 introduces residual connections, which help alleviate the vanishing gradient problem during training, allowing for deeper architectures to be trained effectively. In contrast, VGG16 relies on a simpler architecture with a stack of convolutional layers followed by max-pooling layers. Despite the difference in their architecture, both of these networks can extract informative features from images. The extracted features are used as the input of three AD models: iF, LOF and OCSVM.

Thus, the methodology incorporates three diverse strategies for anomaly detection, specifically designed for those data types and analytical approaches. These approaches utilize a consistent evaluation framework, which comprises multiple runs (10), incorporates statistical and deep features, and employs various thresholding techniques for detecting anomalies. The following provides a brief overview of each approach:

A. ***Approach 1: AD with Statistical Features:*** This study evaluates the effectiveness of the key statistical features, like mean, standard deviation, kurtosis, skewness, and P2P, computed for each standardized sample, and the traditional AD algorithms in detecting anomalies. Three models, iF, LOF, and OCSVM, were implemented. A comprehensive analysis was conducted across 31 combinations of these features to explore their effectiveness in AD. The anomaly score generated by these models was compared with the custom thresholds like three sigma ($\mu - 3\sigma$), one percent, and minimum anomaly score + standard error.

B. ***DL-based End-to-End AD:*** The second strategy utilized end-to-end DL models, specifically AE and VAE, which are designed for scalogram images. This method employs reconstruction loss as a measure for AD. Anomalies are expected to have a larger reconstruction loss. The same thresholding techniques are applied to the reconstruction loss to differentiate between normal and anomalous instances. This approach explores the ability of AE and VAE to capture and reconstruct the intricate patterns present in scalogram images.

C. ***Hybrid Approach (DL + Traditional AD):*** The third methodology expands the analysis of scalogram images by employing feature extraction through the use of pre-trained DL architectures like ResNet50 and VGG16 neural networks. Similar to the first approach, the models iF, LOF, and OCSVM are implemented to the extracted features to get the anomaly scores, and the anomalies were detected utilizing the same thresholding techniques. Employing ResNet50 as a feature extractor, each image results in a feature vector of size 2048, and using VGG16, each input image results in a feature vector of size 512. These features are then fed as the input of the AD models.

3.4. Threshold Techniques

The AD algorithms generate the anomaly scores. Anomaly scores in iF are typically calculated based on the number of splits required to isolate each data point in a decision tree. Data points that require fewer splits to isolate are considered more anomalous and receive higher anomaly scores. Therefore, lower anomaly scores indicate normal behavior, while higher scores indicate anomalies. Similarly, LOF computes anomaly scores by comparing the local density of data points around each point to the density of its neighbors. Points with significantly lower density compared to their neighbors are assigned higher anomaly scores. Thus, higher LOF scores denote more anomalous behavior. Similarly, anomaly scores in OCSVM are determined based on the distance of each data point from the boundary of the region containing normal data points. Points lying farther away from this boundary are considered more anomalous and receive higher anomaly scores.

Three custom thresholds are used for this research: three sigma, one percent, and the minimum anomaly score (or reconstruction loss) plus the standard error. For $\mu - 3\sigma$, the mean of these scores (μ) is calculated, along with their standard deviation (σ). The $\mu - 3\sigma$ threshold is then determined by subtracting three times the standard deviation (3σ) from the mean ($\mu - 3\sigma$). This threshold serves as a boundary for identifying anomalies; samples with anomaly scores exceeding this threshold are considered anomalous. Additionally, for models such as AE and VAE, the reconstruction errors of normal training samples are used instead of anomaly scores. The $\mu - 3\sigma$ threshold is calculated in the same manner, but based on these reconstruction errors, providing a consistent criterion for anomaly detection across different types of models. Moreover, the one percent threshold is determined by selecting the value below which only one percent of the normal training scores or reconstruction errors fall. This threshold is established to identify anomalies among samples with exceptionally low scores, indicating significant deviations from the norm. Furthermore, the minimum value plus the standard error threshold is calculated by adding the standard error to the minimum normal training score or reconstruction error. The standard error provides a measure of the variability or uncertainty associated with the estimation of the minimum value. This threshold aims to capture anomalies beyond the minimum score while accounting for potential fluctuations.

3.5. Evaluation Framework

A. ***CWRU and PU datasets:*** The methodology follows a consistent evaluation framework across all approaches. Initially, the training data is split evenly into two halves. One half is utilized for model training, while the other half is combined with 90% of randomly selected test data to establish a diverse testing scenario. The test data includes various types of bearing health datasets collected from

the CWRU dataset, each comprising 413 instances. We created a total of five datasets, as depicted in Table 1. The 'All Faults' dataset is the combination of all fault types, namely B007, IR007, and OR007, excluding the Normal type, resulting in 1239 instances.
Additionally, we extracted five distinct health states from the PU bearing dataset. These states encompass a normal state, two artificial damages featuring OR faults, and two real damages featuring IR+OR faults, with each class containing 4967 instances. Consequently, a total of six datasets were generated, as illustrated in Table 1, in which the 'All Faults' dataset comprises all four faulty states datasets (except the normal).

B. ***HUMS Dataset:*** After the PP of the HUMS dataset, as mentioned in section 3.1, the resulting 808 data samples from each of the four sensors, were divided into train and test sets. As mentioned in an earlier section, 282 data files from the first 34 load cycles, from Day 17 to Day 20, were taken as a training set in this research, and the remaining 526 data files, from Day 21 to Day 27, were taken as the test set.

4. Experimental Results

As we have mentioned earlier, we implemented the iF, LOF, and OCSVM models which were fed with the combination of the key statistical features computed for each sample. We also employed end-to-end DL-based AD algorithms, including AE and VAE, to detect anomalies using scalogram images. Additionally, we applied ResNet50 and VGG16 architectures to extract features from the scalograms and implemented iF, LOF, and OCSVM techniques for detecting anomalies. From the experiments conducted, we obtained the following outcomes.

4.1. Results for the CWRU and PU Dataset

Tables 3 and 4 present the performance of various anomaly detection algorithms achieved for the CWRU and PU datasets, respectively. These tables represent that the feature combinations of kurtosis, skewness, and P2P excel other combinations, and the threshold $\mu-3\sigma$ performs better than other techniques. Here, the term "best average F1 score" refers to the highest F1 score calculated by averaging the F1 scores obtained from 10 separate runs. The term "Overall" denotes the best score achieved across all datasets, reflecting the highest performance observed collectively across all evaluated datasets. Abbreviations K, P2P, Sk, M and Std represent Kurtosis, Peak-to-Peak, Skewness, Mean and Standard deviation, respectively. Moreover, the average F1 score over 10 runs for each of the datasets for each method is shown as a bar graph in Figure 5 and 6. The first three bar clusters, representing models iF, LOF, and OCSVM, denote the use of the respective AD models for the feature combinations kurtosis, P2P, and skewness. The subsequent bar clusters, from ResNet-iF to VAE, use the scalogram images as input. The threshold for all of these models is $\mu - 3\sigma$. Figure 5 illustrates notable performance trends of the ResNet-iF and ResNet-OCSVM models across all dataset types for the CWRU dataset, whereas figure 6 illustrates notable performance trends of ResNet-OCSVM models across all dataset types for PU dataset.

Table 3. Experimental results for the CWRU Dataset.

Dataset	CWRU
Model	iF
Best Average F1 Score	0.99826221 (OR007)
Overall	K, P2P, Sk; $\mu - 3\sigma$
Model	OCSVM
Best Average F1 Score	0.0.997340705 (OR007)
Overall	K, Sk, P2P; Min+stdError and $\mu - 3\sigma$

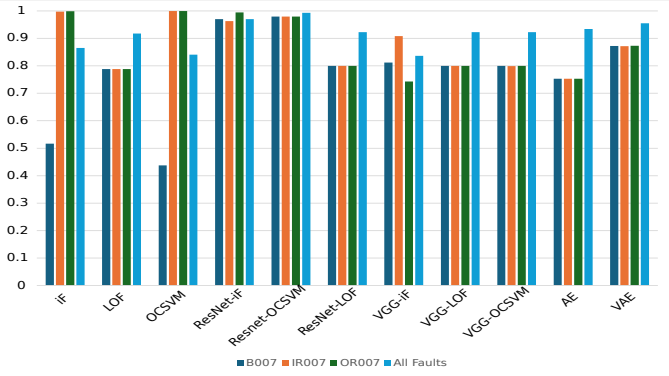

Figure 5. Comparison of Models' Performances on the CWRU Dataset.

challenge, the winning team (Peeters et al., 2024) claimed the record number #175 (Day 23/ 20211214, 104944) to be the earliest convincing fault detection. However, the data challenge committee pointed out that records #264 (Day 24/ 20211216, 112716) and #272 (Day 24/ 20211216, 120021) as contenders. As further research continues, different results are claimed, proposing different records as the earliest detection. In the latest notice released by the committee[3], records #15 (Day 21/ 20211208, 113917), #50 (Day 21/ 20211208, 135820), #125 (Day 22/ 20211209, 124241), #143 (Day 22/ 20211209, 135146) and #150 (Day 22/ 20211209, 141330) have found to contain the anomalies as well.

Figure 6. Comparison of Models' Performances on PU Dataset

With our various AD detection algorithms, various records (or file numbers) were detected as the earliest detection. However, seeing the most convincing features (kurtosis, P2P, and skewness) and effective algorithms for the CWRU and PU dataset, the results obtained from ResNet-iF and ResNet-OCSVM are considered for this HUMS dataset as well. The iF, LOF and OCSVM algorithms, trained on the combined features of kurtosis, skewness and P2P and threshold $\mu - 3\sigma$, predicted #15 (Day 21/ 20211208, 113917), #50 (Day 21/ 20211208, 135820) and #150 (Day 22/ 20211209, 141330) as the first three consecutive faults. Taking the ResNet-iF and ResNet-OCSVM models and $\mu - 3\sigma$ as a threshold, the earliest anomaly prediction was found to be the file #11 (Day 21/20211208, 112723).

5. Discussion and Conclusion

Identifying faults in machinery poses significant challenges, particularly in accurately classifying fault types. Conventional supervised machine learning methods have limitations due to the need for abundant labelled data, expert supervision in labelling, and their inability to generalize to unseen faults. To tackle these challenges, this article explores the potential of semi-supervised learning-based anomaly detection techniques in the field of machinery fault diagnosis. This study specifically focuses on identifying abnormal patterns in machinery vibration signals, which are crucial for preventing breakdowns and ensuring safety and productivity. Our experimental results highlight the effectiveness of certain feature combinations, such as kurtosis, skewness, and peak-to-peak, in conjunction with a threshold of three sigma. Furthermore, we found that models like ResNet-OCSVM and ResNet-iF, as well as deep learning-based methods like VAE, demonstrate promising performance. However, it's worth noting that DL-based techniques often come with higher computational resource requirements and longer training times, as depicted

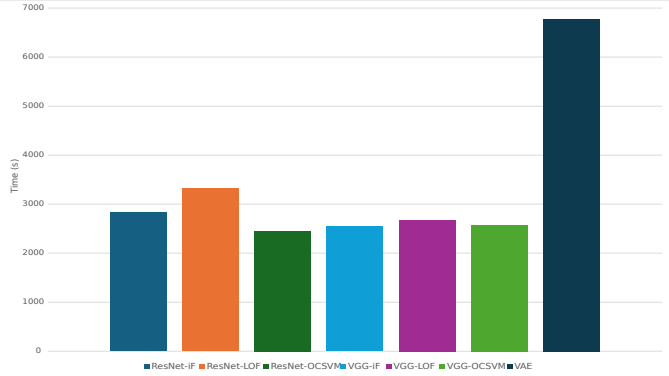

Figure 7. Comparison of Model Performances Based on Runtime: The figure illustrates the time taken by various models to complete 10 runs of anomaly detection using all 4 test sets from the CWRU dataset. Notably, all models operate on the same input, namely, scalograms.

in figure 7. Interestingly, simpler traditional methods, sometimes, outperform or perform equally well compared to complex DL methods. Given their simplicity and lower computational demands, prioritizing these simpler approaches may be more practical in many scenarios.

Our research examines seven AD methods across various feature representations using benchmark datasets, including the CWRU bearing, PU bearing, and HUMS planet gear rim crack dataset. Our findings provide valuable insights with significant practical implications, suggesting that simpler approaches may be, sometimes, effective in real-world applications due to their ease of implementation and reduced computational burden. DL methods, indeed, have shown promising results in MFD, but their practicality may be limited by resource constraints. Therefore, incorporating semi-supervised learning-based AD techniques alongside simpler traditional methods can enhance fault detection systems in industrial settings. We, therefore, would like to recommend that future researchers proceed with simpler methods initially, then transition to DL-based methodologies if necessary for MFD.

ABSTRACT

We introduce an object detection model specifically designed to identify failure modes in images of bearing components, including the inner ring, outer ring, and rolling elements. The method effectively detects and pinpoints failure features, subsequently determining the associated failure mode within the image. With images sourced from real-world bearing applications, our model can recognize various ISO-failure modes such as surface-initiated fatigue, abrasive wear, adhesive wear, moisture corrosion, fretting corrosion, current leakage erosion, and indents from particles. The proposed model could be used in an assistive tool where failure modes give insights on how to prolong average future bearing life in an asset and therefore reduce related costs and environmental impacts.

1. INTRODUCTION

Bearings are extensively utilized in a wide range of rotating equipment and are essential for ensuring their proper function. Bearing failures can lead to unplanned downtime with unforeseen costs, or even result in hazardous situations. Sensor-based condition monitoring has been an important tool for the prediction of these undesired events and are a key ingredient for a predictive maintenance strategy (Randall & Antoni, 2011). In this paper, the focus is on a subsequent stage after sensor-based fault detection, that is, a visual inspection of the replaced disassembled bearing to further prolong the average future bearing life in an asset (SKF, 2017).

A visual inspection of the bearing provides additional information on how to prevent problems from reoccurring. This includes altering the bearing design, lubrication or operation and maintenance procedures. Another important application of bearing inspections is quantifying its damage severity, such as spall size. This information can be fed back to sensor-based condition monitoring systems enabling supervised machine learning for bearing diagnostics and prognostics. Inspections are also being used to determine whether a bearing qualifies for remanufacturing (Chiarot, Cooper Ordoñez, & Lahura, 2022). Remanufacturing is a process which enables re-using the bearing by means of polishing or grinding its components, potentially doubling its life. To summarize, visual bearing inspections can significantly prolong average future bearing life in an asset and therefore reduce related costs and environmental impacts, e.g., due to the manufacturing process of the bearing.

Unfortunately, visual postmortem analysis of bearings require an application engineer with many years of experience, which is something not always readily available. This limits its scalability to be applied to a large population of bearings used in an asset. In this work we propose an image-based deep learning algorithm, which can assist the technician replacing the bearing. For example, a picture can be taken of the bearing components with a smart-phone, where the software automatically provides insights on proposed maintenance actions, altering bearing designs, its remanufacturability and provide an automated connection in supervising condition monitoring algorithms.

Bearing failures can occur due to a wide variety of reasons (Liu & Zhang, 2020), where each failure category can lead to a unique footprint observable during visual inspection (SKF, 2017). The different categories of bearing failures have been standardized and well described in (ISO-15243-2017, 2017), also referred to as bearing failure modes, where, in total,

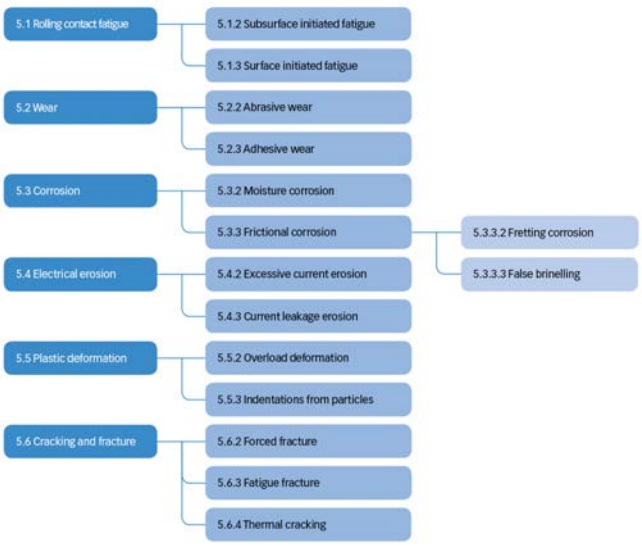

Figure 1. *ISO 15243-2017 failure mode classifications. Image taken from (SKF, 2017).*

seven main categories of failure modes are proposed. An overview of the different failure modes is shown in Figure 1. In Figure 2 an overview is shown on the most common failure modes based on collected statistics from bearing inspections (SKF, 2017).

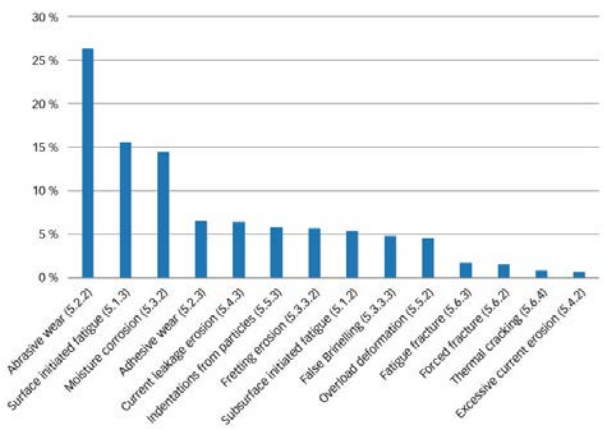

Figure 2. *An example of SKF's field failure statistics, detailing the frequency of various failure modes. Image taken from (SKF, 2022).*

Applying deep learning algorithms to automate visual inspections in PHM applications is not new. A significant amount of work has been done in the field of structure health monitoring. Examples include crack detection in concrete structures caused by, e.g., changing loading and corrosion (Azimi, Eslamlou, & Pekcan, 2020). More examples can be found from the steel industry, that is, detection and classification of steel surface defects (Fu et al., 2019; Wang, Xia, Ye, & Yang, 2021). However, to the authors knowledge there is no specific method to classify bearing failure modes.

In this work a framework of selecting a deep-learning based object detection model is introduced. The object detection model is specifically tasked to identify failure modes in images of bearing components, including the inner ring, outer ring, and rolling elements. This model effectively detects and pinpoints failure features, subsequently determining the associated failure mode within the image. As a first step, the selected model is trained for the top 7 most common failure modes, namely: abrasive wear, surface-initiated fatigue, moisture corrosion, adhesive wear, current leakage erosion, fretting corrosion, and indentations from particles (Figure 2).

2. Dataset

The foundation of bearing failure mode object detection model lies in the curated dataset. The dataset encompasses a broad spectrum of bearing images, taken from industrial centres across the globe and showcases various bearing types along with the one or more of the top seven primary failure modes identified for diagnosis. This breadth in dataset variety was crucial for the development of a model capable of accurately identifying and classifying a range of real-world bearing failures captured in their operational environment.

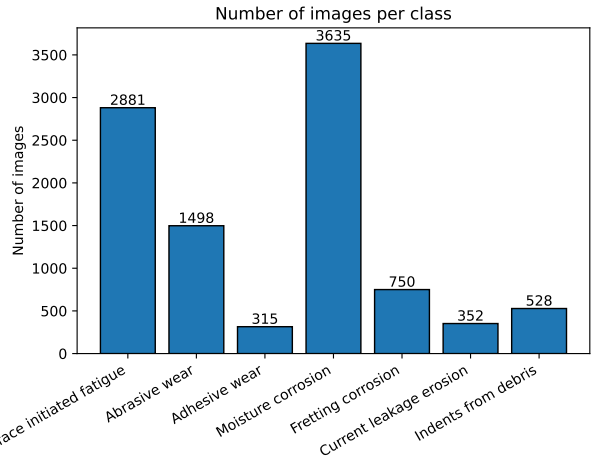

Figure 3. *Final number of images per failure class after selecting process and annotation done by expert.*

The precision in our dataset was ensured by an expert led data labelling team based on SKF employee's experience. Specialists in bearing maintenance meticulously labeled and annotated each image, drawing accurate bounding boxes around the designated failure modes. During the annotation process images were selected based on their representation of the failure mode, making sure the failure mode characteristics and features are within clear view according to the ex-

pert. Furthermore, an assessment was made on the quality of the image itself, filtering any blurry images. Images objects other than bearing components (maintenance tools, tables, etc) were also removed from the training set. In the end the dataset comprised of 11k images across the 7 chosen failure modes as shown in Figure 3. Images were normalized, padded and resized to 640x640 pixels. Additionally, augmentation techniques were applied to the images before ingesting into the model.

Here the bar graph illustrates a significant class imbalance within our object detection dataset, where certain classes are overly represented with a high number of images, while others have markedly fewer instances. This imbalance poses a challenge for effective model training, as it can lead to biases towards the more prevalent classes, potentially compromising the model's ability to accurately detect and classify less represented objects. Addressing this issue is crucial for enhancing the model's overall performance and ensuring a balanced sensitivity across all classes. To overcome this, as a first step, the shift-scale-rotate augmentation was applied with a rotation limit set to +/- 15 degrees. This method involves stochastic affine transformations that adjust the original images through shifting, scaling, and rotating. Such transformations significantly increase the dataset's variety without the need to collect new samples.

3. Proposed Methodology

The methodology employed in developing an object detection model aimed at detecting failure modes in images of bearings was twofold: firstly, leveraging out-of-the-box (pretrained) models, and secondly, fine-tuning these models on the earlier described dataset split into an 80%-20% training and test set, respectively.

3.1. Model Selection

To determine the optimal pre-trained model for our application, we conducted a comparative analysis of several state-of-the-art models. Each model was evaluated using its default parameters, with the only modifications being the image size and batch size. Specifically, all models were trained with images resized to 640x640 pixels and a batch size of 4. The models included in the study were as follows with their respective backbone (Zou, Chen, Shi, Guo, & Ye, 2023):

- EfficientDet (D0)
- EfficientDet (D4)
- Retinanet (Resnet - 101 - 2x)
- Retinanet (Resnet - 101 - 1x)
- Retinanet (Swin)
- Yolo-x (Yolo - Tiny)

The models were compared using the COCO metric. The COCO metric, used for evaluating object detection models, includes several key components: Average Precision (AP) and Average Recall (AR) across multiple IoU thresholds (0.50 to 0.95). The metric also evaluates performance across different object sizes (small, medium, large), providing a comprehensive and standardized assessment of a model's detection capabilities. This robust evaluation ensures accurate localization and detection across varied conditions (Lin et al., 2014).

3.2. Training the Model

The dataset, characterized by class imbalance among different failure modes, necessitated a tailored approach to model training. To mitigate the effects of class imbalance, focal loss was integrated into the model's loss function (Lin, Goyal, Girshick, He, & Dollár, 2017). This modification aimed to amplify the loss associated with misclassified examples, particularly those from underrepresented classes, thereby enhancing the model's sensitivity to such cases. The models were trained with a learning rate of 1e-4 for 20 epochs.

One of the paramount challenges encountered during training was the potential for overfitting. To counteract this, techniques such as early stopping, layer normalization, and weight decay were employed. Additionally, model performance was evaluated using the test set to ensure generalizability beyond the training data. Early stopping as a regularization technique was also used to prevent overfitting, by halting the training process before the model's performance on the test set starts to degrade. By terminating the training at this optimal point, early stopping ensures that the model retains its ability to generalize well to new, unseen data, thereby mitigating overfitting and improving the model's overall predictive performance.

4. Results

Figure 5 shows the results of the comparative study of different model architectures. The study revealed that EfficientDet and RetinaNet emerged as top candidates in terms of accuracy in contrast to the Yolo methods. The RetinaNet model, with its ResNet backbone, was ultimately selected based on its performance.

The implementation of early stopping mechanisms helped mitigate this risk by halting training once the test loss plateaued, as shown in Figure 6. This strategy proved invaluable in preserving the model's generalizability.

Example model predictions for the different failure modes are shown in Figure 4. Looking at the confusion matrix in Figure 7, the Retinanet model detection threshold was set in a way that left around 32% of the images without any predictions resulting in low recall. Among the images with predictions, there was a notable emphasis on precision, as evidenced by a significant number of predictions aligning along the matrix's

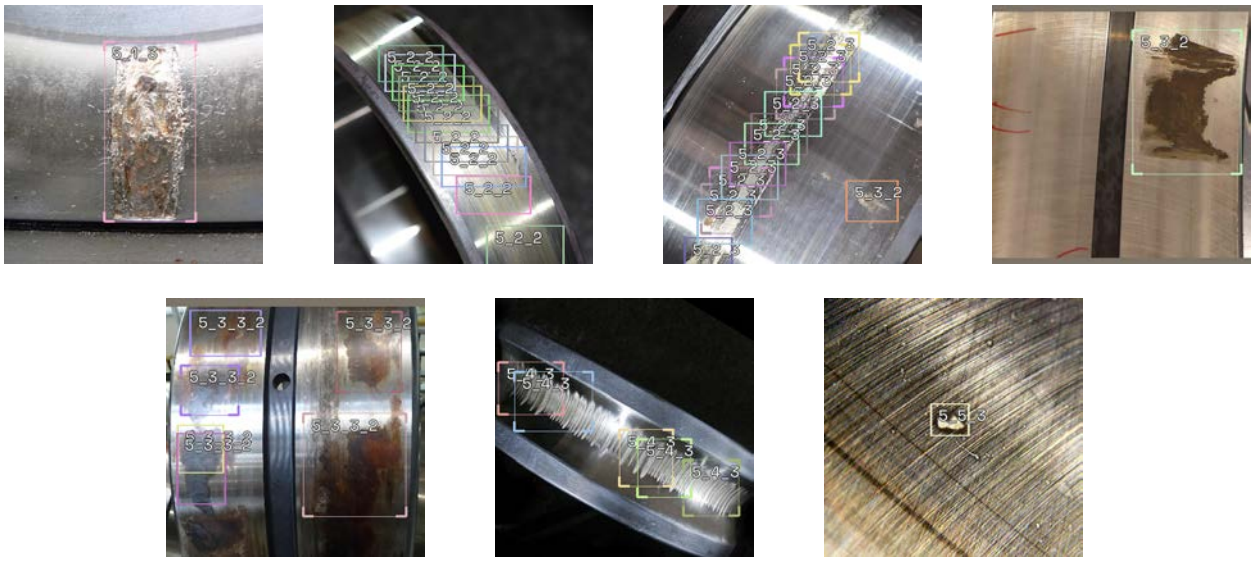

Figure 4. Example predictions for several failure modes. From left to right, top to bottom: Surface initiated fatigue, abrasive wear, adhesive wear, moisture corrosion, fretting corrosion, current leakage erosion and indentations from debris.

diagonal.

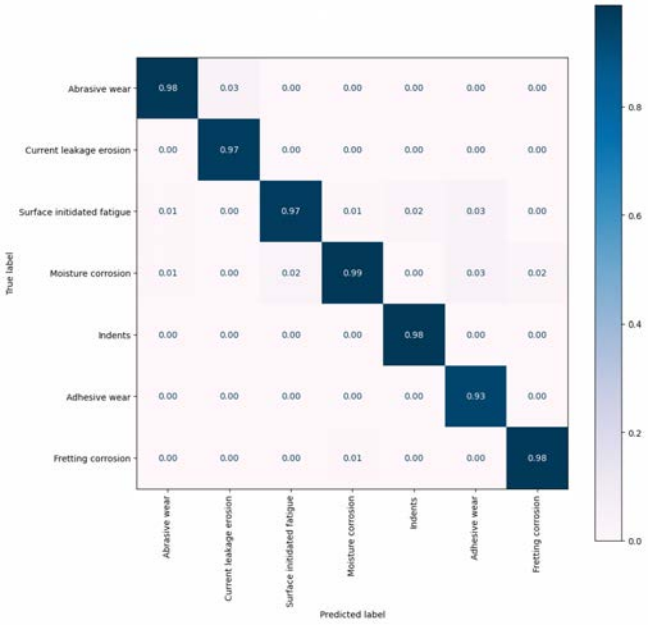

Figure 7. *Confusion matrix for the top performing model (RetinaNet - ResNet 101, fpn) model applied to the test set. Displayed results pertain exclusively to images with predictions.*

In evaluating the performance of the object detection models, we have observed a notable discrepancy between the model's precision and recall, as measured by the COCO metric system. Specifically, our model demonstrates high precision (as shown in Figure 7), indicating a strong ability to correctly identify and label objects when it decides to do so. However,

this is adjacent to a significantly lower recall, suggesting that the model is more conservative in its detection, often missing objects that should have been detected. This characteristic leads to a lower overall COCO metric score, which incorporates both precision and recall into its evaluation. Despite this, the high precision of our model still presents substantial utility in specific applications where the cost of false positives is high, and accuracy in the detection of identified objects is paramount. In such scenarios, our model's ability to minimize incorrect detection — ensuring high confidence in the positive detection it makes — can be more valuable than detecting every possible object, underscoring the importance of considering application-specific requirements when evaluating model performance. Therefore, while the overall COCO metric may be lower, the high precision of our model affirms its applicability and effectiveness in contexts where precision is critically valued over recall.

5. Conclusion

The model, selected through bench-marking various neural network architectures, was trained to detect seven primary bearing failure modes, addressing challenges such as class imbalance and image rotation inconsistencies. Key to the success was the meticulous collection and preparation of images. A dataset comprising 11k images of bearings with annotated failure modes was curated to train the model. Through thorough data gathering, precise annotation, and strategic data augmentation, we created a robust dataset that improved the accuracy of the model and real-world applicability. RetinaNet, with its ResNet 101 - fpn backbone, was chosen for its performance. This work shows the feasibility of such a model to be used in an assistive tool where failure modes give insights on how to prolong average future bearing life in an asset and therefore reduce related costs and environmental impacts.

ABSTRACT

To assist subject matter experts in investigating electronic failures of drilling tools, an innovative risk assessment approach for oil well drilling operations is developed that relies on synthetic time-series data to emulate environmental factors encountered downhole, explicitly focusing on temperature, shock, and vibration. The approach involves utilizing load cycle counting to extract meaningful features from each environmental channel measured by the drilling tool. The results from experiments with features related to dwell periods (dwell time and dwell damage) and load cycles (cycle means and cycle ranges) show a significant correlation between load cycle features and the risk label. Subsequently, a tree-based machine learning model is trained to label drilling operations based on synthetic data. Several models have been trained initially with comparable results. However, the advantage of using a tree-based model, specifically extra trees, is explainability and the stochastic aspect, which translates into model robustness when applied to real data. Preliminary results from a case study indicate that this new approach is highly effective in categorizing environmental risks associated with drilling operations. This risk assessment method can significantly enhance the decision-making process in investigating electronic board failures by offering reliable decision support.

1. INTRODUCTION

The drilling process has undergone a remarkable transformation in the oil and gas industry, evolving into a complex and sophisticated endeavor. This increased complexity stems directly from the necessity of accessing and extracting valuable resources hidden deep within the earth's crust. To accomplish this daunting task, the industry relies heavily on drilling tools, which are the technological cornerstones of these operations.

Drilling tools represent exceedingly intricate systems enriched with electronics, comprising a multitude of electronic boards, each meticulously designed to fulfill specialized functions of paramount significance to the success of drilling operations. These electronic boards function as the central hubs of technological operations, assuming responsibilities encompassing data acquisition, signal processing, management of control systems, and the facilitation of seamless communication (Kang et al., 2022). Thus, the reliability and performance of these electronic boards are inexorably linked to the overall effectiveness of drilling endeavors. However, the harsh operating conditions encountered downhole, including elevated temperatures, dynamic vibrations, and substantial shocks, render these boards susceptible to complex failure modes, potentially resulting in drilling operation failures. Failed drilling operations can lead to significant financial losses and environmental concerns. Therefore, health assessment and prognostics of electronic boards in drilling tools is essential to ensure that proactive maintenance is carried out in advance to

prevent drilling operations from failing.

The current health assessment and prognostics models for electronics are predominantly data-driven. For instance, physics-of-failure-based prognostics combine sensor data with models that evaluate a component's deviation from normal operation (Pecht & Gu, 2009). Another example is the use of accelerometers to monitor the response of printed circuit boards to vibrations and predict their remaining life (Gu, Barker, & Pecht, 2009). Similarly, (Vichare & Pecht, 2009) propose a technique that extracts load parameters from time-series data to estimate remaining life and assess damage. This method focuses on identifying valuable features for prognostics without requiring the storage of large volumes of data. Additionally, (Prisacaru, Gromala, Han, & Zhang, 2022) detect faults in electronic packages through the Mahalanobis distance and clarify them using a clustering technique. They also employ Echo state networks to perform degradation assessment and remaining useful life prediction. Additional literature on data-driven approaches for electronics health assessment and prognostics can be found in the following review articles: (Bhat, Muench, & Roellig, 2023), (Bhargava et al., 2020), and (Michael G. Pecht, Myeongsu Kang, 2018).

In the context of electronic boards used for oil well drilling operations, (Kale, Carter-Journet, Falgout, Heuermann-Kuehn, & Zurcher, 2014) propose a probabilistic approach that uses operational data, drilling dynamics, and historical maintenance information to predict reliability and life of electronics. (Bhatnagar, Cassou, Masry, & Mosallam, 2021) develop a data-driven fault detection approach tailored to electronic boards in intelligent remote dual-valve systems . Similarly, (V. Gupta et al., 2023) present an automatic fault detection method based on support vector machines for resistivity subsystems in Logging-While-Drilling (LWD) tools. (Sobczak-Oramus, Mosallam, Basci, & Kang, 2022) introduce a data-driven fault detection approach for transmitter subsystems in LWD tools . Finally, (Mosallam, Kang, Youssef, Laval, & Fulton, 2023) propose a data-driven fault diagnostics approach for three power supply boards in LWD tools.

Obtaining comprehensive data and corresponding labels throughout the equipment lifecycle is essential for building data-driven models for health assessment and prognostics of electronics. Subject matter experts usually derive data labels through failure investigations, but this process can be costly and time-consuming for complex equipment. Specifically, investigating electronic board failures in drilling tools requires manually examining extensive operational environment data measured by the tools. This process is labor intensive and prone to human error, making it challenging. Considering this challenge, this paper proposes an innovative risk assessment approach for oil well drilling operations to assist subject matter experts in investigating electronic failures. One of the primary advantages of this approach is its ability to harness the power of supervised learning for efficient and objective risk assessment, compared to manual inspections of operational environment data.

Literature has shown that various factors, such as temperature, humidity, vibration, dust, electrical stress, etc., affect the performance and life of electronic components (Michael G. Pecht, Myeongsu Kang, 2018). Among these factors, failures attributed to environmental conditions like temperature, humidity, and vibration constitute a significant 84% of electronic failures (Bhargava et al., 2020). Given the paramount importance of environmental factors in electronic failures, this paper seeks to develop a method to aid the subject matter experts investigate the specific environmental factors contributing to electronic failures.

However, only temperature and vibration are considered in the proposed method. We did not account for potential factors such as dust, humidity, chemicals, and radiation. This omission is because drilling tools do not typically measure these parameters for electronic boards. The physical arrangement of electronic boards within these tools inherently protects against exposure to dust, humidity, radiation, and chemicals that may be present in the wellbore. These tools are typically enclosed within robust steel tubing, shielding internal electronics from direct contact with these environmental factors. Moreover, before tool deployment, field engineers frequently introduce nitrogen into these tools, reducing the likelihood of exposure to potentially harmful substances. As a result of these protective measures and practices, the risk of electronic board damage due to dust, humidity, radiation, and chemical exposure is significantly mitigated.

The rest of this paper is structured into four sections. The first section offers a detailed presentation of the proposed method. Following that, a case study is presented. Finally, the last section summarizes the findings and suggests potential avenues for future research.

2. Proposed Method

The proposed method consists of three steps: data generation, preprocessing and feature extraction, and modelling, as illustrated in Figure 1.

2.1. Data generation

To leverage the power of supervised learning, labeled environmental data are needed. We generate synthetic time series programmatically to remove the need for expert-labeled data. Drilling tools regularly record measurements concerning the environment, specifically, temperature, shock peak values, and vibration root mean square values; therefore, in our experiment, we generate synthetic time series data that emulate drilling conditions for each of the three channels. The simulated data incorporate various sources of random-

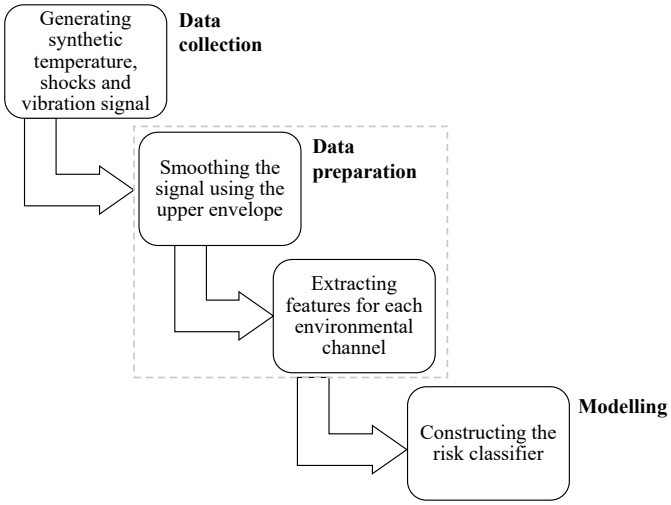

Figure 1. Proposed method.

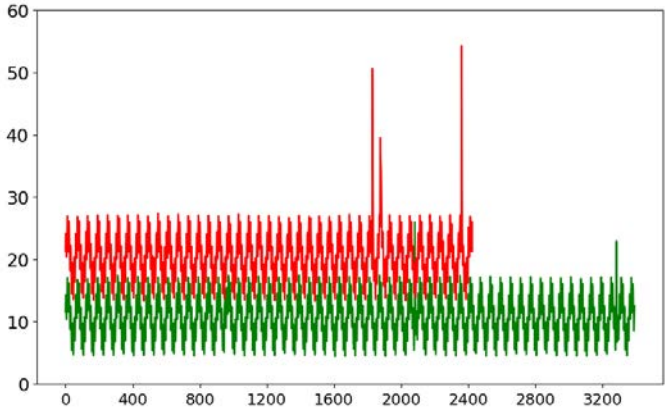
ness, including sinusoidal waves with random time-variant amplitude and frequency, Gaussian noise, random spikes, and random shocks with random decay rates. Specifically, low-risk time series data exhibit lower parameter values for random number generation than high-risk time series data. For instance, the mean and standard deviation for generating low-risk temperature data's Gaussian noise are set to 40 and 3, respectively, while the amplitude for temperature shocks falls between 30 and 70. On the other hand, the mean and standard deviation for generating high-risk temperature data's Gaussian noise are set to 80 and 10, respectively, while the amplitude for temperature shocks falls between 50 and 100.

2.2. Data preparation

To effectively use the generated environmental data, preprocessing and optimal feature extraction are required. The preprocessing step consists of smoothing the signal using the upper envelope of the signal, as shown in Figure 2. After the preprocessing step, the environmental features can be extracted. For each environmental channel (i.e., temperature, shocks, and vibration) we compute two features based on dwell periods and two features based on load cycles, using the rainflow cycle counting method for the latter (Lee & Tjhung, 2012).

(a) Raw signal



(b) Preprocessed signal

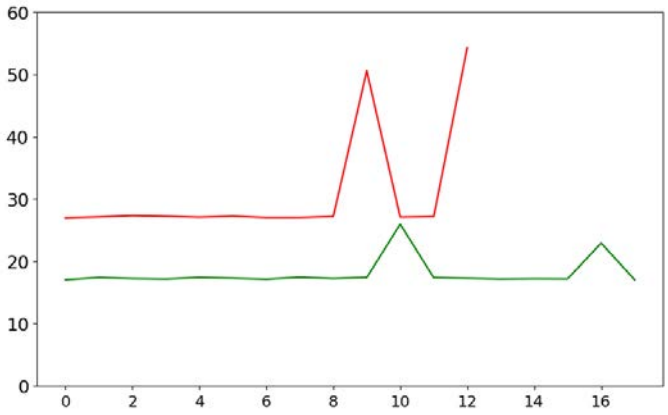


Figure 2. Generated vibration signal for a high-risk run (red) and a low-risk run(green), before and after preprocessing.

2.3. Feature extraction using rainflow cycle counting

Rainflow cycle counting is a method used in fatigue analysis to quantify the number of stress cycles experienced by a component or material (Endo, 1974).

The process involves analyzing a time series of stress or strain data to identify and count individual cycles. These cycles represent the repeated loading and unloading of a material, which can lead to fatigue failure over time. Rainflow cycle counting is especially useful for irregular or variable ampli-

tude loading conditions, where the stress levels vary over time (Lee & Tjhung, 2012).

The method consists of four steps, as illustrated in Figure 3:

1. *Hysteresis filtering* (Figure 3a) entails removing cycles smaller than an amplitude gate that contribute minimal damage. This is accomplished by setting a gate with a specific amplitude. Any cycle with an amplitude below this gate is excluded from the load-time data. The gate is projected sequentially from left to right starting from each turning point in the time series. If a turning point falls below the gate's threshold, it is omitted from the time history. (Endo, 1974)(Lee & Tjhung, 2012).
2. *Peak-valley identification* (Figure 3b) consists of locating the points in the data where the direction of the signal reverses. In a cycle, only the highest and lowest values are pertinent for fatigue life assessments. Therefore, any intermediate data points between these extremes within a cycle can be disregarded as they do not contribute to the fatigue calculation. (Endo, 1974)(Lee & Tjhung, 2012).
3. In *discretization* (Figure 3c), the amplitude dimension of the signal is divided into a set number of equal bins. Each data point is then mapped to the center of its corresponding bin to facilitate cycle counting. Centering the data samples within their bins slightly modifies their amplitudes, therefore it is crucial to utilize an adequate number of bins in the analysis to minimize significant alterations in amplitudes (Endo, 1974)(Lee & Tjhung, 2012).
4. In *four-point counting* (Figure 3d), the identified peaks and valleys are connected to form hysteresis loops, or closed paths that represent complete stress cycles (Endo, 1974)(Lee & Tjhung, 2012). This is done using the following steps:
   (a) Select four consecutive points: $S1, S2, S3, S4$.
   (b) Compute inner stress: $|S2 - S3|$.
   (c) Compute outer stress: $|S1 - S4|$.
   (d) If the inner stress range is less than or equal to the outer stress range, a cycle is counted, otherwise it is not counted.

Using the method described above, the extracted features are as follows:

1. *average cycle mean*, where the cycle mean represents the mean values of the initial and final points of a cycle
2. *average cycle range*, where the cycle range represents the absolute difference between the initial and final points of a cycle
3. *dwell time*, representing the cumulative time during which the signal oscillation is lower than a set threshold
4. *dwell damage*, representing the average amplitude during the dwell time

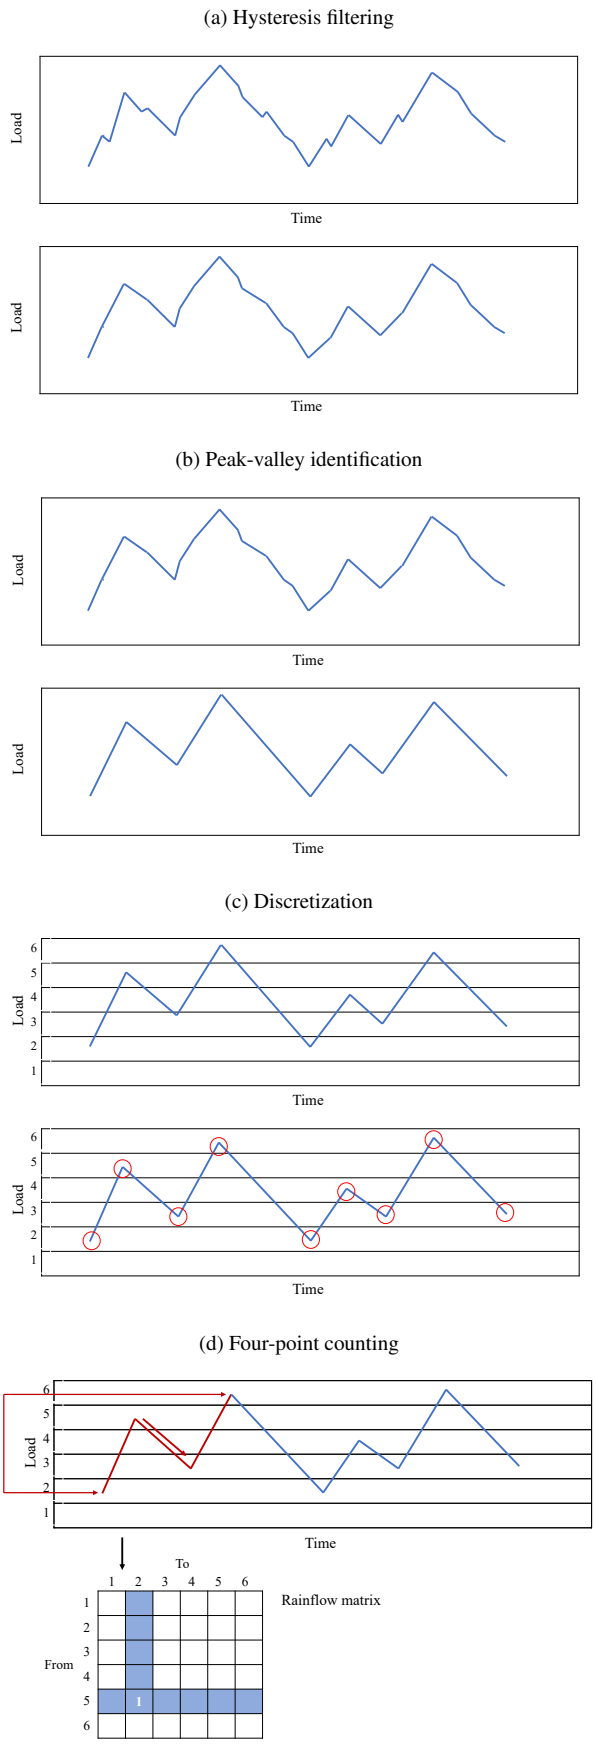

Figure 3. Rainflow cycle counting steps.

		Predicted label	
		Positive	Negative
Actual label	Positive	True positive (TP)	False negative (FN)
	Negative	False positive (FP)	True negative (TN)

Figure 4. Confusion matrix for a binary classification problem.

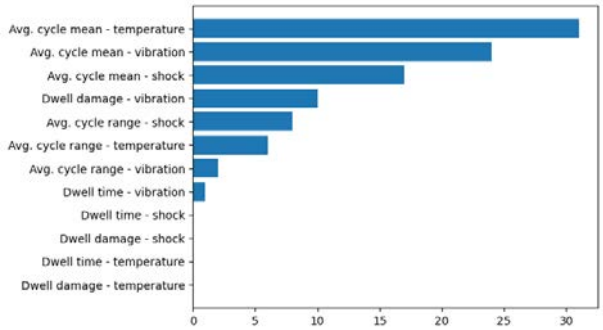

Figure 5. Model feature importance.

2.4. Modelling

We model the problem as a binary classification problem, where we interpret the positive class as high environmental risk, and the negative class as low environmental risk.

For risk classification three models were trained: logistic regression (LaValley, 2008), random forest (Biau & Scornet, 2016), and extra trees (Geurts, Ernst, & Wehenkel, 2006). The random forest and the extra trees models consist of an ensemble of 100 trees, and the Gini index was used as the splitting criterion. Logistic regression, as well as the ensemble tree-based models are less prone to overfitting and thus have the potential to generalize better to real data.

3. Case Study

A number of 1128 examples were generated, out of which 80% were used for training and 20% for testing. The training set was further split into train and validation sets in the same ratio using k-fold cross validation with 10 folds. The data were split as to preserve the class balance.

To evaluate the models on a labeled subset of the data we make use use of the confusion matrix (Fawcett, 2006), illustrated in Figure 4. In a binary classification problem, the confusion matrix has four sections:

1. True positives (TP): the number of instances where the model correctly predicts the positive class (high risk).
2. True negatives (TN): the number of instances where the model correctly predicts the negative class (low risk).
3. False positives (FP): the number of instances where the model incorrectly predicts the positive class.
4. False negatives (FN): the number of instances where the model incorrectly predicts the negative class.

To compare the models, we use the area under the receiver operating characteristic (ROC) curve (ROC AUC score). The ROC curve plots the true positive (TP) rate, defined as

$$\frac{TP}{TP + FN},$$

against the true negative (TN) rate, defined as

$$\frac{TN}{TN + FP}$$

It is a graphical representation of a binary classifier at different classification thresholds. The ROC AUC score is represented by the area under the ROC curve, where a score of 0.5 indicates a random model (Bradley, 1997).

The three trained models output a ROC AUC score of 1 on the validation set, indicated in Table 1. The application of the trained models is to assess environmental risk on electronic boards. Therefore, an important aspect is the ability of the model to successfully transfer knowledge from synthetic data to real data. In this regard, the stochastic features of the extra trees represent an advantage for increasing robustness (Geurts et al., 2006).

Table 1. Comparative ROC AUC score for the three trained models.

Model	ROC AUC score
Logistic regression	1.00
Random forest	1.00
Extra trees	1.00

We evaluate feature importance for the classification problem using Shapley values. This step helps to reduce feature redundancy and improve model interpretability. Shapley values are a method derived from cooperative game theory that has been adapted for use in explaining the predictions of machine learning models. They provide a way to fairly assess the impact of each feature for a particular prediction in a model (Merrick & Taly, 2020).

Using this method, Figure 5 indicates that for the extra trees model, the most impactful features are the average cycle means on each environmental channel, which is consistent with the feature correlation matrix in Figure 6.

Feature correlation in a machine learning model refers to the

Figure 6. Feature correlation matrix.

degree to which the variables (features) in the dataset are related to each other, as well as with the target variable. For this experiment we use the Pearson correlation coefficient (Kendall & Stuart, 1973) and we specifically study the correlation between the features and the target variable, denominated as risk. In Figure 6 we notice the highest correlation between the average cycle means on the temperature, shock and vibration channels, and the risk variable.

In the second iteration of experiments, we restrict the training to these three features.

During the validation step, the model achieves promising classification results, as indicated by the confusion matrix in Table 2. Based on the confusion matrix, we define the following metrics:

$$Accuracy = \frac{TP + TN}{TP + TN + FP + FN}, \tag{1}$$

$$Precision = \frac{TP}{TP + FP}, \tag{2}$$

$$Recall = \frac{TP}{TP + FN}, \tag{3}$$

$$F1score = \frac{2 * TP}{2 * TP + FP + FN}. \tag{4}$$

The results on the validation set are consistent with the results on the test set after the training is completed, which can be seen in Table 3, despite the 0.52 score for data drift. Data drift indicates a difference in the statistical properties of the data. Therefore, the classification scores prove the robustness of the extra trees model and the potential for such a model to be used for assessing risk on real data.

Table 2. Confusion matrix on the validation set, where the positive class is equivalent to a high-risk run and the negative class is equivalent to a low-risk run.

	Predicted positive	Predicted negative
True positive	93	0
True negative	0	86

Table 3. Metrics measured on the test set.

Metric	Value
Accuracy	1.00
Precision	1.00
Recall	1.00
F1 Score	1.00
ROC AUC	1.00
Data drift	0.52

4. Conclusion and Future Work

This paper presented a data-driven approach for assessing environmental risk in electronic boards based on supervised machine learning. The method makes use of synthetic data and consists of extracting features with respect to dwell time and load cycles, showing that the latter have a larger impact on the performance of the models. The extra trees model achieves promising results on the synthetic data, but further work is needed to address the potential mismatch between training and test data in practical applications.

To address this issue, we plan to collect real-world environmental data and use it to fine-tune the model to better handle the variability of different environments. Additionally, we could explore the use of transfer learning techniques to adapt the model to new environments and improve its robustness to different types of data.

Overall, the proposed approach shows potential for assessing environmental risk in electronic boards, but further research is needed to optimize the model for real-world applications.

ABSTRACT

This paper introduces a cutting-edge methodology for the monitoring of abrasive wear, particularly focusing on SAG (Semi-Autogenous Grinding) mills liners. The lack of a regular inspection regime has historically led to opportunistic and thus, irregular wear measurements that are challenging to integrate into machine learning algorithms for condition-based maintenance. The study unveils a virtual sensor designed to estimate the mill liner's remaining thickness, aiming to offer daily updates and assist the maintenance team in determining the optimal timing for liner replacements without the need for halting operations. This approach is positioned as a strategic response to the critical need for efficient maintenance strategies, addressing the inherent challenges in real-world industrial settings where data quality may be poor and operational realities dominate. A significant aspect of this methodology is its emphasis on uncertainty quantification, vital for informed maintenance decision-making. This novel approach has been successfully applied to SAG mills at Minera Los Pelambres, showcasing its potential for broader applications across scenarios characterized by sporadic data collection. The results showcase an error of ±7.4254 mm of remaining thickness on the validation set, demonstrating the effectiveness of the methodology. The key contributions of this work lie in its ability to utilize low-quality data effectively and its low complexity, reducing barriers to implementing predictive health monitoring (PHM) algorithms. The successful implementation highlights the methodology's adaptability and flexibility, marking a significant advancement in the domain of maintenance strategy for the mining industry.

1. INTRODUCTION

SAG (Semi-Autogenous Grinding) mills are indispensable assets in the mining industry, serving as the cornerstone of ore processing operations. The significance of these mills cannot be overstated, as any downtime incurred due to maintenance activities can translate into substantial financial losses. The costliness of SAG mill stoppages underscores the critical need for effective maintenance strategies to ensure continuous operation and productivity.

Within the maintenance team at Minera Los Pelambres, there arose a strategic initiative aimed at reducing the duration of mill downtime attributed to inspections. To support this endeavor, the concept of the virtual remaining liner sensor was conceived. A virtual sensor, by definition, offers an approximation of a state based on other measurable variables or states, serving as an indirect measurement. In this instance, the objective was to estimate the remaining thickness in millimeters of a specific component of the mill liner online and with daily frequency updates. The overarching goal was to provide the maintenance team with a decision support tool to determine the optimal timing for liner replacement without necessitating mill shutdowns solely for inspections. One of the major challenges in implementing this system was the absence of a regular inspection schedule for the mill. Historically, inspections were performed opportunistically, aligned with planned mill shutdowns. This approach resulted in irregular wear measurements, complicating their utilization in ML algorithms designed to predict wear and determine the remaining liner thickness accurately.

The endeavor to minimize downtime due to maintenance activities has long been a focal point, with condition monitoring tasks representing approximately 13% (Kawahata, Schumacher, & Criss, 2016) of total mill downtime. Traditional

approaches to address this challenge, such as discrete element method (DEM) (Wu, Che, & Hao, 2020) simulations, have proven to be exceedingly complex and costly to implement in productive environments, necessitating expensive software and extensive time investments to achieve realistic simulations.

This paper presents a methodology specifically tailored to address the challenges inherent in real-world industry environments, where data quality is often poor, and operational considerations are paramount. By focusing solely on wear monitoring issues prevalent in the industry, this methodology emphasizes the importance of incorporating operational insights into the model design to ensure effective utilization by maintenance teams. The majority of degradation monitoring algorithms are developed using synthetic data or data obtained under suitable acquisition settings, like the measuring method proposed in (Powell & Chandramohan, 2011) (appropriate and stable sampling rates, low measurement error). However, few academic works focus on solving real-world problems where data quality is poor, as the results are naturally less impressive than those generated in studies with high-quality laboratory data, enabling the use of state-of-the-art machine learning algorithms to achieve high precision (Li et al., 2022). The most significant contribution of this work is to provide a methodology that utilizes low-quality data to its fullest potential. The low complexity of the method reduces the barriers currently faced by the industry in implementing PHM algorithms.

This challenge is predominantly practical rather than theoretical, as the methodology was conceived with real-world industrial scenarios in mind, the approach is quite easy to implement. Leveraging neural networks and feature engineering based on phenomenology, the proposed approach is successfully implemented to monitor the liners of SAG Mills at Minera Los Pelambres, providing a decision-support tool for the maintenance team. The methodology is designed to infer deviations from an average wear rate curve, utilizing features that represent stress factors on the mill derived from both historical lining data and real-time mill operation information. The predictive modeling aspect of the methodology employs neural networks, these networks offer accurate inferences of wear progression, allowing for proactive maintenance strategies and the timely identification of potential issues. Complementing the data-driven approach, the methodology incorporates feature engineering grounded in the phenomenology of abrasive wear. This ensures that the monitoring scheme is not solely reliant on learned patterns but also integrates domain knowledge, enhancing interpretability and generalization. A distinctive feature of the methodology is its focus on uncertainty quantification in wear monitoring during the online operation of the model, this is crucial for decision-making, providing the maintenance team with insights into the reliability of wear assessments and facilitating the prioritization of maintenance interventions.

Incorporating uncertainty quantification in industrial monitoring is essential for enhancing intelligent maintenance decision-making. This approach provides a probabilistic perspective on operational data, facilitating a more nuanced understanding of equipment behavior and maintenance needs. The key benefits include:

1. **Enhanced Decision-making**: Uncertainty quantification allows for informed, risk-aware decision-making. By understanding the range of possible outcomes and their probabilities, maintenance teams can make decisions that improve safety, operational efficiency, and financial performance.

2. **Optimized Maintenance Scheduling**: It aids in identifying the most opportune moments for maintenance actions, balancing preventive and corrective strategies. This optimization minimizes operational disruptions and costs while extending equipment lifespan.

3. **Risk Management**: Understanding model uncertainty helps in managing the risks associated with maintenance activities. Identifying high-risk scenarios enables prioritization of critical maintenance interventions, ensuring operational continuity and safety.

4. **Confidence in Predictive Models**: Quantifying uncertainties builds confidence in predictive maintenance models by transparently communicating their reliability. This transparency is crucial for trust among operational staff and stakeholders.

The successful implementation on SAG Mill liners at one of the world's largest copper mine validates the methodology's efficacy. Beyond its application to this specific context, the methodology is highlighted for its flexibility and adaptability to other scenarios. Notably, it accommodates few and irregular measurements of the asset's state, making it applicable in situations where data collection may be limited or sporadic.

However, unlike traditional approaches such as discrete element method (DEM) simulations which are complex and costly to implement, this methodology provides a straightforward and cost-effective alternative. By leveraging low-quality data and emphasizing uncertainty quantification, we address the practical challenges faced in real-world industrial settings. This approach not only simplifies the implementation of PHM algorithms but also ensures robust predictions even with sporadic data collection. Additionally, the incorporation of phenomenology-based feature engineering enhances the interpretability and reliability of the model, setting it apart from purely data-driven methods.

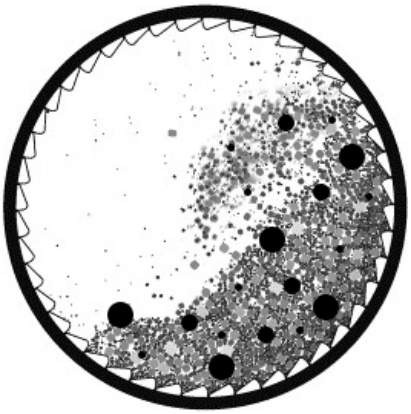

Figure 1. SAG Mill illustration.

2. SAG MILLS BACKGROUND

SAG mills consist of rotating drums containing metal balls that cascade and impact against the mineral (Figure 1), effectively grinding it. The collision between grinding balls and mineral particles fractures and further grinds the mineral, producing finer material. SAG mills are distinguished by their large diameter and short length compared to ball mills. The interior of the mill is lined with lifter plates to lift the material inside, facilitating the cascading material flow for grinding. Figure 1 illustrates this operation. Various lifter configurations and positions line the interior of the mill. Of particular interest is the discharge end cap, where worn or fractured components could lead to ball escape and downstream processing issues.

To assess the condition of the mill liners, a procedure known as a ”faro” is typically conducted. A faro is akin to a radiographic examination of the mill, providing precise measurements of the liner condition. However, these stoppages are costly. There has never been a consistent schedule for the faros, therefore the sampling rate is inconsistent, the only constant measurement made is at the end of the liners life when it is removed from the mill. The virtual sensor developed in this study aims to reduce the frequency of faro inspections, offering online monitoring capabilities to track the remaining liner thickness, particularly focusing on the discharge end cap, where liner failure poses significant operational risks.

The availability of SAG mills is paramount in mineral processing, as every hour of downtime translates to substantial financial losses, valued in thousands of dollars. Optimization of maintenance activities is crucial to minimize mill stoppages, balancing the risk of failure with maintenance requirements.

Given the criticality of mill uptime, any condition monitoring initiative aiding in optimal maintenance scheduling adds significant value. The virtual sensor developed in this study aligns with this objective, providing the maintenance team with decision support tools to optimize faro inspection schedules without necessitating mill shutdowns. This approach not only reduces downtime but also mitigates the risk of operational disruptions downstream.

The current market offers various solutions for monitoring the liners of SAG mills, each with its own set of advantages and challenges. Many of these solutions rely on expensive hardware or require interventions directly on the mill cylinder (Dandotiya, Lundberg, & Wijaya, 2011). However, few effectively leverage historical data to optimize monitoring processes.

One significant challenge is the difficulty of integrating additional monitoring equipment into large-scale machinery already in production. SAG mills are massive industrial units critical to the mineral processing chain, and any modifications or additions to these machines must be carefully implemented to avoid disrupting operations. Installing new monitoring devices often involves intricate engineering work and may require halting production for extended periods, leading to significant downtime and revenue loss for mining companies.

Moreover, the harsh operating conditions within SAG mills present further challenges. These mills operate in environments characterized by high temperatures, dust, and vibrations, which can adversely affect the performance and longevity of monitoring equipment. Ensuring the reliability and durability of monitoring devices under such conditions is essential but often requires additional investments in ruggedized hardware and protective enclosures. Mill liners are located deep within the mill cylinder, necessitating specialized equipment and skilled personnel for installation and maintenance tasks. Any monitoring solution that requires frequent access to the liners may incur significant logistical challenges and operational disruptions.

In light of these difficulties, there is a growing need for innovative monitoring solutions that can leverage existing data infrastructure and minimize disruptions to mill operations. Solutions that harness historical data and employ non-intrusive monitoring techniques offer promise in this regard, providing valuable insights into liner wear patterns while minimizing the need for costly hardware installations and production stoppages.

At Minera Los Pelambres, where three SAG mills—SAG1, SAG2, and SAG3—are operational, the focus is primarily on SAG1 and SAG2 due to their comprehensive data records and identical machinery specifications. The successful replication of the methodology for SAG3 underscores its potential scalability and applicability across multiple mill units, albeit not covered in this document.

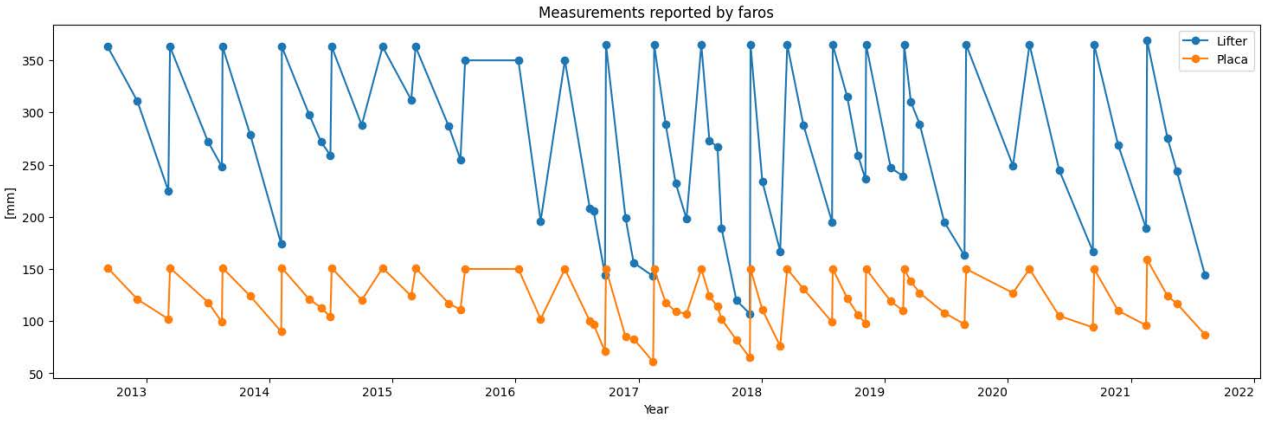

Figure 2. Historic remaining liner mesurements SAG1.

3. Data and Processing

The methodology involves two primary data sources: operational tags related to the mill's functioning and mineralogy, and liner wear measurements reported through inspections. Operational tags, which are time series data from sensors or states, can be extracted at various granularities, they are stored via Pi Systems, a platform for operational data management developed by OSIsoft. It plays a crucial role in this project by serving as the source of operational data. This platform captures, stores, analyzes, and visualizes real-time data from industrial processes. Pi System has its own data cleaning protocols which are critical to ensuring data quality and reliability before analysis, and these protocols were considered in the project's data processing strategy. Given that Pi Systems are commonly used across various industries to manage data, it is important to delve into how data is handled and processed within the methodology. The first step in data processing involves cleaning and imputing these tags. The main issues addressed in the data are outliers, non-numeric values, and missing values. The cleaning process categorizes tags into four types:

- Tags representing percentages: Values above 100 or below 0 are set as NaN (empty value).
- Tags for positive variables with distributions similar to normal: Values below zero and those above the 99th percentile distribution (outliers) are set as NaN.
- Binary variable tags, which include two variables:
  - Rotation direction: Non-numeric values are present, with two relevant states indicating clockwise and counterclockwise rotation. Clockwise is replaced with 1, counterclockwise with -1, and other messages with NaN, to then interpolate them with the closest value.
  - Mill state: Relevant messages indicate whether the mill is stopped (0) or operating (1). Other messages are set to 0.
- Tags that do not require cleaning.

Non-numeric values, often error messages from the tag storage system, are addressed next. Messages indicating a value above/below defined ranges are replaced with the tag's post-cleaning maximum/minimum value. Remaining NaN values are imputed linearly. The tags are cleaned on an hourly basis, including:

- Grinding hardness
- Feed water
- Load cell
- Stator current
- Noise detector
- F80
- Rotation
- Granulometry (of the incoming mineral) 100, 200, 325, 48, 65, 125 Inches
- Filling level
- Solids percentage
- Power
- Pressure
- Noise
- Speed

Following the removal of non-numeric values, data transformation begins, incorporating liner wear measurements. The term 'campaign' refers to the lifespan of the lining. A campaign begins when the lining is installed and ends when it is retired. These measurements are taken with the mill stopped and vary across campaigns, with up to 5 intermediate measurements in some campaigns and a median of 3. The above Figure (2) shows SAG1 grate wear monitoring over time, with two curves representing different grate positions as reported by faros. Points on the curves are measurements, and lines

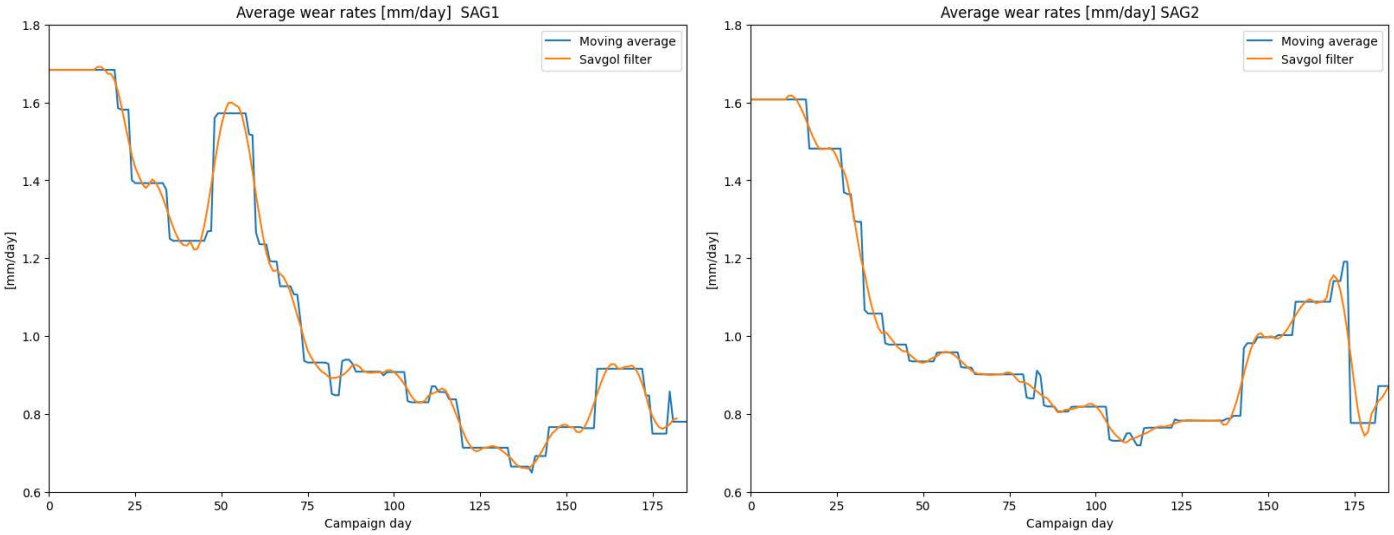

Figure 3. Average wear curves for the lifter position.

represent linear interpolations between points. This highlights the irregularity and varying wear rates in SAG1's history, a pattern consistent across other mills. Almost all the campaigns have a measurement at the start of the lining's lifespan and one near to its end.

Within each campaign, segments between contiguous measurements are defined to calculate consumed thickness and total operational hours, yielding a wear rate in [mm/hour], which is converted to [mm/day]. The objective is to update the liner's remaining millimeters daily. To achieve this, average wear rate curves for SAG1 and SAG2 are calculated (Figure 3). Operational days within each campaign are assigned a wear rate, and using all campaigns, daily wear rates are averaged to produce the curves shown in the next figure. A Savgol filter is applied to obtain the final average wear curve used throughout the study.

The difference between the curves is mainly due to SAG2 receiving more recirculated material, which is less abrasive. Finally, new variables are generated, including accumulated minaral-flows, moving averages, time window dispersions, and others detailed below, aggregated daily and indicating the mill's operational percentage per day.

- Accumulated mineral-flow.
- Clockwise mineral-flow.
- Counter-clockwise mineral-flow.
- Accumulated counter-clockwise flow.
- Accumulated clockwise flow.
- Velocity dispersion over a 72-hour window.
- Accumulated velocity dispersion sum.
- Accumulated power (electric consumption).
- Load cell weight moving average.
- Load cell weight dispersion over a 72-hour window.
- Accumulated load cell weight dispersion sum.
- Noise power moving average.
- Noise power dispersion over a 72-hour window.
- Accumulated noise power dispersion sum.
- Operational day of the campaign.
- Day of the campaign.
- Percentage of clockwise operation time during the campaign.

These enhancements prepare the variables for model input, with accumulations specific to each campaign.

4. Proposed Methodology

The initial decision was to utilize a unified model for both SAG1 and SAG2, justified by the fact that they are essentially the same machinery, albeit with some operational differences. All input variables are aggregated on a daily level, aiming for the model to approximate daily wear of the mill, subsequently accumulating it throughout the campaign for real-time wear monitoring.

After defining the model's input variables, the next step was addressing its output. Resulting from the daily aggregation of data, each data row contains the daily average of tags and created variables, a daily mill utilization percentage, and the interpolated wear rate for that specific day. However, the model does not output this daily wear rate directly; instead, it uses the deviation from the interpolated wear rate compared to the previously mentioned average rates. The creation of the output for the regresor and the histogram of this deviations is

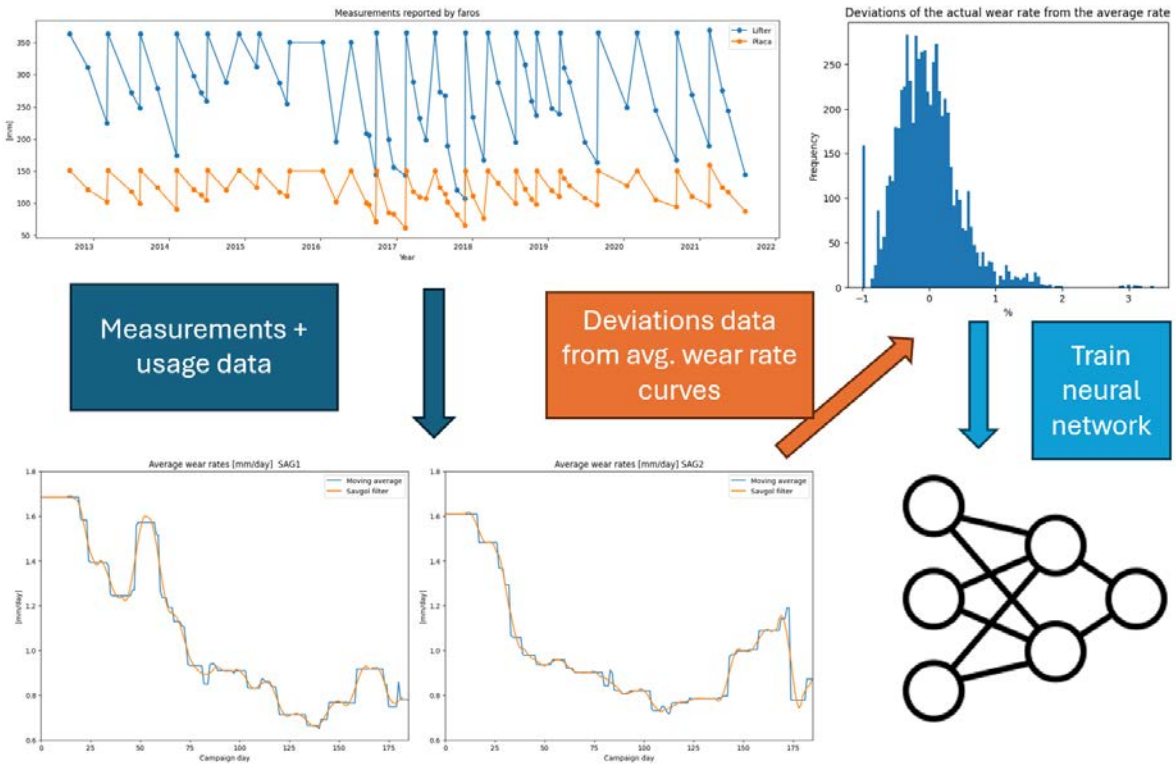

Figure 4. Computation of the deviations from the average wear rate curve.

illustrated in Figure (4). The wear expression in Equation (1) is derived based on the cumulative effect of daily operational conditions on the liner's wear rate. Specifically, we start with the basic principle that the wear on any given day is influenced by both the average wear rate for that day and deviations due to specific operational conditions. Mathematically, this can be expressed as:

$$s(T) = \sum_{i=1}^{T} (\delta_i + \delta_{model}(x_i)) * \alpha_i \tag{1}$$

where T denotes the current day, s represents the lining state measured in millimeters, δ_i is the average wear rate for operational day i, δ_{model} is the model's output, x_i is the model input, and α_i is the day i utilization percentage.

The training set was determined by selecting campaigns with a significant number of measurements to create average wear curves. Considering the irregularity of measurements per campaign and their impact on model training, campaigns with only one intermediate measurement, typically towards the campaign's end, were excluded from the training set (and included in the validation set) due to their limited information contribution about the wear pattern. Thus, the training set comprised 36 campaigns, with a testing set of 8 campaigns chosen for their recency (in order to test the methodology with the most recent campaigns) and lack of more than one measurement.

To train the model, only days from the training campaigns with at least 21 operational hours were used, addressing the distinct data distribution during mill stoppages or startups. The model (in production and testing) was fed all days regardless of operational hours, adjusting outputs by the calculated utilization percentage to prevent unexpected results from low-operation days.

Several types of regressors were tested, including linear regression, decision trees, and support vector machines; however, the neural network was chosen due to its superior interpolation capability and its effectiveness in handling the complexities and variations present in the historical wear data. A Multi-Layer Perceptron (MLP) neural network with three hidden layers and slight dropout was trained using the training set, aiming to minimize the error between the prediction and the actual deviation from the average wear rate curve. The network's performance was then tested against the validation campaigns, focusing on minimizing the projection error, defined as:

$$e_{proy} = \sqrt{\sum_{k=0}^{N} (s^k(T) - s^k_{real}(T))^2} \tag{2}$$

where k indexes the validation campaigns, and $s^k_{real}(T)$ rep-

resents the actual liner measurements for that campaign in millimeters.

The network's output represents a percentage deviation, which is then converted to millimeters of liner wear before being adjusted by the daily utilization percentage, ensuring the model accurately reflects operational impact on wear. The distinction between the metric training the neural network and the projection error metric highlights the goal of accurately modeling the actual mill state through the accumulation of neural network results.

5. RESULTS

Recalling from the previous section, the model was developed for the component known as the grate, which, as shown in Figure 2, is monitored at two positions on the grate, named lifter and plate. Therefore, there are two models, one for each position, and the results for both models, which follow the exact procedures described earlier, will be reported. The best model generated for the plate achieved a projection error of 7.4254 mm, whereas the lifter model had an error of 8.701 mm. Below is the table highlighting the projection errors for both models, two example campaigns (Figures 5 and 6) are given in order to illustrate the performance of both models, comparing their results with the faros and with the curve generated by integrating the average wear rates (also weighted by the daily utilization rate), which will serve as a reference. The projection error obtained for those two validation campaigns is also reported.

Table 1. Reported Projection Errors

Model Position	Projection Error (mm)
Plate	7.4254
Lifter	8.701

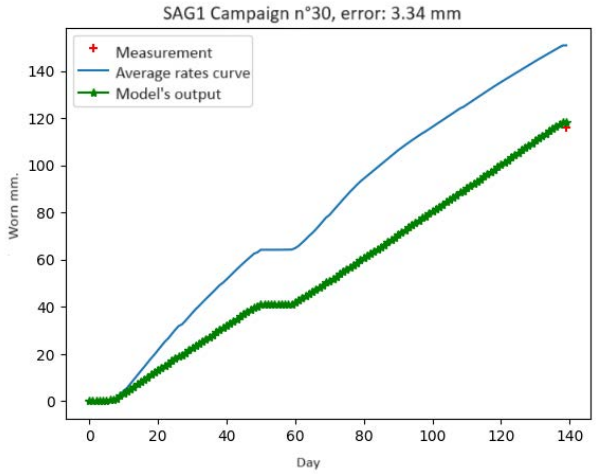

Figure 5. Model evaluation example with campaign 30 (validation) SAG.

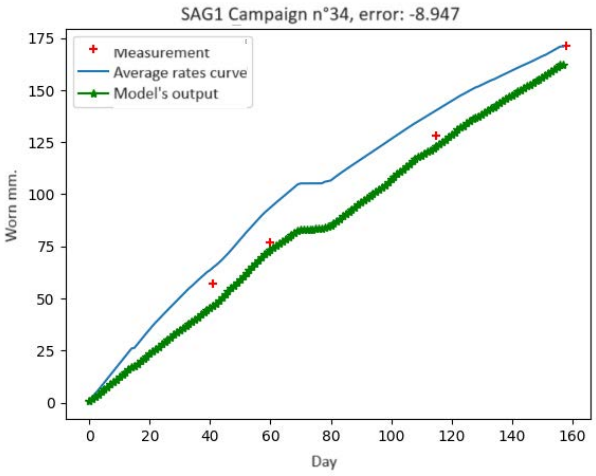

Figure 6. Model evaluation example with campaign 34 (validation) SAG.

5.1. Analysis

The study demonstrates the viability and effectiveness of modeling SAG1 and SAG2 operations jointly. Given that they are identical machines whose variables operate within the same ranges despite differences in their operational patterns, a unified model approach fosters a more robust solution. This robustness stems from training a neural network with data from both mills, offering a larger dataset per model than would be available if two separate models were trained for each mill, also avoiding over-fitting on a single mill's typical operation. This approach not only improves the model's accuracy but also its general applicability across identical machinery.

A significant insight from this work is the advantage of establishing an 'average' operational reference for each asset, as exemplified by the average wear curve against which each mill's wear is calculated. This methodology allows for the development of a model that calculates deviations from 'normal' operation, ensuring predictions remain within reasonable bounds. The histogram of deviations (used as output of the regresor) showed in Figure 4 confirms that there are no significant deviations from the average, highlighting the model's reliability in providing plausible calculations from an operational perspective. This trait is critical for maintaining operator trust in the model, a confidence that could be undermined by implausible model outputs.

The project faced considerable challenges due to the scarcity and poor quality of intermediate wear measurement data. Effective data handling and processing were crucial for maximizing the utility of the available information. Campaigns with only one measurement were primarily useful for validating the model's wear projections and offered limited value for training purposes.

The obtained results are satisfactory, yet they lack a crucial aspect to function online: integrating recent measurements to adjust predictions and quantify uncertainty.

5.2. Online Operation and Uncertainty Quantification

Implementing real-time functionality and accounting for measurement updates in the model necessitates a dynamic approach to incorporate new measurements from inspections, a crucial enhancement given the model's reliance on up-to-date information. A particle filter, a key algorithm in this study, offers an effective tool for state estimation in online settings when incorporating real-time measurements. This Bayesian recursive estimator employs discrete particles to approximate the posterior distribution of the estimated state, making it suitable for online state estimation with available measurements and a system model correlating model states with measurements. It involves initialization, prediction, and correction steps, recursively calculating state estimates.

In the context of this work, a simplified particle filter was implemented as follows:

1. **Initialization**: With an initial measurement always available, particles are sampled from a normal distribution centered on this initial measurement, with variance related to measurement error. Each particle's weight is initialized as $\frac{1}{N}$, where N is the number of particles.

2. **Model Prediction**: Particles follow the model's trajectory, with added noise to introduce variability among the particles.

3. **Measurement Update**: Upon receiving a measurement, the posterior state distribution is calculated using the particles, with new weights computed based on each particle's likelihood given the measurement. If a weight disparity condition is triggered, a resampling step occurs. The process returns to the previous step upon completion.

This particle-based approach generates a probability distribution of the state to be estimated, acknowledging and addressing the inherent uncertainty, thus offering a solution that manages the uncertainty associated with the state estimation process effectively. The variance of the particles in the particle filter was calculated based on the projection error, allowing the filter to produce calibrated uncertainty quantification.

For instance, in campaign 34 of SAG1 (Figure 7), the particle filter had minimal impact due to the model's consistent accuracy. However, in campaign 27 (Figure 8) of SAG2, a significant deviation was corrected by the filter upon the third measurement, thereby improving model performance towards the campaign's end.

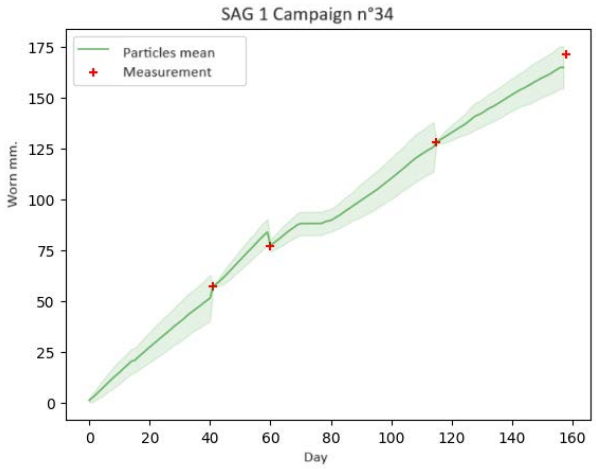

Figure 7. On-line operation of the model with the particle filter, SAG1 campaign 34.

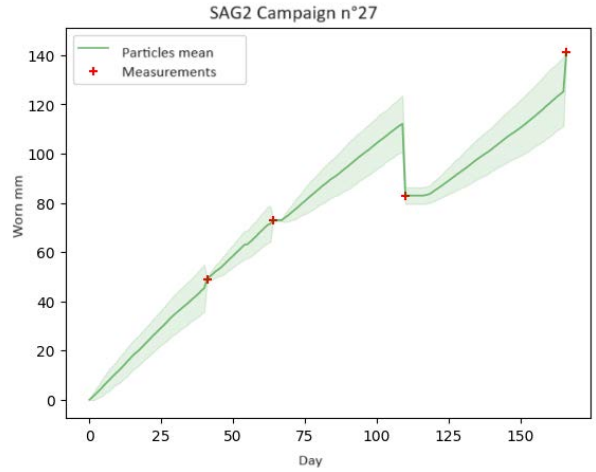

Figure 8. On-line operation of the model with the particle filter, SAG2 campaign 27

6. Conclusions

This paper presents an innovative methodology for abrasive wear monitoring in SAG (Semi-Autogenous Grinding) mills, addressing the challenge of irregular wear measurements due to the lack of a regular inspection regime. The introduction of a virtual sensor aims to estimate the liner's remaining thickness, providing daily updates to assist the maintenance team in scheduling liner replacements efficiently. This method proves critical in enhancing maintenance strategies, particularly in environments where data quality may be compromised and operational realities prevail. A key feature of this approach is the emphasis on uncertainty quantification, which is crucial for informed maintenance decision-making.

The successful application of this methodology to SAG mills at Minera Los Pelambres demonstrates its effectiveness and

potential for broader adoption. Achieving an error of ±7.4254 mm of remaining thickness for the plate position and ±8.701 for the lifter in the validation set underscores the models precision. The methodology's ability to utilize low-quality data and its simplicity are among its most valuable contributions, reducing the barriers to implementing predictive health monitoring (PHM) algorithms and marking a significant advancement in maintenance strategies for the mining industry.

ABSTRACT

The development of high-quality health indicators based on Artificial Intelligence (AI) for condition monitoring, reflecting the degradation process and trend, remains a key area of research. Unsupervised deep learning methods, such as deep autoencoders and variational autoencoders, are often employed to establish health indicators for rotating machinery. However, commonly used methods frequently face challenges in controlling and evaluating the quality of learned features that represent this distribution, which subsequently impacts the accuracy of the test data analysis and anomaly detection. Additionally, the empirical nature of threshold setting adds an element of uncertainty to detections.

The research propose a novel approach for constructing gear health indicators and performing anomaly detection using Generative Adversarial Networks (GAN), with a particular emphasis on the f-AnoGAN structure. The research focuses on modeling the distribution of vibration signals acquired from healthy systems using adversarial learning. By comparing test samples against this modeled distribution, the degree of similarity or dissimilarity acts as an indicator of anomalies. Owing to the generative process of the GAN architecture (creating data from randomly sampled low-dimensional noise), GAN-based modeling overcomes the limitation of autoencoders by aiming to reconstruct the continuous distribution of systems in healthy conditions from a limited set of healthy (training) samples. In this way, it offers more generalizability than traditional model learning. Moreover, this study proposes a new method for establishing thresholds based on distribution fitting by the anomaly score of healthy data. The proposed f-AnoGAN-based model and thresholding technique is applied, tested and evaluated in a gear-pitting degradation dataset and result in more accurate and timely fault detection, markedly enhancing the ability to identify subtle faults in systems over traditional methods.

1. INTRODUCTION

Gears are an indispensable element of rotating machinery, widely employed across industry, including aerospace, rail transport, and industrial sectors (Chen, Jiang, Ding, & Huang, 2022; Salameh, Cauet, Etien, Sakout, & Rambault, 2018). The malfunctioning of gears constitutes a prevalent reason for the failure of machine systems, which can result in substantial economic losses and may even pose risks to human safety (Lee et al., 2014). Consequently, monitoring gear conditions and accurately predicting component failure and fault progression are crucial.

The employment of vibration based condition monitoring at both system and component levels represents a universally endorsed technique within the realm of health monitoring for rotating machinery (Elasha et al., 2014; Teng, Wang, Zhang, Liu, & Ding, 2014; Öztürk, Sabuncu, & Yesilyurt, 2008). The meticulous measurement and subsequent analysis of vibration signals are instrumental in the precise identification of in-

cipient faults, thereby enabling the implementation of preventative and predictive maintenance prior to deterioration and corresponding issues. This proactive approach significantly contributes to the sustenance of system reliability and safety. Moreover, vibration analysis serves as an invaluable source of insight regarding the mechanical condition, since deviations in pivotal rotating elements, such as gears, manifest within the vibration signals (Zhu, Mousmoulis, & Gryllias, 2023; Hendriks, Dumond, & Knox, 2022). The utilization of signal processing tools for the examination of vibratory data aids in the extraction of critical information and indicators spanning both frequency and time-frequency domains. Nevertheless, it is imperative to acknowledge that the interpretations derived from these signal processing outcomes frequently require the expertise of seasoned operators.

With the advancement of artificial intelligence, its application in gear fault detection has gained increasing attention. Artificial intelligence, especially machine learning and deep learning methods, can process and analyze vast amounts of data, uncovering complex patterns and relationships that may be elusive to human experts. This reduces reliance on deep expert knowledge while enhancing the efficiency and accuracy of fault detection, enabling even non-experts to effectively diagnose faults. Among the various techniques, Convolutional Neural Networks (CNN) have demonstrated their versatility in state monitoring applications, including the detection and diagnosis of gear pitting faults (Zhang, Liu, Wang, & Gu, 2022; Xiang, Yang, Hu, Su, & Wang, 2022; Shi et al., 2022; Kim, Na, & Youn, 2022).

Viewing fault detection as a classification problem is a widely adopted strategy. However, obtaining clean, ample, and balanced healthy and especially faulty data, is challenging. Thus, various unsupervised one-class classification methods have been introduced. Unsupervised training methods, which infer based solely on information from healthy data, are limited by their output being the probability of a sample being normal. Thus for detection in a continuous progress, such as a degradation, this type of methods lacks of ability to represent trend. These methods primarily involve two steps: firstly, through the neural network's learning, mastering the distribution of healthy data and gauging the deviation of test data from this baseline; secondly, establishing reasonable thresholds for anomaly detection. A popular method is Deep Support Vector Data Description (DSVDD) (Ruff et al., 2018; Liu & Gryllias, 2020; Peng, Liu, Desmet, & Gryllias, 2023), which uses the Euclidean distance between hidden layer feature representations to characterize the extent of faults, allowing for trend assessment. However, DSVDD faces limitations in feature space representation capability and a lack of control over hidden layers/features.

An alternative unsupervised learning approach involves self-supervised schemes like Autoencoder (AE). By encoding and decoding complete data through neural networks, these models learn the intrinsic structure of the data (C. Zhou & Paffenroth, 2017; Ren, Sun, Cui, & Zhang, 2018; Mao, Feng, Liu, Zhang, & Liang, 2021). Yet, the characteristic of data compression in autoencoders limits their generalization ability, showing a significant dependency on the training data.

Recent years have seen generative models emerge as a new research focus. From the perspective of mechanical fault detection, Generative Adversarial Networks (GANs) (Goodfellow et al., 2014) have been applied primarily in data augmentation tasks (He, Tian, & Zuo, 2022; K. Zhou, Diehl, & Tang, 2023; Qin, Wang, & Xi, 2022; Wang et al., 2019). (Ding, Ma, Ma, Wang, & Lu, 2019) proposed a GAN-based anomaly detection method for bearing fault diagnosis, where the discriminator is used as an anomaly detector. (Dai, Wang, Huang, Shi, & Zhu, 2020) introduces an adversarial learning strategy to optimise the training of autoencoder(the method is also known as adversarial autoencoder) for the establishment of rotating machinery health indicators.

However, the essence of GANs lies in their use of adversarial learning to better fit the distribution of training data, allowing the direct generation of new data from this distribution. This aligns with the upstream task of various anomaly detection algorithms, which is to simulate the distribution of training data.

This study explores the potential of Generative Adversarial Networks in the task of anomaly detection for rotating machinery, based on vibration signals. It proposes a scheme for constructing a gear health indicator using GANs, along with a corresponding threshold setting and an anomaly detection system, aimed at detecting pitting initiation as early as possible. The methodology is validated on a dataset from a gear-accelerated degradation test.

The rest of the paper is organised as follows. In Section 2, the proposed anomaly detection methodology including model training, construction of health indices, and the threshold setting scheme is presented in detail. Then in Section 3 the experimental set up is described, the proposed methodology is applied on the experimental dataset and its effectiveness is analysed. The paper closes at the final section with some conclusions and the potentials of the proposed method in the field of rotating machinery health monitoring.

2. Proposed Method

The proposed detection scheme can be divided into three independent steps:

1. **Offline Distribution Learning**, by generative adversarial learning. In this step, the model is trained only by a limited number of partitioned healthy signals. The generator uses low-dimensional random noise as input and upscales it to the same dimension as the actual samples.

The objective of the generator is to produce signals from the random noise (i.e., feature space) that are as realistic as possible. This process can be considered as the model's grasp of the intrinsic structure of the training signals.

2. **Health Indicator Formation**, by the fast AnoGAN (f-AnoGAN) structure. The well-trained generator from step 1 can upscale any arbitrary low-dimensional feature set to obtain sufficiently realistic signals. This result can be interpreted as having obtained a continuous, infinite set of training samples. Therefore, for a test sample, its state related with health can be determined by whether an identical sample (or, as similar as possible) can be found within this continuous healthy set. The process of finding the corresponding sample, according to the f-AnoGAN structure, is assisted by an independently trained encoder working alongside the generator. After obtaining the corresponding sample for the test signal, the Euclidean distance is measured between signals to gauge the test sample.
3. **Fault Detection**, by a thresholding method. The discrepancy measured as outlined in step 2 is compared against a pre-determined threshold. Samples exceeding this threshold are flagged as potential anomalies, indicating a departure from the healthy signal distribution and hence, identifying possible faults.

2.1. Generative Adversarial Network (GAN) Training

2.1.1. Training Strategy

The training of GAN, depicted in Figure 1, alternates between updating the discriminator (also referred to as the Critic in the context of WGANs) and the generator. The discriminator (Critic model)'s task is to evaluate the realism of both real and generated samples, while the generator aims to produce data that are indistinguishable from real data. The key innovation of WGAN-GP (Gulrajani, Ahmed, Arjovsky, Dumoulin, & Courville, 2017) lies in the gradient penalty term, which enforces a soft version of the Lipschitz constraint by penalizing the gradient norm of the Critic's output with respect to its input.

2.1.2. Loss Composition

Generator Loss: The generator's objective is to minimize the negative average score of the generated samples evaluated by the discriminator:

$$L_G(\theta_G) = -\mathbb{E}_{\tilde{x}\sim P_g}[C(\tilde{x})] \tag{1}$$

where θ_G represents the generator's parameters. The generator is trained to produce samples $\tilde{x}$ that maximize the discriminator's (critic's) score $C(\tilde{x})$, pushing it towards generating more realistic samples.

Discriminator Loss: It includes two components - the average score for the real samples and the average score for the generated (fake) samples.

The objective of the GAN's training can be expressed as:

$$\min_{\theta_G} \max_{\theta_C \in \mathcal{C}} \mathbb{E}_{x\sim P_r}[C(x)] - \mathbb{E}_{\tilde{x}\sim P_g}[C(\tilde{x})] \tag{2}$$

where θ_C represents the critic's parameters. The goal is to train the critic to assign higher scores to real samples $x \sim P_r$ and lower scores to generated samples $\tilde{x} \sim P_g$.

However, the optimizing objective (2) is still not effective enough in the practice of GAN training, and researchers are often plagued by pattern collapse, which has spawned more related studies. Among them, the study of (Gulrajani et al., 2017) has attracted attention by introducing the gradient penalty:

Gradient Penalty (GP): Is calculated by first interpolating between real and fake samples, and then computing the gradient of the critic's scores with respect to these interpolated samples. The penalty is the squared deviation of the gradient norm from 1, averaged across the batch. The final loss function is as follows:

$$\begin{aligned} L(\theta_C) =& \mathbb{E}_{x\sim P_r}[C(x)] - \mathbb{E}_{\tilde{x}\sim P_g}[C(\tilde{x})] + \\ & \lambda \mathbb{E}_{\hat{x}\sim P_{\hat{x}}}\left[(\|\nabla_{\hat{x}} C(\hat{x})\|_2 - 1)^2\right] \end{aligned} \tag{3}$$

where $\hat{x}$ is sampled uniformly along straight lines between pairs of real and generated samples, and λ is a hyperparameter that controls the strength of the penalty, which is set as default value 10 to ensure Critic's gradient comply with the Lipschitz constraint.

This strategy encourages the generator to produce samples that are realistic enough to receive high scores from the discriminator, while the discriminator is penalized for having a gradient norm far from 1, ensuring that it behaves like a smooth function (Gulrajani et al., 2017) that provides useful gradients to the generator throughout the training process.

2.2. Indicator Formation

As previously mentioned, following the training of the GAN, the generator can now represent the complete and continuous distribution of healthy samples found within the training set. Subsequently, the difference between the test signal and the healthy distribution need to be measured to quantify the degree of anomaly in a new signal.

However, this learned distribution is implicit, which means that it is impossible to explicitly write out the mathematical form of this learned data distribution. In the final implementation of AnoGAN (Schlegl, Seeböck, Waldstein, Schmidt-Erfurth, & Langs, 2017), this process is simplified to whether a similar signal can be sampled from the distribution of the

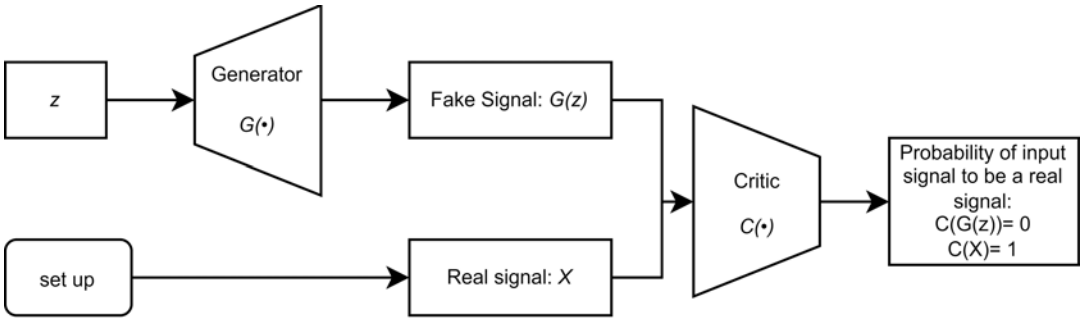

Figure 1. WGAN-GP Training Strategy

generated signal (D_{gen}), that is, finding z in the noise space (the distribution of Z, D_Z, is normally defined as a Gaussian distribution). This process is further reduced iteratively using back-propagation for a substantial number of iterations, such as 10,000 iterations, after which the final sampling result is considered the closest match to the test sample in D_{gen}.

However, the drawbacks of this process are evident; iterating multiple times for a single sample is computationally inefficient, especially when considering practical downstream applications. Moreover, using gradient descent optimization in isolation carries a significant risk of the sampling being trapped in local minima, which can adversely affect the quality of signal sampling in D_{gen}.

To enhance efficiency, the f-AnoGAN introduces an independent encoder for the sampling process. In GAN models, reliable mapping from D_z to D_{gen} is established. The aim of the independent encoder in f-AnoGAN is to facilitate the reverse process: mapping from the complex data distribution D_{gen} back to the simple feature space D_z. This process aids in quickly searching feature vectors z that match the new test sample best, enhancing both accuracy and efficiency in anomaly detection tasks. The obtained vector z is used to generate the corresponding health data $x_{gen} = G(z)$. The generated signal(x_{gen}) is then considered as the generated health signal closest to the tested signal to complete the corresponding indicator calculation.

To train the model, the encoder takes the generated signal X_{gen} as input and Z as output to train the parameters. The formation of the encoder can be depicted in Figure 2.

The loss of the training process of the Encoder is defined as:

$$\begin{aligned} \text{Loss} &= \text{Loss}_{\text{szs}} + \text{Loss}_f \\ &= \text{MSE}(X_{\text{gen}} - G(E(X_{\text{gen}}))) \\ &\quad + \text{MSE}(C(X_{\text{gen}}) - C(G(E(X_{\text{gen}})))) \end{aligned} \tag{4}$$

As mentioned earlier, the detection relies on the discrepancy between the test data and the generated healthy data. The discrepancies in this work are defined as two independent parts:

1. the Euclidean distance in the signal space
2. the Euclidean distance in the feature space, defined by the Critic

The Health Indicator (HI): the Anomaly Score (AS) is defined as the weighted sum of these two distances. In this research, this weighting parameter is not discussed emphatically and both distances are considered equally important, thus, for a tested data x, AS can be expressed as follows:

$$AS = \|x - G(E(x))\| + \|C(x) - C(G(E(x)))\| \tag{5}$$

2.3. Detection Part - Thresholding

The described method evaluates any signal to obtain a unique quantified indicator AS. For anomaly detection tasks, it is necessary to set a threshold based on the AS collection of the given healthy samples. The aforementioned method is applied to evaluate the healthy signals in the validation set to obtain the AS. Then, for the resulting Set_{AS}, the maximum likelihood estimation is used to estimate the parameters according to the assumed distribution type. In this step, research first establishes a distribution bank that includes all common and interesting distributions. Afterward, for Set_{AS}, different distribution estimates can be obtained, Dis_1, Dis_2, etc., along with the estimated distribution parameters. The AIC is taken as the matrix to compare and evaluate different distributions, and to select the optimal distribution based on this comparison as the parametric expression of the AS collection. The resulting dis is the distribution expression of the healthy signals. This distribution is inferred based on actual vibration measurements, and given the potential instability of operating conditions in the actual experimental process, and various interferences in signal measurements (such as the electrical environment), there are outliers in both the AS collection and the estimated distribution. This is also why similar studies do not use the maximum value of the validation's AS as the threshold for judging anomalies. In this method, the threshold setting is based on the estimation of the threshold according to the Distribution's Cumulative distribution function (CDF). In this paper, the AS corresponding to $CDF(\text{AS}) = 0.99$ is

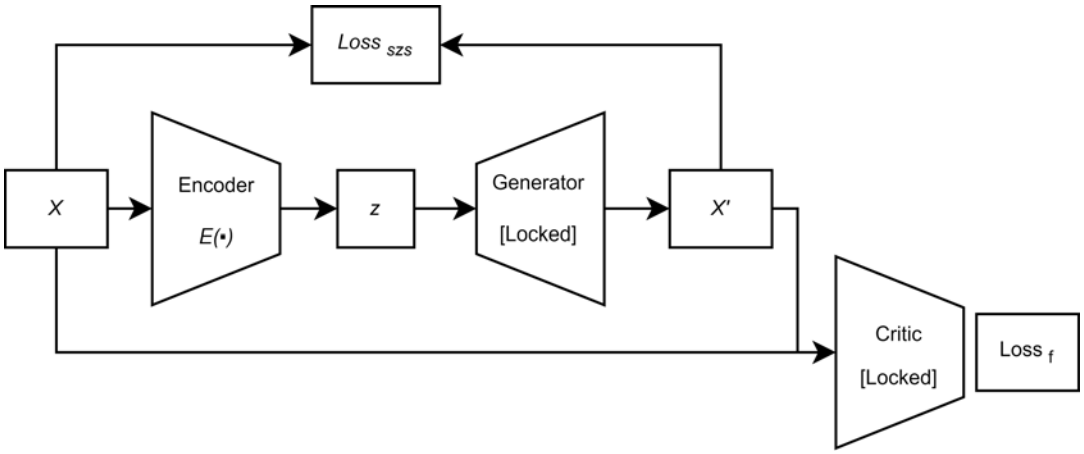

Figure 2. Encoder formation in f-AnoGAN

used as the threshold for judgment of anomaly.

3. Application of the Methodology and Results

3.1. Description of the data

The data used for validating the anomaly detection approach in this research were derived from a comprehensive gearbox degradation test (Van Maele et al., 2023).The measurements were conducted on an FZG multi-stage gearbox test rig (Figure 3), where the input and output of two gearboxes were mechanically interconnected, thus forming a mechanical closed loop. The load was provided by a friction disk coupling mechanism situated between the gearboxes, which applies torque to the gear meshing system through angular displacement between two discs at either end. Throughout the test, the torque, applied manually, was maintained at 60-90Nm, and the gear under test was set to a speed of 2560 rpm.

Figure 3. Photo of the multistage FZG test rig

Within the gearbox under investigation, the transmission system consists of three pairs of meshing gears, with their specific locations indicated in Figure 4. The test employed two pairs of helical gears made of 20MnCr5 steel, featuring 41 (monitored) and 38 teeth, respectively. Unlike standard, industrial gears, the gears under observation were not hardened (250HV) to ensure pitting would occur on the monitored surfaces within a reasonable time frame (Van Maele et al., 2023). A camera was used during the operation to periodically record the visual information of the gear surfaces at fixed intervals for the study and quantification of surface pitting. Specifically, the system was slowed down to 1rpm for image capture every 30 minutes during operation. The camera system took five shots of each meshing surface during the collection process, and the sharpest image was algorithmically selected to serve as the basis for quantifying the pitting area. Thus, after the test concluded, a quantitative description of the process of surface pitting area evolution over time was obtained, providing a metric for the degradation process.

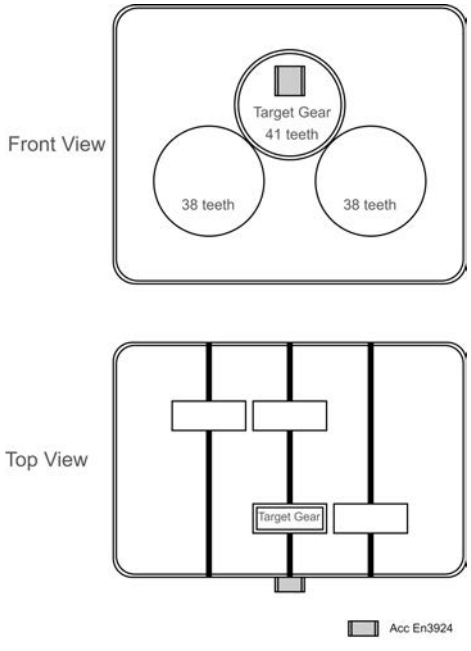

Figure 4. Sketch of the test gearbox setup

In addition to the visual information, during the test also torque,

speed, and most importantly, vibration signals were measured. The locations of the vibration sensors are indicated in the accompanying diagram. Vibration signals were sampled at 10-minute intervals, with each sample collected at a sampling rate of 25600Hz over a duration of 10 seconds. In total, this accelerated degradation test lasted approximately 205 hours.

Overall, the test yielded 999 valid vibration data entries (indicating failure after 999 cycles) and 300 sets of synchronized gear surface information. According to tribologists' analysis, significant and observable pitting occurred on all gear surfaces after the 33 cycle.Figure 5 is a depict of the observed degradation process of pitting.

In this study, the vibration signal in the X-direction from the vibration sensor EN-3924, which lies closest to the tested gear, was utilized. A health indicator built on a generative model was used to track the degradation of gears, aiming for earlier detection of pitting formation, which would, in turn, guide maintenance activities.

3.2. Data preprocessing

In this research, the training data were prepared with the following preprocessing steps to use more informative samples. It is postulated that the degradation features are primarily concentrated in the gear mesh frequency (GMF), its harmonics, and the features and structures of the sidebands. In this test, with the input shaft rotating at 2560 rpm, the velocity of the intermediate and target gears was calculated as $v_2 = v_1 \times \text{gear_ratio} = 39.5$Hz, and the gear mesh frequency was GMF $=$ Teeth_num $\times\ v_2 = 1622$Hz. Table 1 contains the characteristic frequencies of the test rig and the test.

Table 1. Characteristic frequencies of the test gearbox

Speed (Input Shaft)	2560 rpm
Speed (Driver Gear)	42.7 Hz
Speed (Target Gear)	39.5 Hz
GMF (Target Gear)	1622.6 Hz
2*GMF (Target Gear)	3245.2 Hz
3*GMF (Target Gear)	4867.8 Hz

Accordingly, the following preprocessing was applied to the data: initially, vibration signals were passed through a filter targeting the 1500-5000Hz frequency band, which includes the harmonics from the 1st to the 3rd order of the gear mesh frequency, along with the related band components. Afterward, the Discrete Fourier Transform was applied to isolate the informative frequency band, and then the 1500-5000Hz range was extracted to form the training, validation and test set samples.

The complete experimental dataset consists of approximately 999 independent measurements covering the full lifecycle. For this study, the early-life gear signals are selected as training samples to ensure that the training set comprised entirely healthy data to support model building and parameter optimization. A portion of the healthy dataset was also reserved as a validation set due to the encoder architecture of f-AnoGAN. In f-AnoGAN, unlike the original AnoGAN structure that relies solely on random sampling and gradient descent for sampling in D_{gen}, the model treats the training data as input to build the latent feature z via the encoder. Hence, to establish a threshold for anomaly detection, the new, unseen healthy data is still required as a reference.

Figure 6 delineates the division of the dataset in the test. Due to the run-in and gear bedding-in phases, which led to an unstable operational state of the experimental system, the initial two signals were discarded. The complete training set is composed of 19 independent signals, each sliced into time series of 51200 points with a 50% overlap during segmentation. All models in the study, including the generator, discriminator, and encoder, were trained exclusively with the aforementioned samples as per the described method. Furthermore, following the aforementioned method, 9 independent measurements from the healthy system were retained as a validation set, with the data division and sample generation being identical to the training set. All remaining data, encompassing both healthy and anomalous readings, were used as the final test set. It is important to note that the exclusion of data, as well as the delineation of the training, validation, and test sets, was conducted in chronological order following the accelerated degradation life course. In other words, the training and validation sets represent the early service life of the gears, while the test set includes the entire progression from a healthy state through the onset and development of pitting. Figure 7 illustrates the data pre-processing process.

3.3. Results

To verify the methodology's effectiveness, this study sets up comparative experiments and discusses the performance of the proposed model and the Autoencoder (AE). For the f-AnoGAN architecture, all models are set to be based on fully connected networks. To ensure fairness in the comparative experiments, the main model's structure and the number of parameters are kept as consistent and comparable as possible. This implies that both the generator of the proposed approach and the decoder of the AE, which serves as the benchmark method, undertake analogous functions by upscaling low-dimensional variables in the feature space to the target dimension. Consequently, to guarantee comparability between the two models, their parameters and network structures are configured to be identical. Both G and AE are completed by fully connected neural networks, transforming dimensions from $1000 \rightarrow 2500 \rightarrow 5000 \rightarrow 7001$, finally obtaining the spectrum from 1500-5000Hz (with a resolution of 0.5Hz). Based on these two models, model construction in

each method is respectively completed, i.e., completing the Critic in GAN and implementing the encoder in f-AnoGAN. For the AE, the encoder is set according to the structure of the decoder. The AE uses the Mean Squared reconstruction Error (MSE) as its training loss and evaluates the health indicator during an assessment based on the MS reconstruction error.

For the proposed method, the training process generally follows the WGAN-GP (Wasserstein GAN with Gradient Penalty) scheme, setting the model to be trained for 2000 epochs (learning rate = 0.0001) to allow the model parameters to converge. After complete training, the generator can produce specified frequency bands based on any given set of features z. Figure 8 shows examples of training data and Figure 9 shows the generated results after 1990 epochs based on four randomly sampled z values. It is observed that the generated frequency bands closely mimic the features of the training data. From this, it can be inferred that the generator model has grasped the internal structure of the training data, that is, the representation of the service vibration condition of the given gear in the experimental system in the frequency domain. Specifically, the generated samples accurately replicate the gear mesh frequency and its higher-order harmonics, as well as the surrounding sideband performance.

According to the f-AnoGAN architecture, the construction of the Anomaly Score (AS) for any signal is completed with the help of the encoder. Figure 10 illustrates the result of generator sampling based on the aforementioned method and calculating the Euclidean distance in two spaces, with example

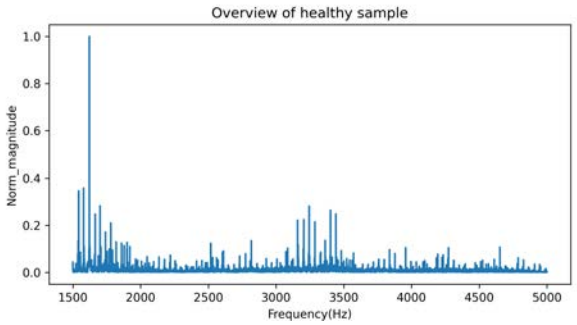

Figure 8. Sample overview in the training set

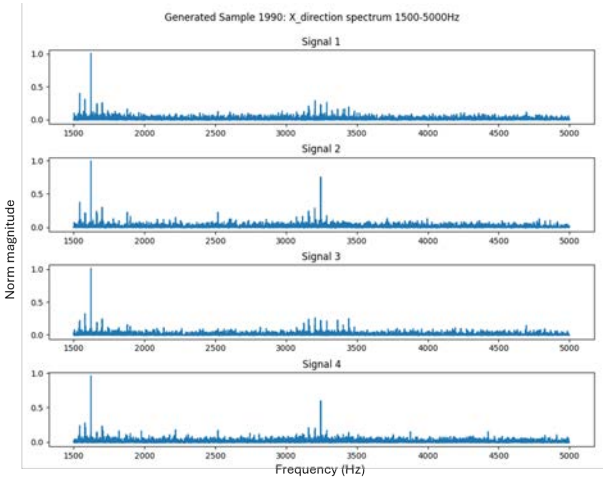

Figure 9. Generated spectrum at the end of the training period

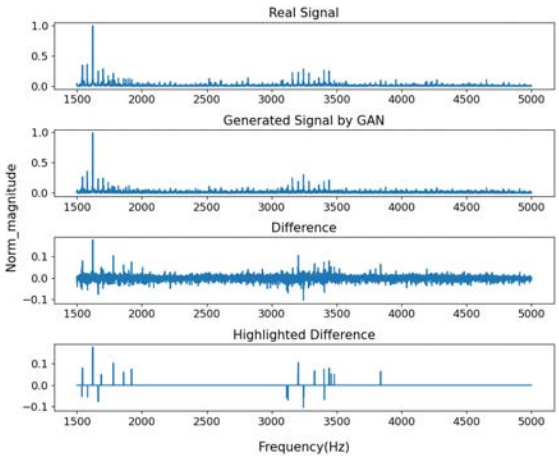

Figure 10. Comparison of the generated spectrum and the original spectrum

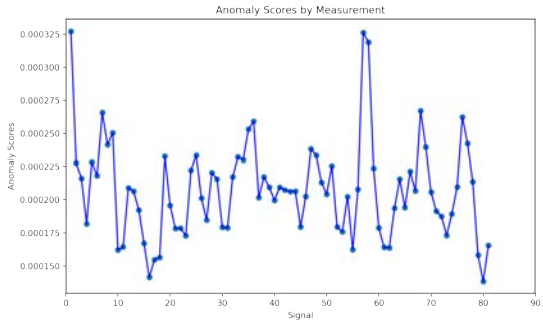

Figure 11. Anomaly score of the validation set (Healthy samples)

signals from the validation set.

Based on all the validation set data, a reference benchmark for anomaly detection, namely the Anomaly Score (AS) collection of healthy data, will be established. Figure 11 shows the AS for 81 samples (from 9 vibration signals) in the validation set 11. The study constructed a distribution bank using some common distributions. Following the aforementioned thresholding method, the fitting of the obtained distribution is as shown in Figure 12. The legend lists the distribution types in the figure, which are sorted in ascending order of the Akaike Information Criterion (AIC). Theoretically, a distribution with a smaller AIC value is closer to the true distribution. According to this criterion, the distribution among tested that best represents the AS of the healthy samples is the lognorm distribution (Figure 12). Additionally its numerical solution for various parameters is obtained, allowing to derive the CDF. Based on the aforementioned method where $CDF(AS_{\text{threshold}}) = 0.99$, the threshold is then determined for determining the anomaly (Figure 13). The threshold is then applied to the test set to evaluate the performance of the proposed method in anomaly detection.

Having completed all the components for anomaly detection as described previously, the Anomaly Score (AS) for each data in the test set is obtained following the aforementioned method. The average AS from the same vibration signal is taken as the AS for that vibration signal. Figure 14 shows the variation of AS across the entire test set in chronological order, along with the threshold performance. The results indicate that, according to the aforementioned method, the onset of failure occurs at the 33rd cycle (Figure 15), which aligns with the onset time of pitting derived from tribologists and visual information.

As a comparison, the AE model was also trained on the training set for 2000 epochs (learning rate = 0.0001), with an early-stopping at patience of 100. Figure 16 illustrates the reconstruction effect and schematic after completing the training.

As mentioned the reconstruction error derived from the AE model served as health indicators. In the comparative experiments, the threshold was established as the mean plus three times the standard deviation of the derived HI. AE-

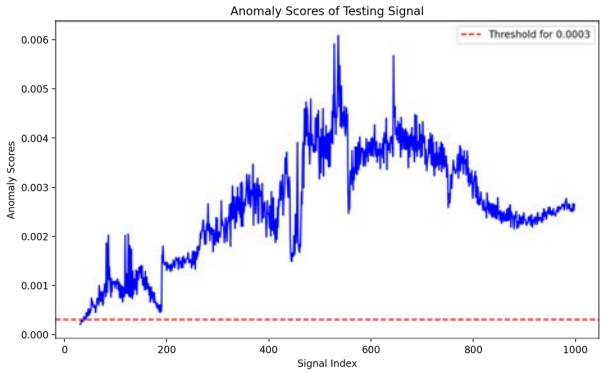

Figure 14. Detection result of f-AnoGAN-based anomaly detection method

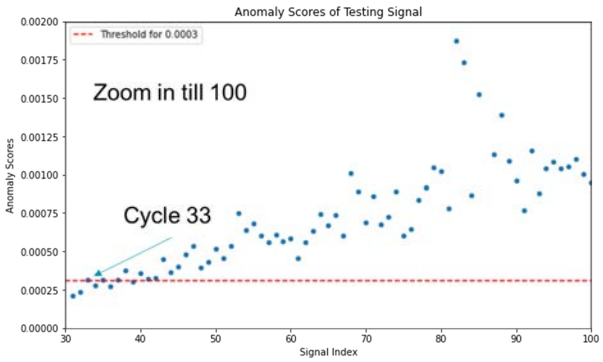

Figure 15. Anomaly Score in the first 100 cycles

based anomaly detection method identified the 38th cycle as the first cycle exceeding the threshold. However, this indicator was less stable, with a significant number of cycles between 38 and 200 falling below the threshold (Figure 18), indicating mis-detections if analogous to a classification problem.

3.4. Discussion

The results indicate that the proposed health indicator scheme and the thresholding method based on the GAN accurately detected the onset of the gear failure. Compared to the traditional unsupervised anomaly detection AE, the GAN-based detection advanced the detection time by 5 cycles. Given that the experiment conducted was an accelerated degradation test, and the gears underwent softening, this gap would be even more significant in actual industrial components.

Furthermore, it is also observed that the AE-reconstruction error, used as a HI, was highly unstable. One reason for this is the instability in the application of torque during the measurement campaign, which gradually diminishes during operation, necessitating the experiment to be halted and torque to be manually reapplied once excessive torque loss occurs. In the trend of HI obtained from AE, each sharp decrease in HI corresponds to the moments when the experiment is stopped and torque is reapplied. The same phenomenon is also observed in GAN-based HI. In GAN-based HI, even though HI is still established based on Euclidean distance, the powerful representation learning capability of the generator model allows it to construct more diverse samples that are more adaptable to certain instabilities in torque interference. Consequently, the differences reflected by HI are more attributable to degradation, with less impact from torque variations. This explains why GAN-based HI demonstrates better trend performance.

4. Conclusion

This work proposes an anomaly detection scheme for the condition monitoring of rotating machinery, focusing on gear fault detection using vibration signals. This method employs Generative Adversarial Networks (GANs) to learn the intrinsic structure and features of the training data's spectrum, particularly aiming to generate non-existent, highly realistic counterfeit samples. Based on the f-AnoGAN architecture, a health indicator is constructed utilizing the quantified Euclidean distance in two independent spaces. The study also employs a distribution fitting-based threshold method to assist in detection. The methodology is validated in a comprehensive

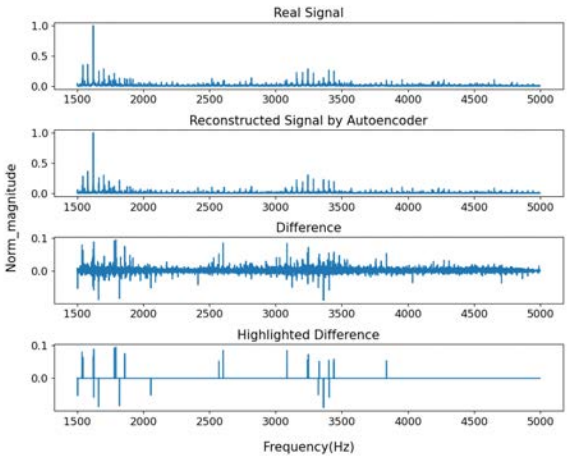

Figure 16. Comparison of the original spectrum and the reconstructed spectrum by an Autoencoder

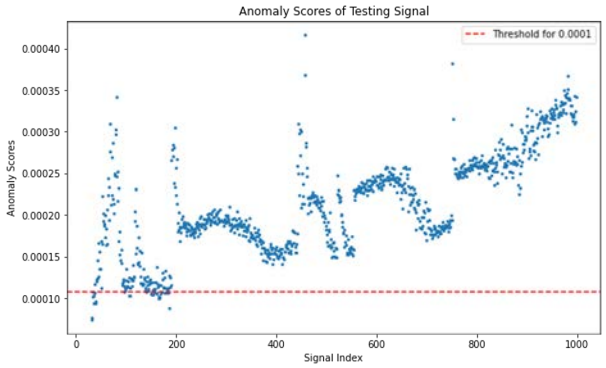

Figure 17. Detection result of Autoencoder-based anomaly detection method

gear accelerated degradation measurement campaign, which includes synchronized visual information collection, thus allowing for precise determination of the initial onset of pitting — the target of anomaly detection based on vibration signals in this research. In comparative experiments, the GAN-based method surpassed traditional unsupervised autoencoders and demonstrated better adaptability to changes in operating conditions, highlighting the performance of generative models with adversarial learning in the field of anomaly detection. Exploring how to better and more controllably utilize its adaptability under changing operating conditions will be the focus of future research.

BIOGRAPHIES

Hao Wen received his Bachelor of Science degree from the China University of Geosciences, China and his Master of Science degree in Mechanical Engineering from the University of Manchester, UK. He joined the Noise and Vibration Research Group in the Department of Mechanical Engineering at KU Leuven, Belgium, as a PhD researcher in 2022. His research interests lie in the areas of fault detection utilizing unsupervised learning and generative modeling.

Djordy Van Maele Received his M. Sc. in electromechanical engineering technologies from Ghent University, Gent, Belgium, in 2021. In 2021 he started working on his doctoral degree in electromechanical engineering, in the field of tribology, at Ghent University until current date.

Jean Carlos Poletto obtained his M.Sc. degree in Mechanical Engineering from the Federal University of Rio Grande do Sul (UFRGS), Brazil, in 2018. He has been developing research on experimental tribology, with active contributions to the field since 2015. Currently, he is working on a joint PhD program between UFRGS, Brazil, and Ghent University, Belgium.

Patrick De Baets received a master's degree in Electromechanical Engineering (1989) from Ghent University. His research, addressing the use of Thin Layer Activation to assess the fretting wear of machine components, resulted in a Ph.D. degree in 1995. He is now a full professor of machine elements and tribology. His research focusses on the tribological response (friction, friction stability and wear) in dry or marginally lubricated conditions of advanced materials such as fibre reinforced composites, high temperature ceramics and various self-lubricating materials. For his research, he has constructed different experimental tribological set-ups, ranging from the N to MN force range. The results of his research have been published in about 300 peer reviewed journal contributions and conference papers and numerous technical reports. Since more than 20 years Patrick De Baets is teaching specialised courses on Machine Design, Machine Elements and Tribology to Bachelor and Master students in Mechanical Engineering. Besides that, he has gained 15 years' experience in teaching general course on mechanical engineering to non-technical audiences, such as e.g. commercial engineering students.

Konstantinos Gryllias received the Diploma and Ph.D. degrees in mechanical engineering from the National Technical University of Athens, Athens, Greece, in 2004 and 2010, respectively. He is currently an Associate Professor of vibro-acoustics of machines and transportation systems with the Department of Mechanical Engineering, KU Leuven, Leuven, Belgium. He also serves as the Manager of the University Core Lab Flanders Make@KU Leuven Motion Products, Belgium. His research interests include condition monitoring, signal processing, prognostics, and health management of mechanical and mechatronic systems.

A Hybrid – Machine Learning and Possibilistic – Methdology for Predicting Produced Power Using Wind Turbine SCADA Data

Maneesh Singh

Western Norway University of Applied Sciences, 5020 Bergen, Norway
maneesh.singh@hvl.no

ABSTRACT

During its operational lifetime, a wind turbine is continuously subjected to a number of aggressive environmental and operational conditions, resulting in degradation of its parts. If left unattended, these degraded components will negatively influence its performance and may lead to failure of the wind turbine. In order to mitigate the risk associated with the failure of components, a wind turbine is regularly inspected and maintained.

Currently, there are two commonly used approaches for making maintenance management (inspection and maintenance) plans. Traditional Approach utilises understanding of failure profile of the components for manually developing maintenance plan for the equipment. Condition-Based Approach utilises data collected by condition monitoring of equipment for developing dynamic maintenance plan. SCADA system offers a low-resolution condition-monitoring data that can be used for fault detection, fault diagnosis, fault quantification and fault prognosis and eventually for maintenance planning.

The monitoring data from SCADA system of a wind turbine is often afflicted with variability and uncertainty. The variability in data is the result of continuously changing environmental conditions and uncertainty arises due to imperfections in the recorded data. The uncertainty may be due to many reasons, including, inherent characteristic of sensing devices, drift in calibration with time, deterioration of sensing devices' sensitivity and response due to environmental attacks, etc.

For handling variability in monitoring data a number of parametric and non-parametric (statistical) predictive models for different aspects of a wind turbine's structure and operation have been proposed. Depending upon its type – aleatory or epistemic – an uncertainty can be handled in a number of ways. Since, the dynamic nature of wind turbine operation does not allow collection of multiple values under the same condition; hence, uncertainty is mostly epistemic in nature. Possibilistic Approach, based on Fuzzy Set Theory, is especially suitable for handling epistemic uncertainty that may arise due to imprecision or lack of statistical data.

Aim of the ongoing research is to develop a methodology for detecting sub-optimal operation of a wind turbine by comparing Measured Produced Power against Predicted Produced Power. Unfortunately, variability and uncertainty associated with the recorded data make accurate prediction of produced power challenging.

This paper presents methodologies for predicting produced power using SCADA data while simultaneously accounting for variability and uncertainty. The methodologies utilise either parametric (example, power curve) or machine learning (example, XGBoost) models for handling variability; and Possibilistic Approach for handling uncertainty.

1. INTRODUCTION

1.1. Background

The world has two conflicting needs, on one side is the need to generate and supply more energy to bring people out of poverty and improve their living standard; on the other side is the need to reduce reliance on fossil fuel so as to cut down on emissions that cause global warming. These conflicting needs have acted as a spur to find economical and clean alternative sources of energy. In recent years, wind power has become one of the major sources of alternative energy and its share is expected to continuously grow in the coming decade (Global Wind Energy Council, 2021).

Due to various financial, social ("not-in-my-backyard" syndrome), environmental (meteorological conditions) and geographical (topological features) reasons the wind turbines are often located in remote areas where they experience harsh environmental conditions. The inconsistent and aggressive environmental conditions, like, wind velocity, humidity, temperature, precipitation and icing, degrade the vulnerable components. If left unattended, these degraded components

will result in deterioration of performance and at times failure. To prevent that from happening, maintenance of wind turbines is needed throughout their lifetime. It is estimated that maintenance costs comprise of a significant proportion (10-25%) of the total annual operational cost (Nilsson & Bertling, 2007).

Currently, there are two commonly used approaches for making maintenance management plans (tasks and schedules):

(a) **Traditional Approach** – In which understanding of the failure profile (failure causes, failure mechanisms, failure modes, failure rates, etc.) of components is used to develop maintenance concept and maintenance plan for the equipment.

(b) **Condition-Based Approach** – In which data, collected using condition-monitoring equipment or Supervisory Control and Data Acquisition (SCADA) systems is analysed for fault detection, fault diagnosis, fault quantification and fault prognosis and maintenance planning.

The Traditional Approach analyses structural, environmental and operational attributes to develop corrective or preventive maintenance plans. The preventive maintenance plans are often time-based, for example, preventive maintenance activities of wind turbines are normally planned at 3 to 6-month intervals based upon the age and condition of the turbine (Nilsson & Bertling, 2007). Since these time-based inspection and maintenance plans are expensive to execute, there have been efforts to develop methodologies based on formalized risk analysis, e.g., Risk Based Inspection and Maintenance or Reliability Centered Maintenance. This involves understanding failure profile and carrying out risk analysis & risk evaluation for preparing maintenance plans that are more efficient and effective than time-based or incidence-based maintenance plans (Fischer, Besnard & Bertling, 2012).

The Condition-Based Approach improves upon the inspection and maintenance plan by using condition attributes to update the equipment's risk assessment by detecting faults. This is achieved by (a) intermittent or continuous monitoring using sensors; (b) data analytics; and (c) developing condition-based maintenance plans. This approach can be applied using either (Tavner, 2012):

1. **Condition Monitoring System (CMS)** – A high-resolution specialized system for detailed analysis of the condition of a machinery by monitoring parameters like, speed, displacement, vibration and oil particles, using sensitive sensors. While specialized Condition Monitoring Systems can give accurate and detailed analysis, they are also expensive to install and use.
2. **Supervisory Control and Data Acquisition (SCADA)** – A low-resolution, usually at 10-minute intervals, standard system in every large wind turbine that monitors parameters for characterising environment, electrical, operational or structural attributes. SCADA system uses this data for controlling the wind turbine's operation after analysing its operating conditions and status. This data can also be used for deducing the health (fault detection, diagnosis and quantification) of the wind turbine.
3. **Structural Health Monitoring (SHM)** – A low-resolution system for monitoring health of a structure, including tower and foundation.

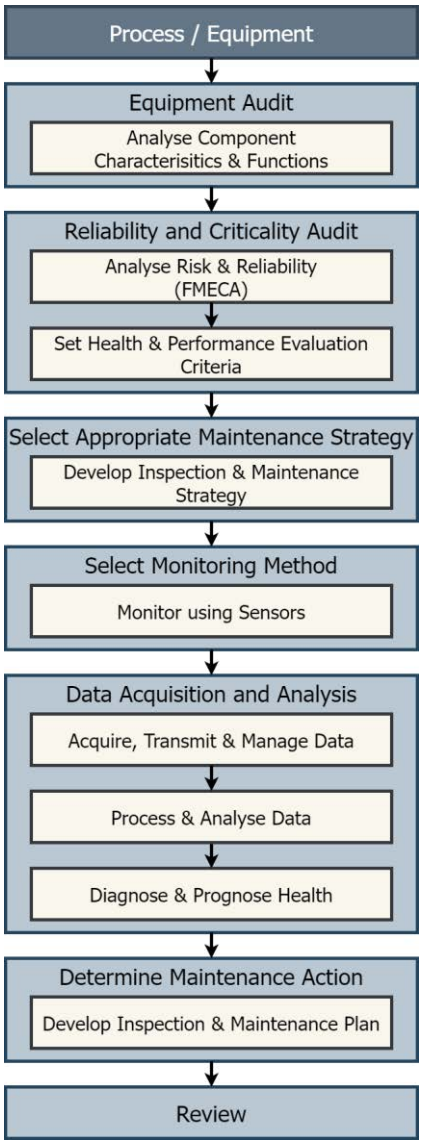

Figure 1. Main steps of a monitoring system (Based on ISO17359).

While Condition Monitoring System (CMS) provides costly but in-depth coverage, SCADA and Structural Health Monitoring (SHM) can provide cheap but wide coverage. Hence, a number of commercially available SCADA systems offer real-time data analysis, using statistical and artificial intelligence techniques, for fault detection of components. Yet, there is a need for better diagnostics, prognostics and control techniques using SCADA (Tavner, 2012; Yang et al., 2018).

Since, both – Traditional and Condition-based – Approaches have their own advantages and disadvantages, most of the maintenance planning is carried out by integrating the two approaches. The integration provides a solution that is robust, effective, and efficient. In an integrated method (Bindingsbø et al. 2023):

- failure analysis is carried out in the traditional manner, and then the results of failure profile is used judiciously to develop a maintenance strategy;
- time for inspection and maintenance of a component is adjusted based upon outcome of condition monitoring.

Figure 1 shows main steps that should be carried out to monitor a system according to ISO17359. According to the standard, condition-monitoring approach has three steps (Equipment Audit, Reliability and Criticality Audit and Select Appropriate Maintenance Strategy) that help in developing maintenance plan using the Tradition Approach. Thereafter, three more steps (Select Monitoring Method, Data Acquisition and Analysis and Determine Maintenance Action) help in improving the maintenance plan by incorporating knowledge of system's condition.

1.2. Supervisory Control and Data Acquisition (SCADA) System

An offshore wind turbine is subjected to severe variations in the environmental and operating conditions. To continuously monitor these variations all modern wind turbines come with a Supervisory Control and Data Acquisition (SCADA) system (Pandit & Wang, 2024).

In a SCADA system, a multitude of sensors constantly monitor various meteorological and operational parameters; and the data is transmitted, processed and stored in SCADA supervisory computers. The parameters that are monitored include (Manwell, McGowan & Rogers, 2009):

- **Position** – blade pitch angle, nacelle direction
- **Temperature** – nose cone, gearbox bearing, gearbox oil, hydraulic system oil, generator bearing, generator stator windings, generator split ring chamber, transformer, busbar section, inverter, controllers, VCP control boards
- **RPM** – rotor, generator
- **Hydraulic Characteristics** – pressure, reservoir level, flowrate
- **Environmental Characteristics** – wind speed, wind direction, temperature, humidity
- **Electrical Characteristics** – active power, reactive power, voltage, current, phase displacement, frequency

Apart from the data collected using sensors that are connected to a wind turbine, a number of data streams from nearby weather stations are also recorded.

The recorded SCADA data is analysed using different deterministic, probabilistic, Fuzzy Logic, Machine Learning, Artificial Neural Networks and Deep Learning approaches to detect, diagnose and quantify failures in the components. Information gained after analysis is used to control the process or operation (Manwell, McGowan & Rogers, 2009; Tavner, 2012).

Based on the data collected and analysed, a SCADA system can perform the following tasks (Manwell, McGowan & Rogers, 2009; Pandit & Wang, 2024):

1. **Controlling Operating Conditions** – SCADA uses the information regarding environment and grid to determine the appropriate operating conditions. It then controls the components (pitch angle, brakes, generator connection to the grid, etc.) so that the turbine operates according to the determined task schedule.
2. **Monitoring for Fault Detection** – SCADA uses the data from sensors (example, bearing temperature, hydraulic oil temperature, etc.) connected to critical components to monitor their behaviour and detect potential faults or spurious behaviour.
3. **Raising Alarm in Case of Faulty Behaviour** – If SCADA detects abnormal behaviour of a component it can raise alarm and notify the operator.
4. **Triggering Safety and Emergency Response** – In case of situations that can escalate into an accident, SCADA can disconnect turbine from the grid and activate brakes to isolate and shut down the operation.
5. **Integrating with Power Grid** – SCADA can control integration of individual wind turbine into the power grid, thereby contributing to feed and stabilisation.

1.3. Condition-based Maintenance Planning Using SCADA Data

The data acquired from SCADA can be used for fault detection, where a fault can be of various kinds, for example, degradation of components, failure of sensors, operation beyond safe operating limits, problems associated with grid. While it may be possible to detect some of these faults directly, for example, failure of sensors resulting in irrational readings, other faults may only be detected indirectly (Manwell, McGowan & Rogers, 2009).

Depending upon the type of fault, the time span between inception to potential failure could be between a few seconds (example, generator earth fault) to a few weeks (example, wear-out of gears). For the faults that have a long time span, analyses of SCADA data using appropriate models for fault diagnosis, fault quantification and finally fault prognosis may help in planning maintenance activities. These activities can be:

- triggered either when some condition indicator crosses a pre-set limit, or
- decided based on combination of Failure mode, Effect and Criticality Analysis (FMECA) with the condition analysis (fault diagnosis, quantification and prognosis) to update the existing maintenance plan.

The recommended maintenance activities may include inspection (visual, auditory, NDT), testing, service (lubrication, cleaning, repair, etc.), repair and replacement tasks. These activities may be either preventive or corrective in nature depending on whether the needed task is carried out before or after failure. Since maintenance activities are planned based on the actual monitored condition, condition-based maintenance strategy offers advantages that are associated with (Bindingsbø et al. 2023, Tavner, 2012):

- maintenance activities being carried out when required and not limited to corrective or preventive maintenance;
- not conducting unnecessary scheduled replacement of parts before their end of useful life.

In spite of these advantages, use of the Condition-Based Approach is still restricted and needs further research and development. This is because of the difficulties associated with the (Bindingsbø et al. 2023):

- quality and quantity of collected data,
- handling of imperfect (spurious, inconsistent, inaccurate, uncertain, or irrational) data collected from faulty sensors,
- interpretation of data for fault diagnosis, quantification and prognosis,
- updating of maintenance plan, and
- handling of unreliable analysis that may trigger false alarm (false positive) or failure to respond (false negative)

1.4. Methodologies for Predicting Produced Power

One of the common methods for analysing the performance of a wind turbine using SCADA data is to understand the power generation as a function of various variables, especially wind speed. A significant difference between the predicted power generation and measured power generation gives an indication of sub-optimal performance, hence, need for detailed examination. For this purpose it is essential to be able to accurately predict power generation under varying environmental and operating conditions (Pandit & Wang, 2024; Wang et al., 2016).

Power curve of a wind turbine is the unique relationship of a wind turbine between the power it generates and the environmental and operational conditions under which it operates. The power generated by a wind turbine is dependent upon the technical (example, radius of the rotor), environmental (example, wind speed, air density) and operational (example, pitch angle, angle between wind and nacelle) attributes (Manwell, McGowan & Rogers, 2009).

In a simplified power balance model, the wind power is converted to rotor power; which in turn is converted to electrical power. The efficiency of conversion of wind power to rotor power is dependent upon wind speed, air density, blade geometry, etc. Ideally, the rotor power should be converted entirely to the electrical power via its drive train system; but in reality, some power is lost as vibration and heat. The energy balance can be expressed as (Manwell, McGowan & Rogers, 2009):

$$P_{Rotor} = P_{Electrical} + P_{Vibration} + P_{Thermal} \quad (1a)$$

$$P_{Rotor} - P_{Electrical} = P_{Vibration} + P_{Thermal} \quad (1b)$$

Where:

P_{Rotor} = Rotor power
$P_{Electrical}$ = Electrical power
$P_{Vibration}$ = Vibration power
$P_{Thermal}$ = Thermal power

Hence, an increased discrepancy between rotor power (P_{Rotor}, predicted using models) and electrical power ($P_{Electrical}$, measured) is an indication of additional loss of energy due to increase in vibrations and heat generation-dissipation. This in turn can be attributed to the falling health condition of the mechanical and electrical drive train components. Thus, analysis of produced power can be used for (Duguid, 2018):

- **Fault Detection** – While exact cause may not be easy to identify, but a significant difference may help in fault detection necessitating further investigation.
- **Suboptimal Performance Detection** – Suboptimal performance, often due to poor control, can be identified using power curve. A comparison in power generation between a local group of wind turbines may also help in identifying those units that are performing sub-optimally.

To predict power generation, a number of parametric and non-parametric (statistical) methods have been proposed (Lydia at al. 2014; Pandit, Infield & Kolios, 2019; Saint-Drenan et al., 2020; Pandit & Wang, 2024). The parametric models are based on functions that correlate different variables and are of different types. For example, linearized segmented model, polynomial power curve, 4/5-parameter logistic function, etc. are based on power equation derived from Bentz's law, which can be expressed as (Manwell, McGowan & Rogers, 2009):

$$P_{Rotor} = P_{Wind} \times C_P(\lambda, \beta) \quad (2a)$$

$$P_{Electrical} = P_{Rotor} \times \eta \quad (2b)$$

$$P_{Electrical} = \left(\frac{1}{2}\rho A U^3\right) \times C_P(\lambda, \beta) \times \eta \quad (2c)$$

Where:

P_{Wind} = Wind power

η = Drive train efficiency ($generator\ power / rotor\ power$), (mechanical & electrical)

ρ = Air density

A = Rotor disc area

U = Air velocity

$C_P(\lambda, \beta)$ = Rotor power coefficient, it expresses the recoverable fraction of wind power and is a function of λ (tip speed ratio) and β (blade pitch angle).

The λ (tip speed ratio) can be expressed as:

$$\lambda = \frac{\Omega R}{U} \quad (3)$$

Where:

λ = Tip speed ratio

R = Radius of the wind rotor

Ω = Angular velocity (in radians/sec)

The maximum theoretically possible rotor power coefficient, $C_{P,max}$ also called the Betz limit, can be determined to be 0.59. The actual value of $C_P(\lambda, \beta)$ is much below the Bentz limit and is dependent upon technical features of the turbine and environmental factors (Saint-Drenan et al., 2020).

According to the **Equation 2c**, produced electric power is proportional to the density of air and cube of wind speed. The density of air is in-turn dependent upon the ambient temperature, humidity and pressure. It can be calculated according to:

$$\rho = \rho_d + \rho_v \quad (4a)$$

$$\rho_d = \frac{P - P_v}{\left(R_{Specific,Dry\ Air} \times T_k\right)} \quad (4b)$$

$$\rho_v = \frac{P_v}{\left(R_{Specific,Water\ Vapour} \times T_k\right)} \quad (4c)$$

$$P_{sat} = 6.1078 \times 10^{\frac{7.5T}{T+237.3}} \quad (4d)$$

$$P_v = \frac{(h \times P_{sat})}{100}$$

Where:

ρ_d = Density of the dry air

ρ_v = Density of the water vapour

T = Temperature (°C)

T_K = $T + 273.15$ (Kelvin)

h = Humidity

P = Total pressure of air

P_{sat} = Saturation water vapour pressure (Tetens' Formula)

P_v = Partial pressure of water vapour

$R_{Specific,Dry\ Air}$ = Specific gas constant for dry air = 287.05 J/(kg·K)

$R_{Specific,Water\ Vapour}$ = Specific gas constant for water vapour = 461.5 J/(kg·K)

The actual operation of a wind turbine is outcome of a number of controls, for example, aerodynamic torque control, yaw orientation control, brake torque control and generator torque control, that work together to create a number of decision combinations. The final operating strategy, which is an outcome of optimisation of diverse and often contradictory goals, determines the control of individual components. These goals include, safe operation, maximising power generation, minimising vibrations, preventing structural damages, integration with grid, etc. (Manwell, McGowan & Rogers, 2009).

Due to the complexities involved in accounting for all the parameters that can effect control and operation, the parametric models are often not accurate. Hence, for predicting power generation of existing wind turbines a number of models based on Artificial Intelligence (Support Vector Machine, Gaussian Process, Random Forest and Artificial Neural Network) have been propounded These models are trained using historical SCADA data and the trained models are later used for making predictions (Ouyang et al., 2017; Pandit, Infield & Kolios, 2019).

1.5. Data Quality for Predicting Power Produced

In spite of all the precautions, the measurements recorded by SCADA system are always afflicted with imperfections or uncertainties of various kinds. Where uncertainty of measurement can be defined as *the doubt that exists about the result of any measurement* (Bell, 1999).

Since, the uncertainties arise due to multiple reasons they are also of different types. Some of them are tangible (can be quantified), while others are intangible (cannot be properly quantified). Some uncertainties can by random and others can be systematic. Because of the difficulties associated with the taxonomy of uncertainties, a number of classifications have been proposed. Unfortunately, there is no consensus regarding these classifications and the proposed classifications have not been widely accepted, resulting in confusions. Traditionally, uncertainties have been classified into two types (Manwell, McGowan & Rogers, 2009; Simon, Weber & Sallak, 2018):

- **Aleatoric** – This type of uncertainty arises due to inherent randomness or variability of the measured parameter. By repeating the measurement, it is possible to express it in terms of mean and standard deviation (interval and confidence level).
- **Epistemic** – This type of uncertainty arises due to the lack of knowledge or data. The factors that contribute to the uncertainty influence all the recorded values, hence, there is limited benefit to be gained by repeated measurement. Epistemic uncertainty can be further classified into:
  - **Bias** – It is a systematic shift from the true value.

- **Inaccuracy** – This is the mean difference between the measured and true value of the measured variable.
- **Imprecision** – It refers to the length of interval between which the measured values lie.
- **Ignorance** – It arises due to limited availability of measurements or knowledge regarding precision.
- **Incompleteness** – It arises due to missing data.
- **Credibility** – It arises due to competence or trustworthiness during calibration, installation, etc.

Epistemic uncertainty can be evaluated based on information like the manufacturer's specifications, past experience, expert opinion or subjective feel.

For the sake of completeness, measurements should be reported along with their corresponding uncertainties. A tangible uncertainty can be quantified using two numbers: interval (width of margin of doubt or dispersion about the mean) and confidence level (confidence that the "true" value lies with that margin. Since the uncertainties of a measurement depends upon a number of factors, it is often difficult to quantify all of them (Bell, 1999).

These uncertainties are severe for wind turbines because of the large variations taking place in the environmental conditions. Most of the errors arise due to:

- **Imperfections Caused by Sensors** – These imperfections arise because of many reasons, including, variations in the parametric values, imperfect nature (bias, noise, etc.) of the instruments, incorrect calibration, drift in the instrument calibration, measurement location, etc. They may be characterised as:
  - **Inherent Imperfections** – Since, environmental conditions constantly change, the sensors report values based on their response time, sampling rate, resolution, sensitivity and statistical analysis. Each of these behaviour introduces different types of uncertainties.
  - **Acquired Imperfections** – During its operation, a sensor is exposed to a number of environmental attacks, like, variations in impacts, wind force, temperature, humidity, condensation, frosting / icing, vibrations, oil / dirt / salt deposition, etc., resulting in its degradation.
- **Imperfection Caused by SCADA System** – In a SCADA system, values are recorded every 10 minutes, hence, the recorded data is actually not of that particular time, but a statistical value based on predefined algorithm.

To ensure confidence in the data used for analysis, a number of corrective measures need to be taken. These include (Manwell, McGowan & Rogers, 2009; Tavner, 2012):

- **Use of High Quality Sensors** – High quality sensors should have structure that is able to withstand environmental attacks; and have superiority of performance in terms of accuracy, precision, reliability, repeatability and reproducibility.
- **Use of Multiple Data Streams** – Multiple and varied data streams can be used to confirm the same fault so that its probability of detection increases, for example, use of vibration and debris count for detecting bearing fault. Apart from the benefits of redundancy, use of different sensors at different locations increases the probability of detection. A negative side effect of this is the collection of excessive number of data streams resulting in data overload. Additionally, "law of diminishing return" dictates that use of multiple sensors for the same task may not provide any new information.
- **Use of Advanced Data Analytics Techniques** – A number of methods have been proposed to handle different types of uncertainties. While aleatoric uncertainty is often handled using the Probabilistic Approach, epistemic uncertainty can be handled using the Possibilistic Approach.

  In Possibilistic Approach, values are not regarded as "crisp point numbers" but as membership functions. By integrating Fuzzy arithmetic, that is based on extended interval analysis, with deterministic or Machine Learning models, the predicted output is not a crisp point but a Possibility Distribution Function. Comparison of this output membership function against acceptance criteria gives likelihood of failure in terms of "Possibility of Failure" and "Necessity of Failure". The advantage of using Possibility Distribution Function, over Probability Density Function, is that no preference is given to values within the range of Fuzzy interval. This suits well for the situations where the available data is sparse. The weakness of the Possibilistic Approach is its imprecise results, which may give over-conservative and, at times, uneconomical recommendations. Thus, Possibilistic Approach may be a useful tool for implementing the philosophy of zero tolerance of accidents where not only the probability but also any possibility of failure has to be eliminated (Ayyub & Klir, 2006; Ross, 2004).

2. MOTIVATION AND AIM OF THE RESEARCH

2.1. Motivation for the Research

As discussed in the previous section, performance of a wind turbine can be judged by comparing Predicted Produced Power and Measured Produced Power. A Significant Difference between the two indicates sub-optimal performance. **Figure 2** shows a flowchart of the methodology that can employed for detecting sub-optimal power production.

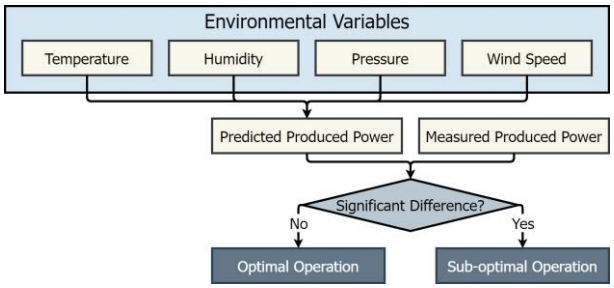

Figure 2. Flowchart showing the proposed fault detection methodology.

It may be possible to calculate Predicted Produced Power by using the four environmental variables; and if the Measured Produced Power (Grid Produced Power) is significantly less than the predicted value, there is a possibility that the wind turbine is operating sub-optimally.
While SCADA data can be used for carrying out this analysis, the methodology has some weaknesses. These weaknesses arise due to:

- lack of reliable models for calculating Predicted Produced Power taking into account all variations and imperfections in the collected data, and
- identification of what constitutes as *Significant Difference* considering the imperfections of the data.

2.2. Aim of the Research

Aim of the research is to develop a methodology for calculating Predicted Power Production using Hybrid (Machine Learning – Possibilistic) Approach while accounting for variability and uncertainty in the SCADA data.

2.3. Scientific Novelty and Importance of the Research

This paper presents work carried out to calculate Predicted Produced Power using wind turbine SCADA data using a Hybrid (Machine Learning – Possibilistic) Approach. The research includes:

- developing Machine Learning models for calculating Predicted Produced Power under varying environmental conditions, and
- handling of imperfections in the collected environmental and operating data by representing them as Fuzzy Membership Functions.

3. METHODS

3.1. SCADA Data Description

To demonstrate feasibility of the proposed methodology, SCADA data made available by the energy company EDP (2016) from four horizontal axis wind turbines located off the western coast of Africa has been used. The data has been recorded over a period of 2 years (2016 and 2017) at a 10-minute averaging interval. The datasets contain values of 76 parameters. For the mechanical components, some recorded parameters are (Bindingsbø et al. 2023):

- **Blades** – pitch angle
- **Rotor** – rpm
- **Nose Cone** – temperature
- **Nacelle** – direction, temperature
- **Generator** – rpm, bearing temperature (drive end and non-drive end), stator windings temperatures in the 3 phases, split ring chamber temperature, active power, reactive power
- **Gearbox** – bearing temperature, oil temperature
- **Hydraulic System** – oil temperature
- **High Voltage Transformer** – temperature
- **Ambient** – temperature, wind speed, wind direction

Associated dataset about meteorological conditions has also been provided for the same time instances. Failure logs containing timestamp, damaged component and associated remarks are also available. For this work, Turbine Number 7 ("T07") has been selected for which the total number of instances are 52445 and 52294 for 2016 and 2017, respectively. The variables that have been used in the calculation of power curve are given in **Table 1**.

Figure 3a shows the effect of Ambient Wind Speed on Generator RPM. The plot can be divided into three regions – (a) Low RPM Region, where Generator RPM < 300; (b) Transition Region, where 300 < Generator RPM < 1250; and (c) High RPM Region, where 1250 rpm < Generator RPM < 1680. When the Ambient Wind Speed is below the *Cut-In Wind Speed* (4 m/s), the frequency of Generator RPM below 300 rpm is high. With the increase in Ambient Wind Speed, the wind turbine adjusts its blade pitch angle so that Generator RPM is normally above 1250 rpm. Above the *Rated Wind Speed* (12 m/s), the Generator RPM is mostly above 1650 rpm. **Figure 3b** shows the effect of Ambient Wind Speed on Grid Produced Power. When the Ambient Wind Speed is below the *Cut-In Wind Speed* (4 m/s), Grid Produced Power is either negative or less than 275 kW. With increasing Ambient Wind Speed, Grid Produced Power increases so that at the *Rated Wind Speed* (12 m/s), Grid Produced Power is mostly *Rated Power* (2000 kW). **Figure 3c** shows the effect of Generator RPM on Grid Produced Power. The figure shows that the power generation drastically increases when the Generator RPM is above 1250 rpm.

Table 1. Selected variables used for developing the model.

Variable	Short Variable Name	Original SCADA Name	Description	Units
Timestamp			10-minute resolution	
Ambient Temperature	Amb_Temp	Amb_Temp_Avg	Average ambient temperature	ºC
Ambient Humidity	Amb_Humidity	Avg_Humidity	Average ambient relative humidity	%
Ambient Pressure	Amb_Pressure	Avg_Pressure	Average ambient pressure	millibar
Ambient Wind Speed	Amb_Wind_Speed	Amb_WindSpeed_Avg	Average windspeed within average timebase	m/s
Generator RPM	Gen_RPM	Gen_RPM_Avg	Average generator shaft / bearing rotational speed	rpm
Grid Produced Power	Grid_Prod_Power	Grd_Prod_Pwr_Avg	Power average	kW

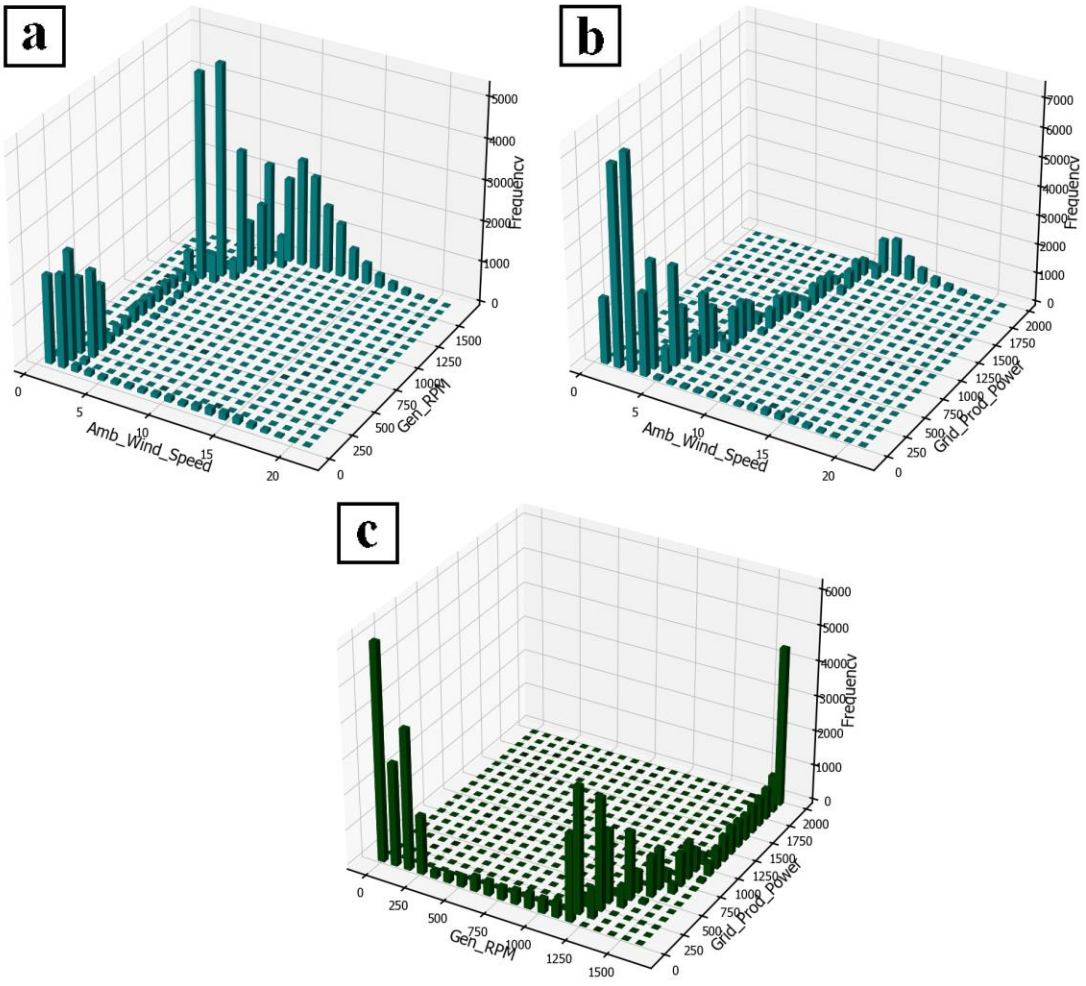

Figure 3. Relationships between Ambient Wind Speed, Generator RPM and Grid Produced Power.

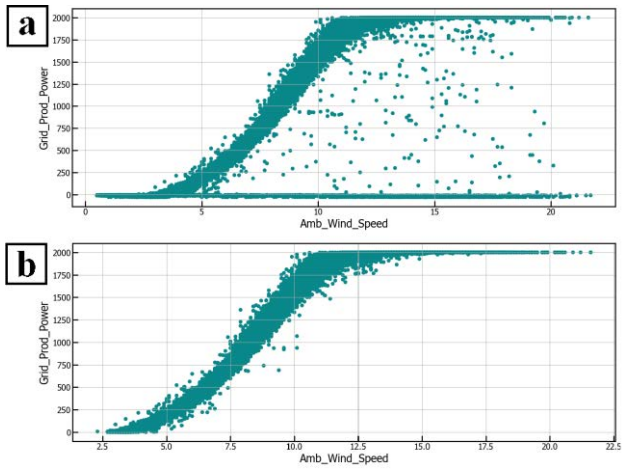

Figure 4. Plot of power generated versus wind speed using SCADA data. (a) Using raw data (b) Using data after removing outliers.

3.2. Data Pre-processing

Data pre-processing is an important step in the development of a Machine Learning model. This is to correct or remove vague, inconsistent, irrational, duplicate or missing values for algorithms to work properly (Bindingsbø et al. 2023).

SCADA data from a wind turbine also contain data that do not conform to the expected power curve and are referred to as "outliers". These outliers arise because of various explainable reasons. In this work, outliers have been identified for the following reasons:

Outlier Rule 1. *Generator RPM = 0 when Ambient Wind Speed => 4 m/s.* Even though the Wind Speed is above the *Cut-In Wind Speed* (4 m/s), the rotor does not move because the wind turbine is in the *shutdown state*. This can be because of various reasons, including the grid condition.

Outlier Rule 2. *Grid Produced Power <= 0 when Ambient Wind Speed < 4 and Generator RPM > 0.* This happens when the rpm of rotor is low, as a result of which power generation is less than the power consumed for operation. The difference is fulfilled by extracting power from grid.

Outlier Rule 3. *Grid Produced Power <= 0 when Ambient Wind Speed => 4 & Generator RPM > 0.* Even though the Wind Speed is above the *Cut-In Wind Speed* (4 m/s), the rotor is moving, power generation does not take place because the wind turbine is "free wheeling" in the *shutdown state*. This can be because of various reasons, including the grid condition.

Apart from these outlier data points, there are some more points that need to be removed. These data points have been recorded during the transition from normal operation to shutdown state or *vice versa*. These points lie scattered and can be identified using DBSCAN, a density-based clustering algorithm (Ester, Kriegel et al. 1996). Two rules that have been used for identifying the outliers are:

DBSCAN Clustering Rule 1. Ambient Wind Speed, Grid Produced Power, eps value = 2, min_samples value = 10

DBSCAN Clustering Rule 2. Ambient Wind Speed, Generator RPM, eps value = 3.45, min_samples value = 10

The results before and after cleaning are shown in **Figure 4**.

3.3. Flowchart for Predicting Produced Power

In order to develop a workable predictive model it is important to understand the process in terms of the structure, environment, and operation. **Section 1** briefly discusses some of these issues and based on this knowledge a simplified flowchart used for calculating Predicted Produced Power is shown in **Figure 5**. The figure also shows that there is a weak correlation between the environmental variables (Ambient temperature, Ambient Humidity and Ambient Pressure) and Grid Produced Power; but there is a strong correlation between Ambient Wind Speed and Grid Produced Power.

3.4. Representation of Variables as Possibility Distribution Functions

As discussed earlier, SCADA data is always encumbered by imperfections. One of the techniques that can be used for handling imperfections of the data is the Fuzzy Logic Approach. In this approach, a fuzzy variable X can be described by its Fuzzy Membership Function, instead of a Probability Density Function

In the Possibilistic Approach, a Fuzzy Membership Function can also be interpreted as a Possibility Distribution Function **(Figure 6)**. α–cut of this Possibility Distribution Function, donated by X_α, is a fuzzy interval $[x, x']$ that contains the values whose likelihood is α. The value of α can be in the range [0,1]. At the base, when the value of α is 0, variable has the interval within which the expected value will "certainly" lie. As the value of α increases, the interval between which the values lie decreases, but the certainty that the values will lie within this interval also decreases.

The α–cut of a fuzzy set is given by (Ayyub & Klir, 2006):

$$X_\alpha = [x, x']_\alpha = \{x \in X | x \leq x \leq x'\} \quad (5)$$
$$\alpha \in [0,1]$$

Where:

x = Lowest real number value of the interval

x' = Highest real number value of the interval

The use of α–cut allows for the concepts of interval analysis to be used (Ayyub & Klir, 2006).

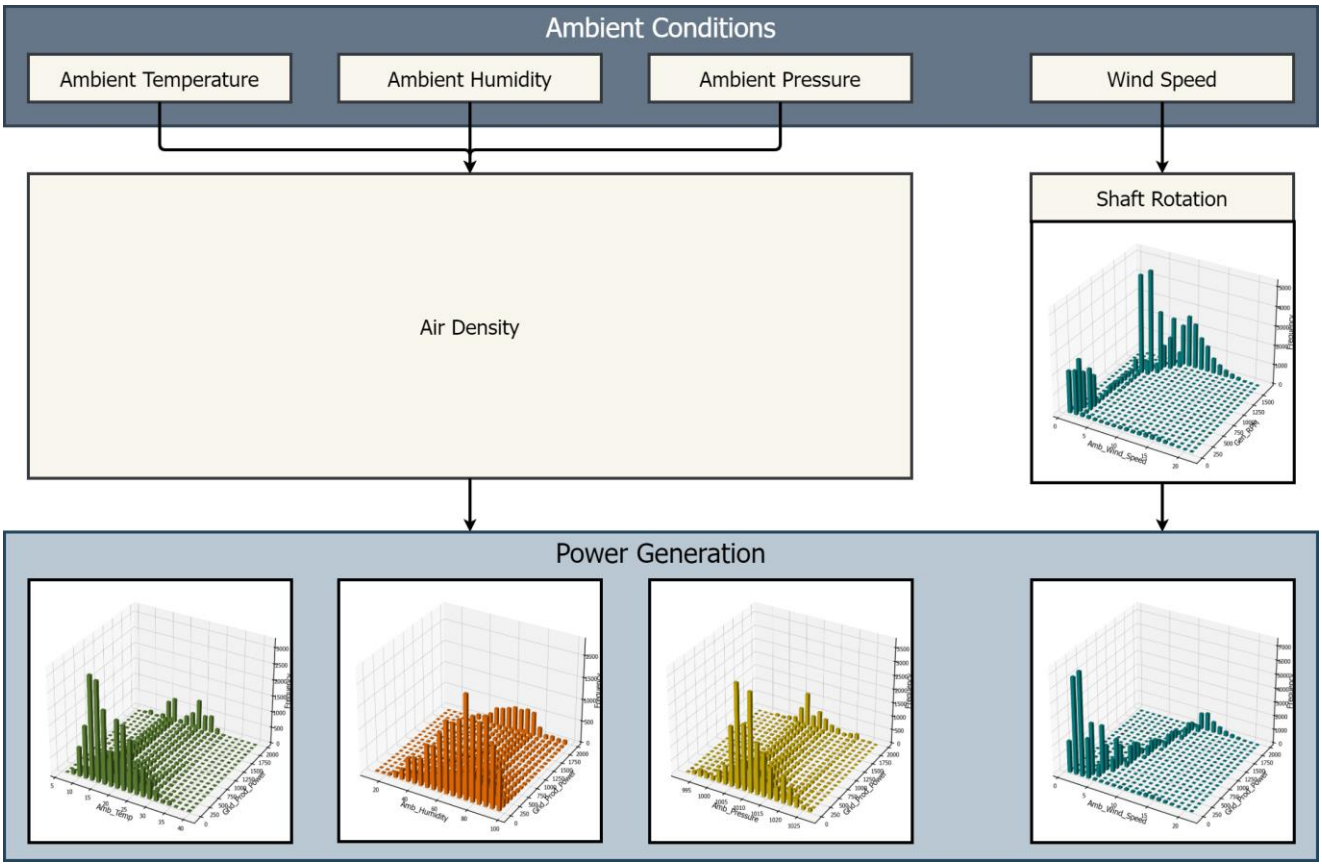

Figure 5. Flowchart showing influence of variables on the calculation of produced power.

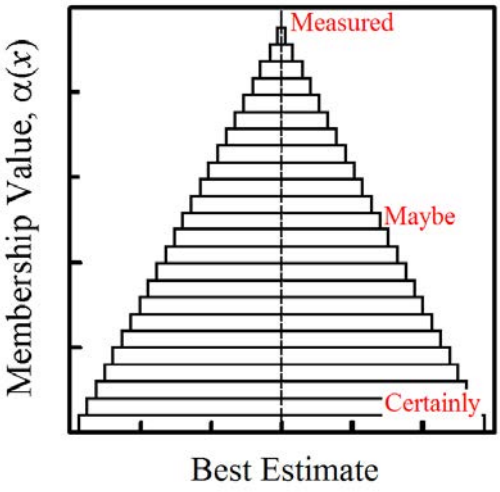

Figure 6. Conceptual illustration of possibility distribution function.

In the absence of detailed study to quantify the interval, limit values that have been used for the calculations are based on the literature and experience. For example, response time and uncertainty of a value recorded by a cup anemometer, depends upon its construction (dimensions, weight, etc.) and degree of deterioration (example, friction caused by corrosion). Under test conditions, a new anemometer can show inaccuracy of about 2%. Under working conditions, this inaccuracy may increase due to corrosion, wear, misalignment, deposition of dust, etc. (Manwell, McGowan & Rogers, 2009). Thus, at $\alpha = 0$ (interval within which the expected value "certainly" lies), the estimated limit of values around the measured values have been estimates as:

- Ambient Temperature : ±1.0°C
- Ambient Humidity : ±1.0%
- Ambient Pressure : ±1.0 millibars
- Ambient Wind Speed : ±0.5 m/s
- Power Coefficient : 0.45 ±0.05

Possibility Distribution Function for a variable is generated by stacking α number of intervals, where the bottom layer, $\alpha = 0$, has interval range:

Table 2. Possible combinations of interval values used for calculating Predicted Produced Power.

Combination	Ambient Wind Speed	Ambient Temperature	Ambient Pressure	Ambient Humidity
Combination_1	Min	Min	Min	Min
Combination_2	Min	Min	Min	Max
Combination_3	Min	Min	Max	Min
Combination_4	Min	Min	Max	Max
Combination_5	Min	Max	Min	Min
Combination_6	Min	Max	Min	Max
Combination_7	Min	Max	Max	Min
Combination_8	Min	Max	Max	Max
Combination_9	Max	Min	Min	Min
Combination_10	Max	Min	Min	Max
Combination_11	Max	Min	Max	Min
Combination_12	Max	Min	Max	Max
Combination_13	Max	Max	Min	Min
Combination_14	Max	Max	Min	Max
Combination_15	Max	Max	Max	Min
Combination_16	Max	Max	Max	Max

$$\left[\begin{matrix}(measured\ value - estimated\ limit\ value),\\ (measured\ value + estimated\ limit\ value)\end{matrix}\right]$$

In the Possibilistic Approach, in order to account for the uncertainty, instead of using crisp values of environmental variables (Ambient Temperature, Humidity, Pressure and Wind Speed) as recorded by SCADA and Power Coefficient, Possibility Distribution Functions of the variables are used. Calculations are carried out using interval values at each α–cut. For each value of α, the interval values of variables are determined. Considering all the minimum and maximum values of the intervals, the minimum and maximum values of the output function are calculated using accepted equations. Different combinations that are possible are shown in **Table 2**. The results of all α–$cuts$ are stacked to build the possibility distribution function of the output function (Ayyub & Klir, 2006).

3.5. Possibilistic Approach

The calculations are done in two steps. In the first step, Possibility Distribution Function for Air Density is generated using **Equation 4**. In the second step, the Possibility Distribution Functions for Air Density, Ambient Wind Speed and $C_P(\lambda, \beta)$ are used to generate Possibility Distribution Function for Predicted Produced Power using **Equation 2**.

3.6. Hybrid (Machine Learning – Possibilistic) Approach

Development of the Hybrid (Machine Learning – Possibilistic) is done in two steps.

In the first step, different Machine Learning models are trained using training dataset and the output from the trained models are evaluated. Models that have been evaluated are:

- Linear Models – Linear Regression (LR), Lasso, Ridge, and
- Tree-based Models – Decision Trees, Random Forest (RF)
- Boosting Models – AdaBoost, XGBoost and LGBoost
- Support Vector Regression (SVR)

Out of these models, XGBoost (RMSE = 186, R^2 = 0.93, MAE = 127) has been selected because it gives acceptable fit and takes short calculation time.

In the second step, the trained model and Possibility Distribution Functions of the environmental variables are used to generate Possibility Distribution Functions for Predicted Produced Power. The calculations are carried out according to the method described in the previous section, except that the calculations are done using the trained Machine Learning model instead of the equations.

4. RESULTS AND DISCUSSION

4.1. Possibilistic Approach

4.1.1. Effect of Environmental Variables on Air Density

Figure 7 shows the results of the calculations carried out for predicting Air Density. Since Air Density increases with the increase in Ambient Pressure, but decreases with the increase in Ambient Temperature and Ambient Humidity; the graph shows seasonal variations of the Air Density. The graph also shows sensitivity to the inaccuracies of recorded values and the "true" value may lie anywhere within the $Certain - Min$ and $Certain - Max$ curves.

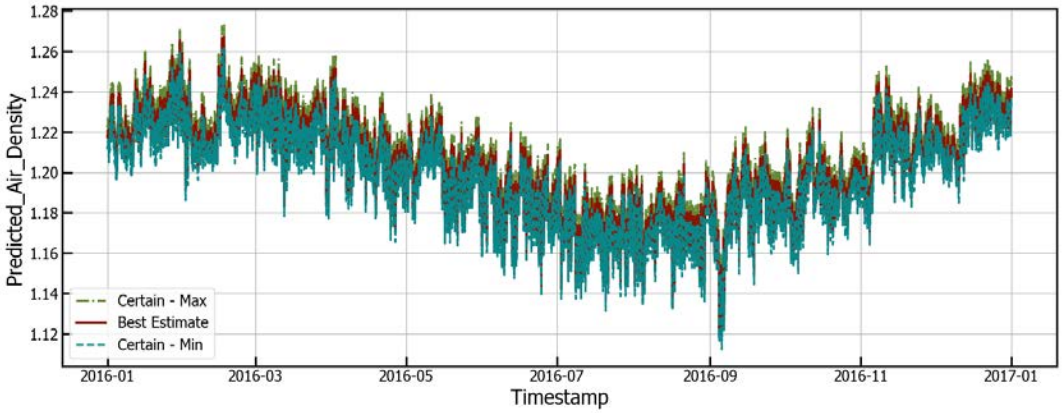

Figure 7. Seasonal variation on Predicted Air Density at $\alpha{-}cut = 0$.

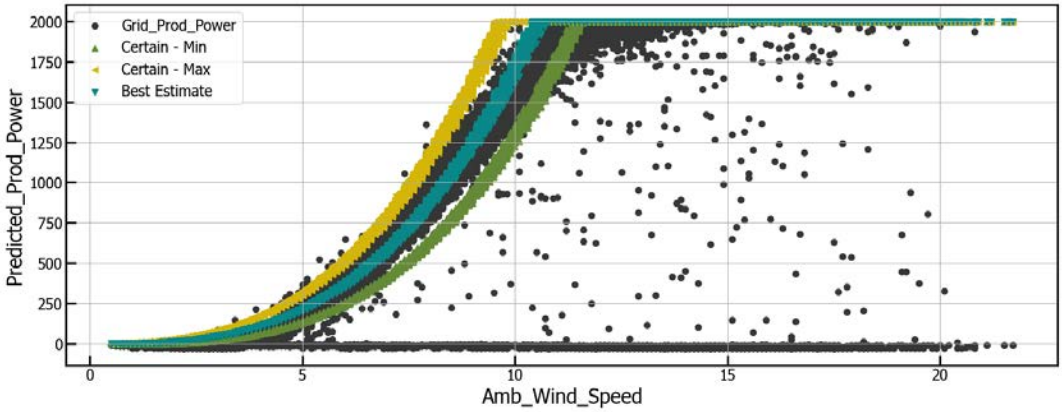

Figure 8. Effect of Ambient Wind Speed on Predicted Produced Power using Possibilistic Approach at $\alpha{-}cut = 0$.

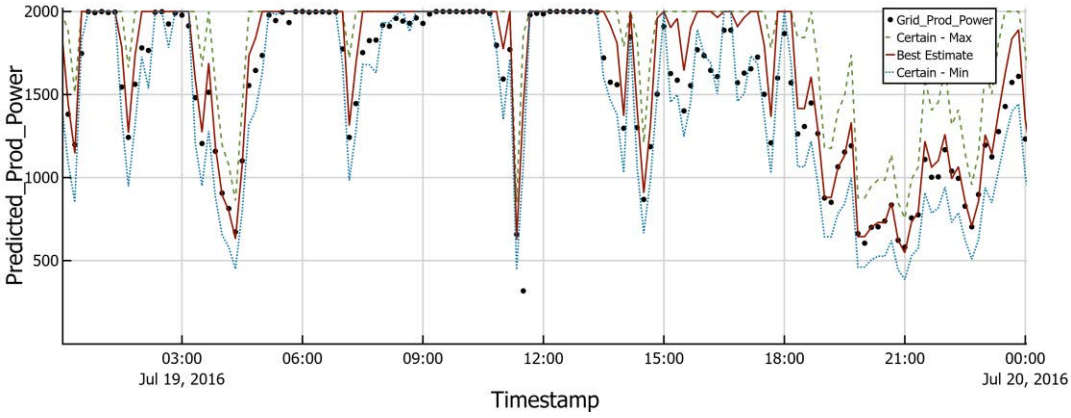

Figure 9. Plot of Grid Produced Power and Predicted Produced Power calculated using Possibilistic Approach at $\alpha{-}cut$=0 for a 24 hour duration (19th July, 2016).

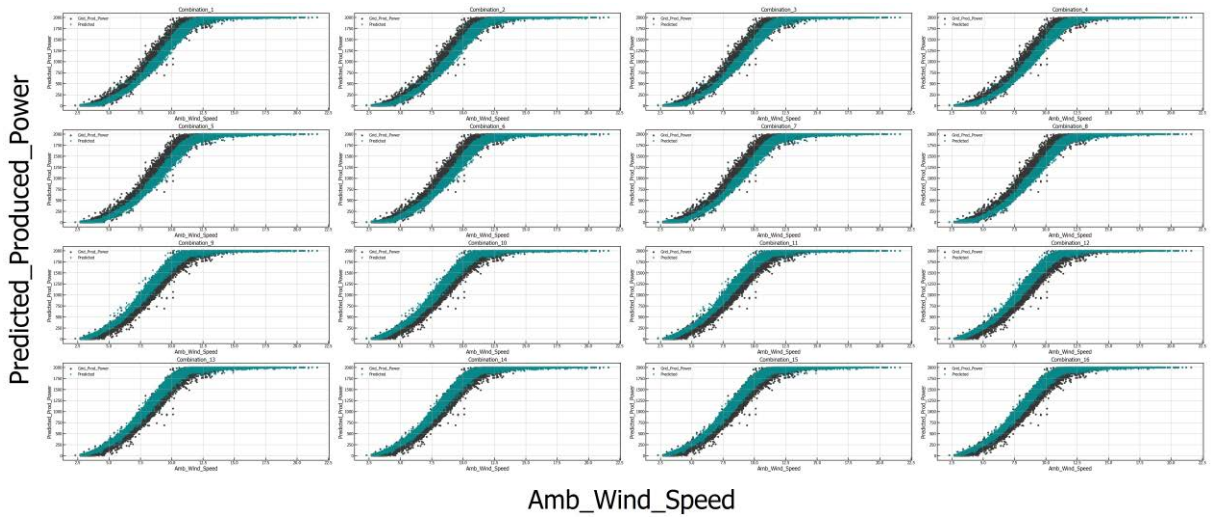

Figure 10. Predicted Produced Power using Hybrid Model for the combinations of interval values given in **Table 2** at α–cut=0.

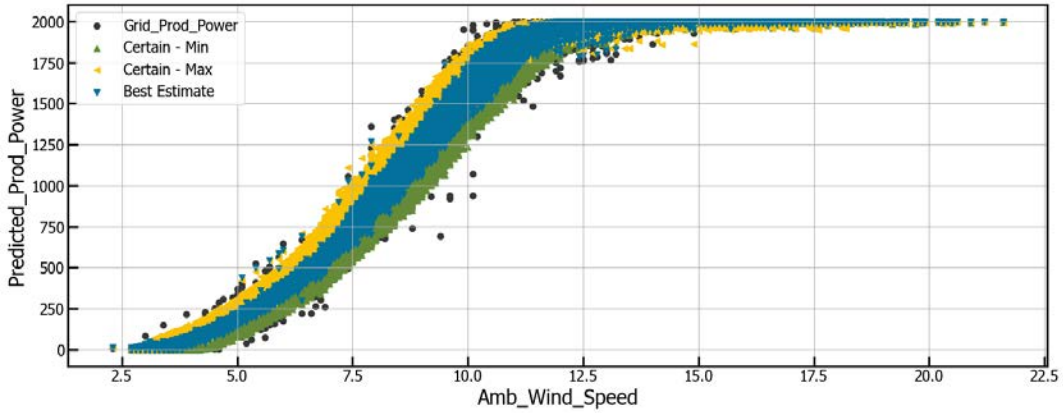

Figure 11. Effect of Ambient Wind Speed on Predicted Produced Power using Hybrid Approach at α–$cut = 0$. $Certain - Min$ is obtained from Combination_6 and $Certain - Max$ is obtained from Combination_11.

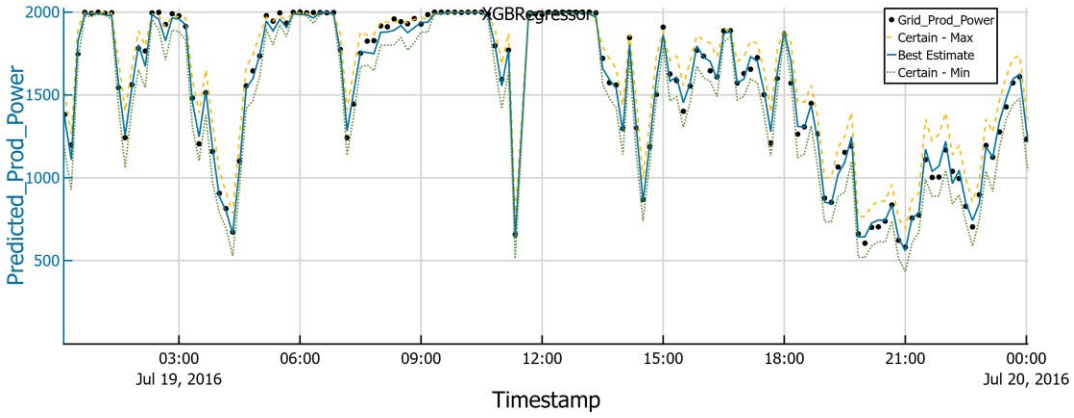

Figure 12. Plot of Grid Produced Power and Predicted Produced Power calculated using Hybrid Approach at α–cut=0 for a 24 hour duration (19th July, 2016).

4.1.2. Effect of Environmental Variables on Predicted Produced Power

Figure 8 shows the effect of Ambient Wind Speed on the Predicted Produced Power. The graph shows that:

- Power curve developed according to the **Equation 2** does not follow the actual trend. A better model, as proposed by Saint-Drenan, Y.-M. et al. (2020), may give better result.
- Spread of measured Grid Produced Power at a particular wind speed has not been accounted for. The spread can arise due to various reasons, like, control of the operation and imperfections in measurements.
- Predicted produced power is sensitive to the inaccuracies of recorded values and the "true" value may lie anywhere within the $Certain - Min$ and $Certain - Max$ curves.

Figure 9 shows plot of Predicted Produced Power and Grid Produced Power for a 24-hour duration (19th July, 2016). The graph shows that measured values generally lie within the boundaries set by $Certain - Min$ and $Certain - Max$ values.

4.2. Hybrid (Machine Learning – Possibilistic) Approach

Figures 10-12 show the results of calculations carried out using Hybrid (Machine Learning – Possibilistic) Approach. **Figure 10** shows the effect of max and min interval values of environmental variables on Predicted Produced Power. The figure shows that combinations have significant effect on the Predicted Produced Power.

According to **Equation 2**, Predicted Produced Power is proportional to cube of Ambient Wind Speed. Hence, Combination_1 to Combination_8 show lower values of Predicted Produced Power as compared to Combination_9 to Combination_16. Within these two sets of combinations, the differences are small because of the relatively small differences in the calculated air density.

Figure 11 shows the effect of Ambient Wind Speed on Predicted Produced Power using Hybrid Approach at $\alpha\text{–}cut = 0$. The figure shows significant effect of measurement uncertainties on the predicted values. $Certain - Min$ is obtained from Combination_6 and $Certain - Max$ is obtained from Combination_11.

Figure 12 shows plot of Grid Produced Power and Predicted Produced Power calculated using hybrid approach at $\alpha\text{–}cut$=0 for a 24-hour duration (19th July, 2016). The graph shows that measured values generally lie within the outer most boundaries set by $Certain - Min$ and $Certain - Max$ values.

A comparison between **Figure 9** and **Figure 12** shows that, in general, (a) Machine Learning model fits better than the parametric model; and (b) the difference between $Certain - Max$ and $Certain - Min$ in the Hybrid Model is less than that in the Possibilistic Model.

5. CONCLUSIONS

This paper presents a simple yet robust methodologies for calculating Predicted Produced Power using SCADA data while accounting for variability and uncertainty. The methodologies utilise either parametric or Machine Learning models for handling variability; and Possibilistic Approach for handling uncertainty. As a case study, the idea has been demonstrated using real-life SCADA data.

To take the research work further, the following tasks have been identified:

- The models do not account for effect of control measures of the wind turbine on produced power. Since, these measures can significantly effect power generation (López-Queija et al., 2022); models that account for control measures need to be used.
- Grid Produced Power has been assumed to have crisp values, but in reality measurement of Grid Produced Power is also afflicted with uncertainties. Hence, calculations need to be done by representing it by a Possibility Distribution Function.
- Having obtained Possibility Distribution Functions of Predicted Produced Power and Grid Produced Power, *Likelihood of Sub-optimal Performance* can be determined using the concepts of Possibility and Necessity Measures.

ABSTRACT

Maintenance decisions range from the simple detection of faults to ultimately predicting future failures and solving the problem. These traditionally human decisions are nowadays increasingly supported by data and the ultimate aim is to make them autonomous. This paper explores the challenges encountered in data driven maintenance, and proposes to consider four aspects in a maturity framework: data / decision maturity, the translation from the real world to data, the computability of decisions (using models) and the causality in the obtained relations. After a discussion of the theoretical concepts involved, the exploration continues by considering a practical fault detection and identification problem. Two approaches, i.e. experience based and model based, are compared and discussed in terms of the four aspects in the maturity framework. It is observed that both approaches yield the same decisions, but still differ in the assignment of causality. This confirms that a maturity assessment not only concerns the type of decision, but should also include the other proposed aspects.

1. INTRODUCTION

Von Leibnitz already dreamt of a universe where decision problems were solved by computations rather than by furious debates. Centuries later, it is much better understood that Von Leibnitz's dream cannot come true. So, one may compute many decisions, but not any decision. Where computed engineering decisions fail, maintenance decisions are typically triggered. Unsurprisingly, maintenance decisions are often hard to compute, or they may even be fundamentally incomputable. However, an inability to compute a decision does not imply that such a decision cannot be supported by computations. This paper will present a maturity framework for computational maintenance decision support.

In this framework, maturity grows as more (advanced) decisions in a maintenance control loop are computed. However, the presented framework not only considers the type of decision, as in existing data maturity models, but relates maturity also to: (*i*) the translation of reality to data (vice-versa), (*ii*) the computability (with models) of the decisions involved and (*iii*) the causality of the relations obtained. A case study will be used to explore the attainable maturity starting from the lowest level. An experience based and a model based approach will be attempted, which both will prove to take the correct decision for an arbitrary validation set. Still, decision makers should care about the approach as causality is managed differently. In the experience based approach, causality will be assigned afterwards. In the model based approach, causality is inherent, as a model that is posited as true is solved. Further, it is observed that it is impossible to compute a true model from only a history of measurements. Therefore, a history of measurements will be indecisive about the approach. Still, the engineering profession established a plethora of guidelines that have often proved to be correct. As these engineering guidelines strengthen (a suspicion of) causality for both approaches, the attainable maturity in data driven maintenance may rise at an acceptable risk.

This paper is organized as follows. Section 2 will introduce the four basic aspects of the framework to assess the maturity in data driven maintenance. Section 3 will portray a typical construction of two different autonomous fault detection and isolation methods (the first step in maturity). Section 4 will demonstrate fault detection and isolation in an iconic case study. Finally, section 5 will discuss the results and section 6 will present the conclusion.

2. BACKGROUND

This section will introduce the four basic elements that jointly determine the maturity in data driven maintenance and thus

constitute the proposed framework. Section 2.1 addresses the challenges in computing a "real" decision, section 2.2 will discuss the challenges in using (engineering) models to compute decisions. Then section 2.3 will relate the flow of the maintenance control loop with a conventional data maturity model. Finally, section 2.4 discusses the difference between observed associations and causality, and its effect on decision making.

2.1. Obstructions in computing "real" decisions

Data (Latin: givens) are input symbols to a syntactical formal language. Hilbert dreamt of a formal language that could provide a complete, consistent, and decidable foundation of mathematics. Gödel (1931), Church (1936) and Turing (1937) showed that such a formal language is nonexistent and the dreams of Von Leibnitz and Hilbert were destroyed. This means that some problems are fundamentally incomputable. Moreover, even the most potent computing devices may just fail to compute a problem in time. Therefore, problems that are computable in principle may be too complex to compute in practice.

A formal language becomes meaningful by assigning a truth value. Then, a computation may become similarly meaningful and it may eventually represent some reasoning about truth or falsehood. Evidently, Von Leibnitz similarly hoped to compute meaningful decisions as he hoped to settle legal disputes this way. Then, a computed decision involves

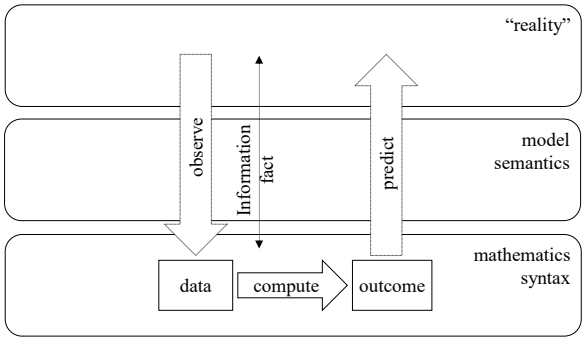

Figure 1. Framework for computing "real" decisions.

Engineers are not necessarily orthodox positivists but the engineering profession is not just about modelling, it also includes building. To circumvent or at least alleviate philosophical controversy, the "reality" in Figure 1 could also be seen as merely a user interface by skeptics who doubt the existence of space-time (Hoffman, 2019).

Any vertical translation in Figure 1 involves an arbitrary human choice, i.e. facts are *made* (Latin: facere) and information is *shaped* (Latin: formare). So, facts and information do not follow from some computable coding operation, they involve arbitrary human choice. For example, observing is not just a mechanical decoding of sound or light waves, it also involves a specific interpretation. Likewise, predicting involves more than just computing an outcome (100101…).

In conclusion, computing a "real" decision may be impossible because (*i*) it is fundamentally incomputable, (*ii*) it is too complex to compute in time, or (*iii*) the translation between "reality" and the syntactical computation is philosophically controversial.

2.2. Maintenance decisions are incomputable

A decision (Latin: cut-off) is the elimination of outcomes that would have occurred otherwise. A computation is a deterministic discrete operation that can be performed on a Turing Machine. In a way, a Turing Machine decides as it halts at a particular outcome (while eliminating all other candidate outcomes). So, syntactical decisions include the acceptance or rejection of a string as a well formed formula in a formal language. However, "real" decisions include a choice that causes a specific outcome, rather than any other outcome.

The computation of a "real" decision requires translations between a syntactical Turing Machine and "reality" (Figure 1). These translations are essential for data driven maintenance where computations from syntactical data should support "real" maintenance decisions. Generally, the engineering profession established a high degree of common sense regarding these potentially controversial translations. This common sense has been made explicit in guidelines that specify the computation of the quality of a design (CEN, 2007), (IACS, 2024). Quality is defined by ISO (2015):

> The degree to which a set of inherent characteristics of an object fulfils requirements.

So, quality reflects a margin between measurable inherent characteristics and subjective requirements. So, quality is not just a measurable "real" variable (Figure 1), rather quality is the result of an arbitrary translation between a measurable reality and some subjective aspiration. Engineers showed a great ability to compute outcomes that (often) appeared to satisfy quality in practice. Also in this case, computations from syntactical data support "real" engineering decisions.

The Church-Turing thesis states:

> If something is computable on a discrete device, then it is also computable on a Turing Machine.

This implies that up until now, no one has been able to construct a discrete computing device for which an equivalent Turing Machine does not exist. Still, some computations that are computable on a Turing Machine in principle, may be too complex to compute on a practical device in time. Engineers showed great ability in constructing devices that autonomously compute "real" decisions as feedback control loops are ubiquitous. So, Von Leibnitz's

dream *often* became attainable after all. As an example, the feedback controller (C) shown in Figure 2 autonomously computes an input signal (U) to the process (P) that yields an output (Y). This computation depends on the error (W) between the output (Y) and the set point.

Still, the delimitations from section 2.1 remain unresolved implying that (*i*) engineering guidelines are occasionally improved by lessons learned from "real" disasters, or that (*ii*) the feedback control loop occasionally oscillates away from the set point. Where engineering computations fail, maintenance is often triggered. Maintenance is defined by:

> The combination of all technical and administ
> actions, including supervision actions, to retai
> restore an item's quality.

This definition paraphrases CEN (2019) and IEC (2015 maintenance is considered as a decision to act, wit intention to cause a quality effect. Figure 2 sho maintenance control loop that should correct the faults autonomous feedback control loop (Tinga et al., 2023) maintenance control loop is typically triggered b detection of a fault, i.e. an observation of some ano Fault isolation is the assignment of a specific fault labe assists in the choice of the recovery action. identification is an assessment of the (evolution in magnitude of the fault. Prognostics is an estimation remaining useful life. Finally, recovery is an actio causes quality. This maintenance control loop follows a Detection and Isolation (FDI) convention (Isermann, 2006).

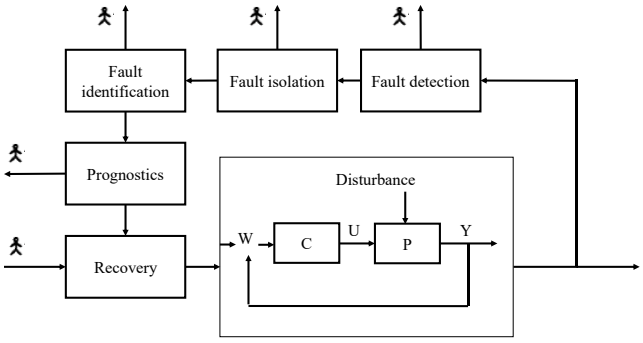

Figure 2. Autonomous control loop extended with maintenance control.

Although the maintenance control loop is thought to be human involved (as indicated by the person symbols in Figure 2), parts of it may still be computed. For example, the fault detection and the fault isolation may be computed before a human takes over. Then, this human may not need to troubleshoot the anomaly as this has been computed autonomously.

In conclusion, engineers have developed a great ability to compute "real" decisions and to construct devices that could similarly do so autonomously. Still, engineering computations occasionally fail which triggers human involved maintenance. Therefore, computing autonomous maintenance is challenging, but parts of the maintenance control loop may still be supported by computations. For that reason, the title of this paper refers to data driven maintenance rather than autonomous maintenance.

2.3. Maturity in data driven maintenance

Data maturity models are widely researched (Al-Sai et al., 2023) and applicable. Figure 3 shows a commonly adopted data maturity classification that includes monitoring,

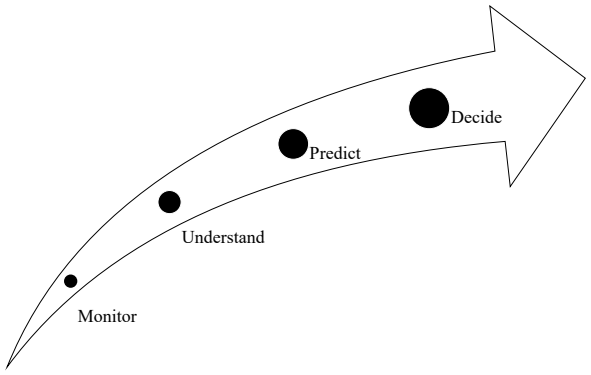

Figure 3. Data maturity model.

A comparison of the data maturity model in Figure 3 with the maintenance control loop in Figure 2 reveals that data maturity grows as more steps in the maintenance control loop are being computed, i.e. monitoring corresponds with fault detection, understanding with fault isolation & identification, predicting with prognosis and deciding with recovery.

Tiddens et al. (2023) observed a relation between an aspired maturity level and the required measurements. This paper intends to be more precise about this relationship by comparing two computations of fault detection and isolation that both provide a correct decision for a specific set of measurements. Still, these two computations will differ in attainable maturity as they translate to "reality" in a different way (Figure 1), i.e. the "real" causal implication of corresponding syntactical computations will be shown to differ. Then, the attainable maturity does not just rely on measurements, but also on a subjective translation.

2.4. Causality

This section will introduce two ways to address causality when computing a "real" decision (e.g. in the case study in the next section). In the experience based approach, a statistical association is computed and the causal assumptions are made separately. In the model based approach, the effect of setting a variable in an engineering (design) model of

equivalences is computed and the causality follows from the deterministic process of the computation itself.

An equivalence is symmetrical, reflexive, and transitive:

$$Y = aX + b \quad (1)$$

A causality is only transitive:

$$Y \leftarrow aX + b \quad (2)$$

In Eq. (1) swapping the terms around the equivalence symbol does not change the meaning of the expression. However, in Eq. (2) swapping the terms around the arrow changes the meaning of the expression from "X causes Y" to "Y causes X". It is important to realize that statistical associations retrieved from measurements are equivalences, but they do not imply causality.

Decisions rely on causality rather than on associations as a choice should bring about an effect that would not or less likely occur otherwise. To validate an individual decision, the effect of each choice would have to be observed whereas only the effect of the choice made is observable. Generally, the problem of observing the causal interactions in an individual experiment is that the counterfactuals remain unobservable. Therefore, the interventional distribution $Pr\big(Y|do(X)\big)$ may wildly differ from the observed distribution $Pr(Y|X)$.

Still, there are ways to strengthen a suspicion of causality across many experiments provided that the cause X in Eq. (2) sufficiently varies. Fisher (1935) proposed random assignment of treatments to eliminate the effect of unobserved confounders and he suggested that unobserved confounders could explain the measured association between smoking and lung cancer (Fisher, 1958). The latter beautifully illustrates the delicacy to use a measured association to support a decision to smoke. Structural Causal Modelling (SCM) proposed by Pearl (2009) also applies to non-experimental research constructs. SCM subsumes Structural Equations Modelling (Wright, 1934), and the Potential Outcomes Framework (Rubin, 2005). The experience based approach to the case study in section 4 will use SCM to specify the independence assumptions needed for a specific causal explanation of a computed statistical association.

Engineers typically use equivalence relations like bond graphs or finite element methods when designing a device. These equivalence relations are acausal, but the computation of their solution is a sequential process that introduces causality, i.e. if one variable in these equations has been set to a known value, the response of the other variables follows by computation. So, there is an intimate relationship between computing the solution of an engineering model and causality (Karnopp et al., 2012). The causal effect of a "real" decision to set one of these variables is similarly computable. The model based approach to the case study will use a bond graph to model the case study and the causality follows from the sequence in the computation itself.

In conclusion, this subsection showed that causality could be assigned after the computation of a statistical association and that causality is just inherent to the process of computing. Both notions of causality will be applied to the case study.

Now these four basic ingredients of data-driven maintenance decision making have been considered, the theoretical concepts will be converted to a practical application in the next two sections.

3. AUTONOMOUS FAULT DETECTION AND ISOLATION

This section will portray a typical construction of autonomous fault detection and isolation. Fault detection and isolation are the first "real" decisions in the maintenance control loop (Figure 2). A Fault Signature Matrix (FSM) will be used to assess the ability to detect or isolate faults. The rows in a FSM list the applicable faults (Table 1). A fault can be defined as an anomaly that precedes a failure (= nonconformity in quality). The columns in a FSM list the features (or symptoms) that indicate the faults (Table 1). The fields in a FSM indicate the relationship between the faults and the symptoms. A FSM could therefore support decisions to detect or to isolate faults (step 1 and 2 in Figure 2). For example, $Fault_0$ in Table 1 is detectable and isolable by the feature F_0. $Fault_1$ and $Fault_2$ are detectable but not isolable by the features F_1 and F_2, while $Fault_3$ is both detectable and isolable by these two features.

Table 1: Example of a FSM.

	F_0	F_1	F_2
$Fault_0$	1	0	0
$Fault_1$	0	1	1
$Fault_2$	0	1	1
$Fault_3$	0	0	1

An Experience Based (EB) and a Model Based (MB) approach to construct a FSM will illustrate two scenarios for the assignment of causality. It will become clear that an EB_FSM merely relates faults to associated symptoms and a causality assignment will require additional assumptions. For a MB_FSM, causality has already been settled in the process of its construction. The objective here is to explore the human involvement. The objective is *not* to review all existing approaches or to exhaustively review the computing of the fault detection and diagnostics. The presented FSM constructions just survey the essential steps to be taken in the

identifying the faults that may predict them.

The history of measurements will often be collected by non-experimental research which precludes control over the collection of *all* relevant fault states and operating regimes. By conceiving many fault states and operating regimes, the collection of the history of measurement may take too long (=complexity issue analogous to computational complexity). Moreover, faults are often a hidden variable. As already signaled by Tiddens et al. (2023), the history of measurements often delimits aspirations to compute fault detection and isolation.

Step 2: choose the features (EB_FSM columns).

The features of choice should be built from the history of measurements. A data scientist may generate an enormous amount of features from the library of signal features (Lu et al., 2023) while ignoring the choice of the faults. Burnham & Anderson (2002) already argued that even vague knowledge regarding related variables reduces the computational complexity of the model selection while avoiding spurious relations. Engineering guidelines may establish common sense about features (Isermann, 2011) that indicate a fault.

Step 3: select a model

Any regression or classification model may be considered to describe the data, but the shortest description is supposed to be the best one (Occam's razor). However, the shortest description of a data string is fundamentally incomputable (Solomonoff, 1964). Therefore, model selection remains rather arbitrary. Still, a suboptimal approximating model could support a dithering decision maker accepting some risk.

Step 4: explain the model

To explain the selected model, i.e. to identify which features strongly relate to a fault, some arbitrary feature importance test may be chosen. However, feature importance scores do not indicate causality, while a decision maker who does not only seek support in deciding *whether* to act, but also in *how* to act, requires causality. Section 2.4 mentioned that

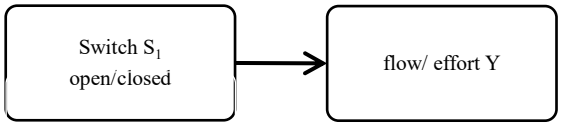

Figure 4. Example of a DAG.

Figure 4 is a directed acyclic graph (DAG) that specifies the causalities in a universe of the variables (S, Y). By Bayesian Network Factorization, the joint probability distribution $Pr(S, Y)$ follows from the DAG in Figure 4:

$$Pr(S, Y) = Pr(S)Pr(Y|S) \quad (3)$$

Eq. (3) specifies the potentially observable association to identify a causality provided that the DAG is true. For example, the causality $Pr\big(Y|do(S)\big)$ is identifiable by the potentially observable association $Pr(Y|S)$, provided that Figure 4 is true. The DAG may be highly controversial, but it is explicit at least (Pearl, 2009).

3.2. Model based fault signature matrices

This section will outline the construction of a MB_FSM that will be used in the case study.

Step 1: construct an engineering model

A device does not come from some natural phenomenon, it is the result of a deliberate design. Engineers typically compute their designs using the laws of physics. These laws of physics hold under idealized conditions and they should adequately approximate the "real" conditions. These approximations are usually reflected in engineering guidelines that prescribe safety margins. Laws of physics and engineering guidelines are arbitrary in principle as they are occasionally updated, but they generally reflect a very high degree of common sense.

Step 2: choose the faults (MB_FSM rows)

Faults should be phrased in terms of drifts in parameters in the engineering model. If other faults (beyond the parameters in the model) should be detected or isolated, the engineering model needs extension or an additional EB_FSM may be needed.

Step 3: choose the ARRs (MB_FSM columns)

From an engineering model of n equations the values of n variables are computable. As (some of) these variables are measured, less equations are needed which enables the formulation of Analytical Redundancy Relations (ARR). An ARR is an equivalence consisting of measurements and parameters from the engineering model. An ARR detects faults that have been defined as parameter drifts, and thus acts as feature or symptom in the FSM.

Step 4: construct the MB_FSM

The faults (MB_FSM rows) have been defined at step 2. The *ARR*s have been defined at step 3, and the fields trivially follow from the presence of the parameters in the *ARR*s. Therefore, the construction of the MB_FSM is autonomously computable from the previous steps.

The *ARR* s are acausal equivalence relations. However, computing the solution of the *ARR*s involves a sequential process where the values of the *ARR*s follow from their variable and parameter values. Similarly, a "real" decision to set a variable or a parameter to a specific value causes the corresponding *ARR*s to change. As a fault in step 2 has been defined as a drift in some *ARR* parameter, this fault causes the *ARR* s to change within the universe of idealized conditions of the engineering (design) model from step 1.

4. CASE STUDY

This section will demonstrate fault detection and isolation by constructing an EB_FSM and a MB_FSM in an iconic case study of a linear time invariant system under feed-forward

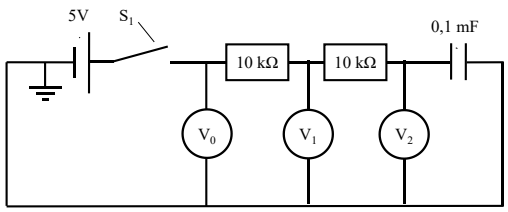

Figure 5. The RRC circuit.

A pulse signal with a period of 20 seconds will trigger the switch S_1. The lines in Figure 6 show the computed evolution of the voltages and the dots show the measured evolution of the voltages for a normal (healthy) state of the circuit.

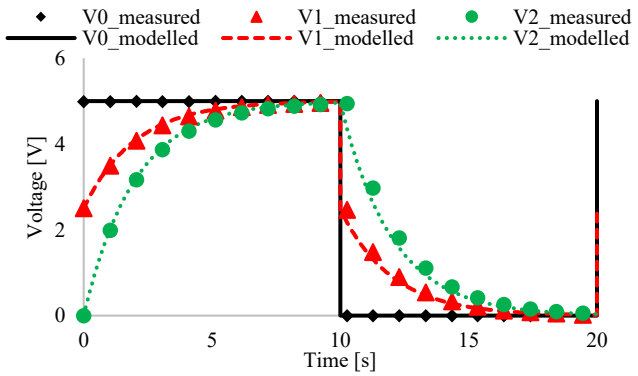

Figure 6. Evolution of the computed and the measured voltages at the healthy state.

Figure 6 confirms that engineers are highly capable of deciding about the "real" behavior of the RRC circuit by computation. Occasionally, the "real" measurements may drift away from the engineering computation which could trigger maintenance. In this case study, two fault treatments have been applied:

1. A decreased resistance R_0 that is in between the voltages V_0, V_1 in Figure 5.
2. An increased capacitance.

Fault detection and isolation would have been trivial if the resistance and the capacitance were directly observable. It is only due to the experimental setup of this case study that the presence and absence of the faults was certain. Therefore, fault labels in Figure 7 and Figure 8 just followed from a known experimental intervention.

Figure 7 shows that in the faulty state (reduced resistance) the measured voltages respond faster to the switch than predicted by the engineering computation (for the healthy state).

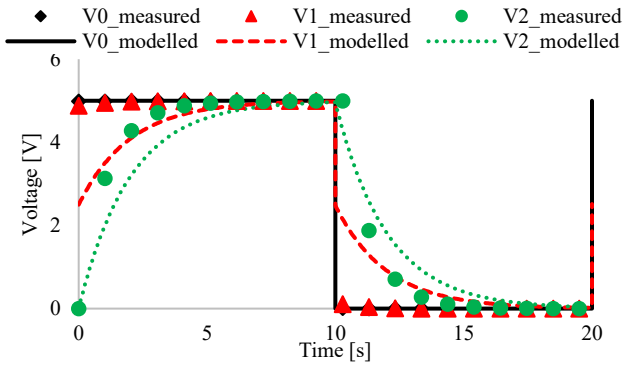

Figure 7. Evolution of the computed and the measured voltages at a decreased resistance R_0.

Figure 8 shows that the measured voltages respond slower to the switch at an increased capacitance than predicted by the engineering computation.

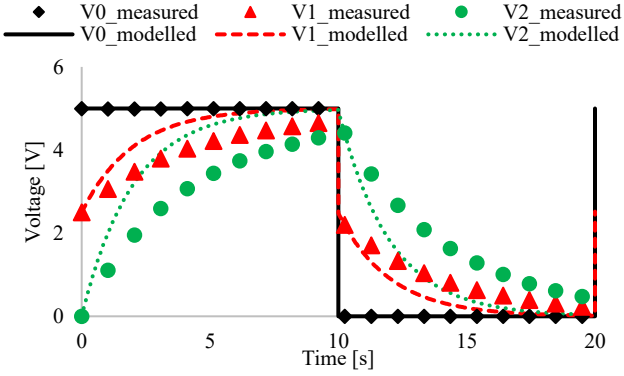

Figure 8. Evolution of the computed and the measured voltages at an increased capacitance.

Note that the operating regime of a pulse signal h influences Figure 6, Figure 7 and Figure 8 as the RRC c is known to operate as a low-pass filter.

Section 4.1 and section 4.2 will explain the construction EB_FSM and a MB_FSM respectively. The focus will the possible obstructions (section 2.1) in computing detection and isolation and not on a quest for the op computation.

4.1. Application of EB_FSM

Let the faults (EB_FSM rows) be a reduced resistance a increased capacitance. Let the features (EB_FSM colu be the *measured* voltages V_0, V_1, V_2, the switch positic and the time T from Figure 6, Figure 7, and Figure 8. that the lines in the three plots are the predictions of an engineering (design) model that should be ignored here.

Let the fields of the EB_FSM be the permutation importance scores of an arbitrary random forest classification. The permutation importance indicates the mean Gini impurity loss of the random forest classification after random resampling of a feature. Note that the EB_FSM fields do not only rely on aforementioned choices, but also on the history of measurements in Figure 6, Figure 7, and Figure 8.

Then, the EB_FSM is given in Table 2.

Table 2: EB_FSM of the case study.

	V_0	V_1	V_2	T	S_1
Resistance R_0 ↓	0,00	0,30	0,06	0,04	0,00
Capacitance ↑	0,04	0,18	0,12	0,16	0,00

Table 2 shows that the voltage V_1 entailed unique information about a decreased resistance as random resampling strongly affects the mean Gini impurity loss of the random forest classification. Similarly, the voltages V_1, V_2, and the time T entailed unique information about an increased capacitance.

The EB_FSM may be used to reduce the complexity of the model selection as Table 2 implies that the random forest classification could still detect both faults when the switch position S_1 is omitted from the history of measurements.

As this paper is not about an improved model selection, details about the arbitrarily selected model will be omitted. It has just been verified that the model of choice correctly predicted all instances in a validation set comprising the same faults that occurred during the same operating regime. So, fault detection and fault isolation (Figure 2) is possible for this specific validation set.

Let the DAG in Figure 9 apply to the EB_FSM (Table 2). This DAG asserts that changes in the resistance R_0, in the capacitance C, or in the switch S_1 cause some hidden flow

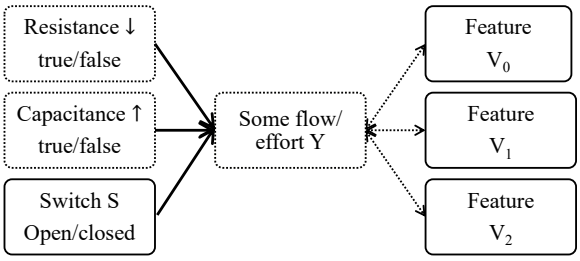

Figure 9. DAG with indicators.

It has been presumed that the switch S_1 in the DAG (Figure 9) does not cause the faults and the EB_FSM confirms that the switch S_1 neither associates with the faults. Similarly, it has been presumed that the time T does not cause the faults (not in DAG) but the EB_FSM shows that the time T still associates with the faults. Still, section 2.4 already mentioned that observed associations (in the EB_FSM) are not compelling for a DAG. A DAG merely specifies the independence assumptions (omitted arrows) of a specific causal explanation for the EB_FSM.

Section 3.1 mentioned that a decision regarding the fault detection or isolation may be incomputable because it is fundamentally incomputable, it is too complex, or it is subject to philosophical controversy. In this case study, the latter prevailed as the DAG is merely postulated afterwards. Therefore, a compelling causal explanation of the computed fault detection and isolation is lacking. In other words, the causality is philosophically controversial. Common sense reflected in engineering guidelines (section 3.1) may alleviate this controversy. The effects of this controversy are:

- Fault detection and isolation beyond the history of measurements (training set) is risky.
- The applicability of the fault detection and isolation is unknown, i.e. it worked for a specific validation set, but it is unknown whether it will work at an unprecedented operating regime.
- The features (like the time T) do not necessarily indicate the magnitude of the fault.

Finally, the fault detection and isolation relied on the arbitrary choice of the classification model, and the feature importance score. Different results might have been obtained had other choices been made.

4.2. Application of MB_FSM

In advance of constructing a MB_FSM, an engineering (design) model will be posited. Let the case study be represented by the Hybrid Bond Graph (HBG) in Figure 10.

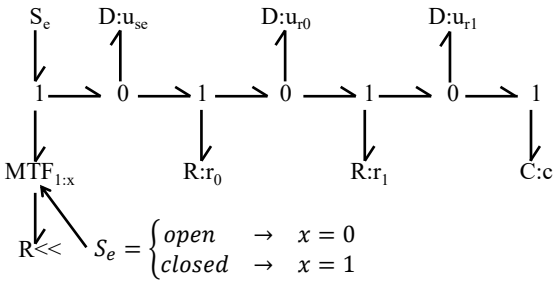

Figure 10. Hybrid Bond Graph of the case study.

The switch has been modelled by a modulated transformer (MTF) as proposed by Borutzky (2012). Figure 10 shows four elements that convert power. As power is the product of an effort variable and a flow variable, the engineering model (Table 3) consists of eight variables and eight constitutive equations that follow from Ohm's Law and Kirchhoff's Law. In this case study, the effort of the source $u_{S_e} = V_0$, and the effort of the resistances $u_{R_0} = V_0 - V_1$, $u_{R_1} = V_1 - V_2$ have been measured which makes three of the equations in Table 3 redundant.

Table 3: Engineering (design) model for case study.

i	$u_{S_e} = 5 \times x \,;\, x \in \{0,1\}$
ii	$0 = u_{R_0} - 10^4 \times i_{R_0}$
iii	$0 = u_{R_1} - 10^4 \times i_{R_1}$
iv	$0 = u_C - 10^4 \times \int i_C(t)dt$
v	$0 = u_{R_0} + u_{R_1} + u_C - u_{S_e}$
vi	$0 = i_{R_0} - i_{R_1}$
vii	$0 = i_{R_0} - i_C$
viii	$0 = i_{R_0} - i_{S_e}$

Let's now construct an MB_FSM of the case study using this engineering model. Let the faults (MB_FSM rows) be a drift in the resistance R_0 and a drift in the capacitance C. As a drift may include an increase as well as a decrease, these fault definitions are more generic than the ones in Figure 7 and Figure 8. Note that the history of measurements (Figure 6, Figure 7 and Figure 8) is not needed for the construction of a MB_FSM.

Let the features (MB_FSM columns) be defined by the ARRs that follow from the measured variables in the engineering model (Borutzky, 2021), (Samantaray et al., 2006).

The ARR_1 is given by:

$$0 = \frac{V_0 - V_1}{R_0} - \frac{V_1 - V_2}{R_1} \tag{4}$$

The ARR_1 follows from (ii), (iii) and (vi) in Table 3, and the voltages V_0, V_1, and V_2.

The ARR_2 is given by:

$$0 = V_0 - V_2 - (V_{0x} - V_{2x}) \times e^{-\frac{(T-x)\times C}{R_0+R_1}} \tag{5}$$

In Eq. (5), V_{0x}, V_{2x} represent the voltages at the time of the last switch transition. The ARR_2 follows from (iv) and (v) in Table 3, the evolution in u_{S_e}, and the measurements V_0, V_2, T.

Let the fields of the MB_FSM be given as shown in Table 4, revealing an indicator function on the presence of the drifting parameters in the ARRs..

Table 4: MB_FSM of the case study.

	ARR_1	ARR_2
Drift in R_0	1	1
Drift in C	0	1

Now, the MB_FSM could be used to evaluate the same validation set as the one used for the EB_FSM. Figure 11 confirms that both ARRs drift away from zero at a decreased resistance as predicted in the MB_FSM (Table 4).

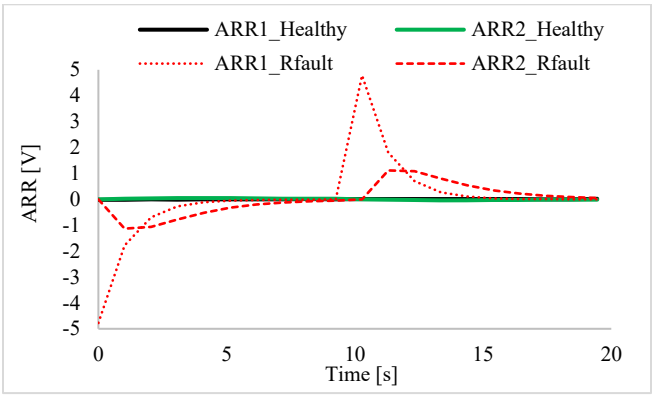

Figure 11. Measured ARRs at a decreased resistance.

Figure 12 confirms that only ARR_2 drifts away from zero at an increased capacitance as predicted in the MB_FSM (Table 4). By choosing a threshold value for the ARRs, the fault detection is autonomously computable. Figure 11 and Figure 12 show that the ARR s can only detect faults as the components in the RRC circuit exchange power shortly after a transition of the switch. The applicability of the fault detection and isolation under various switching regimes is straightforwardly assessable without any history of measurements.

Eq. (4) and Eq. (5) specify the value of the ARR at a given magnitude of the drift in R_0 or C, i.e. a decision regarding the fault identification (i.e. severity of the fault) is partially computable. An autonomously computable fault identification implies a higher maturity in data driven maintenance support (Figure 2) than just isolating the fault. Moreover, the impact of the precision of the measurements is assessable at the stage of design. The precision of the measurements is important to define appropriate threshold values on the ARRs.

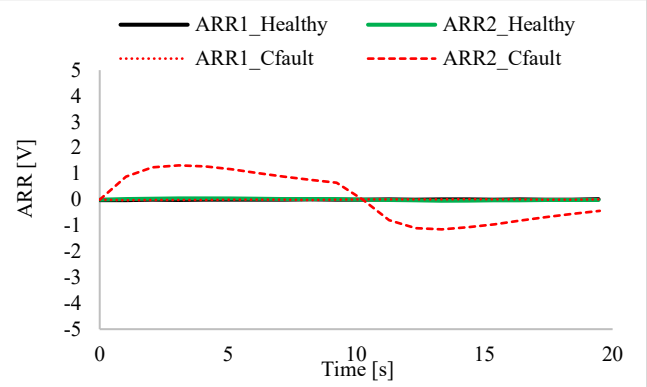

Figure 12. Measured ARRs at an increased capacitance.

Section 2.1 mentioned that a decision regarding the fault detection or isolation may be incomputable because it is fundamentally incomputable, it is too complex, or it is philosophically controversial. In this case study, the latter prevailed as the engineering model is not pertinently true. The fault detection and isolation relied on the applicability of the idealized conditions of the laws of physics that underlie the engineering model. Typically, physical laws are rather robust against changes in these conditions. Still, unmeasured operating conditions may become problematic. For example, large but unrecorded temperature fluctuations may trouble Ohm's Law and consequently the fault detection and isolation (MIL-HDBK-217F, 1991).

If the engineering (design) model were to be true, the MB approach would have resolved the concerns of the EB approach:

- Fault detection and isolation beyond the history of measurements (training set) is decidable. The MB_FSM can even be constructed at the stage of design (without any training set at all).
- The applicability of the fault detection and isolation to work is known. For example, it is known that the fault detection and isolation only works as power is being exchanged.
- The ARRs indicate the magnitude of the fault. Therefore, the attainable maturity in data driven maintenance is potentially higher.

Finally, section 3.2 mentioned that the engineering (design) model may just be incapable to detect or isolate a particular fault. As aspirations should meet capabilities, the engineering (design) model may need adjustments for the purpose of data driven maintenance.

5. Discussion

This section will reflect on the case study. Section 5.1 will discuss the impact on the computability of "real" decisions, section 5.2 will discuss the impact on the maturity in data driven maintenance, and section 5.3 will discuss some practical implications.

5.1. Impact on computing "real" decisions

Section 2.1 mentioned that a decision may be incomputable because it (*i*) is fundamentally incomputable, it (*ii*) is too complex, or it (*iii*) is philosophically controversial.

In this simple case study, the philosophical concerns appeared predominant as the translation between a syntactical computation and a "real" decision required arbitrary human involvement to choose:

- The faults (EB, MB);
- The measurements/ features (EB/MB);
- A classification model (EB/MB);
- A feature importance score (EB);
- A causal explanation (EB);
- An engineering (design) model (MB).

The engineering profession established a high degree of common sense regarding this translation by formulating laws of physics and guidelines. This common sense lacks the solidity of a mathematical proof, and it has been subject to occasional improvement, but it has shown to be effective due to the wide application of engineered devices. Section 2.2 stated that where engineers fail to compute "real" decisions, a human involved maintenance control loop is typically triggered. Still, parts of the maintenance control loop may be computed as shown in the case study. Cases where the computing of "real" decisions is challenging, are also expected to be of high interest to scientists.

In the simple case study, complexity was not an issue. Still, complexity plays a role in other cases. For the EB approach, the inference of a high dimensional model from a large history of measurements may require excessive computing time. Section 3.1 stated that complexity may impede the collection of a history of measurements that includes all relevant system states. Particularly under a non-experimental research construct, the required time is uncontrolled. For the MB approach, the solving of a high dimensional engineering (design) model may similarly bump into complexity concerns.

Fundamental incomputability precluded the selection of a true EB_FSM model (section 3.1). Similarly, the truth of the engineering model (Table 3) was ultimately an incomputable postulate. Fundamental incomputability is also an issue in cases of software faults as there cannot exist a computing device that separates looping software from software that halts in the general case. If this computing device only had to separate software of some fixed number of input symbols, the computation rapidly becomes too complex to solve in time (Rado, 1962).

5.2. Impact on maturity

Growth in the data maturity model (Figure 3) coincided with the flow of the consecutive decisions in the maintenance control loop (Figure 2). This paper confirms that the computation of fault detection and isolation should be settled before addressing the computation of decisions further downstream the maintenance control loop. Similarly, maturity growth in data driven maintenance should start with computing fault detection and isolation.

In the specific validation set of the case study, the EB approach and the MB approach were exchangeable in terms of missed and false alarms. Still, a decision maker should not be indifferent towards the approach because (*i*) causality is assigned differently, and (*ii*) the meaning of the features differs. Using the EB approach, causality was assigned afterwards using some arbitrary DAG and the features just described the state of the RRC circuit. Using the MB approach, causality was inherent in the solving of the engineering (design) model and the ARRs represented the magnitude of the fault. The latter is part of fault identification (Figure 2) which corresponds with a higher maturity in data driven maintenance.

5.3. Practical impact

The case study revealed that the "real" causal implications of some syntactical computation matter for the attainable maturity in data driven maintenance. In the cases study, both the EB and the MB approach appeared to be not entirely compelling for causality. Still, some references to engineering guidelines were given to alleviate potential controversy. Section 3.1 referred to some engineering guidelines for (*i*) the most relevant faults of specific devices and for (*ii*) typical features to detect these faults. Section 3.2 referred to some engineering guidelines to establish common sense regarding the margins between the computed strength and the "real" strength.

For this iconic case study, the construction of a MB_FSM was easy but for a more realistic case study, the construction of a MB_FSM could become complex. Typically, the knowledge of the engineering models is scattered over various agents who may be unwilling to share them. Consequently, much effort may be wasted on reconstructing design models that are in principle already available. Life cycle modelling as proposed in ISO (2014) is a precondition to apply a MB_FSM efficiently in practice.

The EB approach and the MB approach do not compete as one may also consider a hybrid FSM that adds the ARRs to an EB_FSM. The EB approach that decides on associated symptoms may be an appreciable resort in the absence of a causal explanation. The MB approach demonstrated the potential of a more mature data driven maintenance under idealized conditions.

6. CONCLUSION

This paper argued that some decision problems cannot be solved by any autonomous computation and that maintenance decisions are prone to be computationally challenging. A maturity framework has been proposed that specifies the decisions in a maintenance control loop, and connects these to the aspects of human interpretation, computability and causality. An application of the lowest maturity level to an iconic case study showed that decision makers should not be indifferent to (two) models that provide equal decisions on a validation set in terms of missed and false alarms. Access to a true engineering (design) model allows achieving a higher maturity level in data driven maintenance but it has been observed that a true model cannot be computed from only a history of measurements. Where logic cannot decide, the common sense reflected in engineering guidelines provides a resort at an acceptable risk.

ABSTRACT

In prognostics and health management (PHM), data-driven approaches are crucial for performing prognostics based on historical data, relying on the analysis of extensive datasets to identify patterns and relationships that contribute to predicting or optimizing variables. However, their efficiency is contingent upon the availability of large, high-quality datasets tailored to the specific task at hand.

Yet, real-world applications frequently face challenges as data may not always be readily available due to limitations in data acquisition systems or confidentiality concerns. Paradoxically, the contemporary era witnesses an unprecedented surge in the availability of online databases across various fields. These databases offer a plethora of data that can be harnessed to develop, prototype, and test PHM solutions.

This study endeavors to introduce an innovative approach for assessing the similarity between datasets, specifically tailored for prognostic and health management applications. The objective is to empower the development of PHM solutions for predefined systems without relying on data generated from the system itself, but rather by leveraging analogous datasets. To quantify the similarity between different datasets, we propose a set of criteria and sub-criteria based on the characteristics of datasets. Subsequently, the analytic hierarchy process (AHP), a well-established multi-criteria decision-making approach, is employed to systematically compare the importance of criteria and sub-criteria for each elementary process within the PHM cycle. This dynamic process considers the varying importance of criteria across different phases, acknowledging that a criterion may not be uniformly significant for all elementary processes. The evaluation of dataset similarity incorporates the proposed criteria and sub-criteria, utilizing a fundamental scale of importance intensity and weights assigned through AHP. This holistic approach yields a comprehensive similarity score, enabling a nuanced understanding of dataset compatibility.

To exemplify the efficiency of our proposed approach, we applied it to a practical case study. The study involves assessing the similarity between a run-to-stop database of mechanical bearings and a set of online databases dedicated to the same application. Our solution facilitated the identification of criteria pertinent to the case study, the determination of criterion weights, and ultimately, the calculation of a similarity score for each database. This process proved instrumental in selecting the most similar database, showcasing the practical utility of our proposed approach in real-world PHM scenarios.

1. INTRODUCTION

Prognostics and Health Management (PHM) is an engineering and research field that aims to study fielded systems conditions, predict their possible failures, and take appropriate actions to mitigate those malfunctions effects (Bougacha, Varnier, & Zerhouni, 2022). In this context, data-driven approaches are being increasingly used to convert historical data into models that accurately represent the physical systems' degradation behavior (Tobon-Mejia, Medjaher, Zerhouni, & Tripot, 2012). To perform efficiently, those approaches require the presence of extensive datasets, adhering to established data quality standards, and accurately reflecting the characteristics of the system under study. However, for real systems, data collection is a complicated process that requires setting up sometimes costly acquisition devices, overcoming confidentiality issues, and selecting the characteristics of the data to be collected (data format, relevant variables, data quality

requirements...). This has led to a problem of insufficient amount of data for some PHM applications and uncertainty regarding the characteristics of the data to be collected.
Conversely, the current era is experiencing a proliferation in both the quantity and diversity of online databases, with approximately 31 million databases accessible on the Internet as of August 2020 (Benjelloun, Chen, & Noy, 2020). These publicly accessible datasets span a broad spectrum of domains, encompassing around 4600 domains in August 2020 (Benjelloun et al., 2020), and are amenable to adaptation for analogous problem-solving scenarios.
This theme has motivated this research work. We are interested in finding an approach for datasets similarity evaluation that makes it possible to find, among freely accessible datasets, the most similar dataset to a sample of data from a system studied in order to overcome the problem of lack of data for PHM applications.
In pursuit of this goal, we have introduced a set of criteria grounded in data characteristics to assess the similarity between datasets. Subsequently, we presented a methodology employing the Analytical Hierarchy Process (AHP), a widely recognized multi-criteria decision-making technique. This methodology serves to determine criteria weights and evaluate datasets similarity on the base of those criteria.
The remainder of this paper is organized into four sections. Section 2 summarizes previous works related to data insufficiency, data characterization, and the AHP technique. Section 3 describes the proposed methodology. Section 4 presents an illustrative case study evaluating the similarity between different bearing datasets. In section 5, a reliability evaluation approach is proposed to assess the consistency of the results. Finally, section 6 summarizes the main findings and outlines future directions for research.

2. Related Work

2.1. Solving the data insufficiency problem

The data insufficiency problem was the subject of several research works. Indeed, (Guo, Lei, Xing, Yan, & Li, 2018) require the existence of two conditions for the success of machine diagnosis data-driven intelligent approaches : Labeled data containing fault information is available and training and test data are drawn from the same probability distribution. However, for some systems, it is difficult to obtain massive labeled data (Guo et al., 2018).
One of the solutions proposed in the literature is Transfer Learning. It is defined as follows: Given a source domain D_S with a corresponding source task T_S and a target domain D_T with a corresponding task T_T , transfer learning is the process of improving the target predictive function $f_T(\cdot)$ using related information from D_S and T_S , where $D_S \neq D_T$ or $T_S \neq T_T$ (Weiss, Khoshgoftaar, & Wang, 2016).
The transfer learning approach has been applied to several industrial systems. (Wen, Gao, & Li, 2017) applied deep transfer learning method for fault diagnosis in a big data environment. Their approach was tested on a Case Western Reserve University bearing dataset (Smith & Randall, 2015). (Shao, McAleer, Yan, & Baldi, 2018) developed a deep transfer learning framework for mechanical fault diagnosis and classification, and created a repository of several reference datasets.
Despite its ability to solve the data gap problem, the transfer learning technique requires that the source and target data are similar and of the same distribution.
Another widely used approach is data augmentation. This technique consists in increasing the amount of training data by using the information contained within it (Perez & Wang, 2017).
Various data augmentation techniques have been applied to specific problems. The main techniques fall under the category of data warping, which is an approach to directly augment the input data to the model in the data space. This technique has been applied for several industrial applications and on various types of data. (Li, Zhang, Ding, & Sun, 2020) employed it for fault diagnosis of rotating machines. They applied 5 techniques for data augmentation in the form of digital signals, namely, Gaussian noise, masking noise, signal translation, amplitude shift, and time stretching.
Moreover, this technique is widely used with image data. As an example, we cite the work of (Wang, Yang, Jiang, & Fan, 2020) on image augmentation for crack detection using 9 different techniques.
Certainly, the data augmentation technique is useful to overcome the problem of lack of data for different applications and data types. However, this approach requires the existence of a minimal amount of data to be augmented.
On the other hand, other alternatives are used by researchers and industrialists to generate artificial data, such as physical model-based simulation (Saxena, Goebel, Simon, & Eklund, 2008) or test bench fabrication (Nectoux et al., 2012).

2.2. Analytical Hierarchy Process

The Analytical Hierarchy Process (AHP) was developed by Saaty in the 1970s (Saaty, 1980). This method, used in many fields related to multiple criteria decision-making (MCDM) is considered one of the most useful decision-making techniques (Ahmadi, Arasteh Khouy, Kumar, & Schunnesson, 2009). It's a methodology for relative measurement (Brunelli, 2014) where the focus is on proportions between some quantities rather than their exact measurement.
In AHP, The problem is divided into a hierarchy of qualitative and quantitative criteria, and then, using experience, the degree of relative importance is deducted. According to (Nydick & Hill, 1992), the AHP method is based on 4 steps :

1. Problem structuring
2. Data collection and measurement
3. Normalized weights determination

4. Application and problem-solution-finding

The Analytical Hierarchy Process has been used in several industrial applications to make decisions in different areas. (Cabrita & Frade, 2016) proposed an AHP-based solution to the supplier selection problem using fourteen different criteria. (Ren & Lützen, 2015) used AHP for fuel evaluation and selection under nine criteria for emission reduction from shipping. (Kilic, Zaim, & Delen, 2014) evaluated and selected the best ERP system using an AHP-based solution to solve this MCDM problem.
Hence, the analytical hierarchy process can be considered as a strong decision-making tool that can be used to evaluate and select the best action/alternative in multiple criteria decision-making problems.

2.3. Data Characterization

Databases similarity assessment first requires the establishment of data characterization criteria. Several previous works have addressed the issue of database characterization. However, the definitions and criteria proposed differ from one work to another, and the research has not resulted in unified criteria.
In this context, (Alelyani, Liu, & Wang, 2011) proposed 4 characteristics and studied their effects on feature selection stability. The proposed characteristics are the number of samples, features and classes, and the data distribution. (Bhatt, Thakkar, & Ganatra, 2012) divided thirteen characterization criteria into 2 different groups: phenotype characteristics dealing with entropy and the noise-signal ratio, and characteristics concerning the genotype of a dataset, divided into 2 categories:

- Simple Characteristics concern the attributes and instances' numbers
- Statistical Characteristics that deal with the statistical aspect of data.

(Oreski, Oreski, & Klicek, 2017) characterized data by 11 characteristics in 5 different groups, consisting mainly of standard, data sparsity, statistical, information-theoretic, and noise measures.
On the other hand, data quality has emerged as a fundamental notion for characterizing data. (Strong, Lee, & Wang, 1997) have defined high-quality data as data that is suitable for data consumers. Thus, we can conclude that data with different degrees of quality will lead to different results. (Redman, 1997) proposed four data quality characteristics most studied in the literature: accuracy, consistency, completeness, and timeliness. (Omri, Al Masry, Mairot, Giampiccolo, & Zerhouni, 2021) suggest that for PHM applications, data quality is characterized by volume, accuracy and completeness.

3. Proposed Approach

The proposed methodology (Fig. 1) is composed of four different phases. The first phase includes the proposal of similarity criteria and sub-criteria. The second phase is linked to the PHM cycle and the processes that make it up. The third phase details the criteria and sub-criteria weights calculation using AHP technique. The final phase is dedicated to decision-making using the established methodology.

3.1. Problem modeling / Criteria setting

The first step consists of proposing similarity criteria according to which the similarity will be evaluated. This step is also called 'Problem modeling' for AHP applications (Ishizaka & Labib, 2011). In fact, it is recommended to structure the criteria in a hierarchical structure to be able to focus on their importance when assigning their weights (Ishizaka & Labib, 2011). A structure of sub-criteria assembled in clusters (criteria) helps describe the problem more conveniently and reduces bias (Ishizaka, 2004).
To define criteria that are in line with this problem, we mainly rely on the data characterization criteria proposed in the literature. In (Table 1), a non-inclusive list of 17 sub-criteria divided into four criteria is proposed to evaluate the similarity between databases. These criteria can be used fully or partially, depending on the application or case study under consideration.
In addition to the attributes outlined in existing literature, we have introduced two supplementary sub-criteria, namely 'Data extension' and 'Data format.' Specifically, within the context of a given system and application, data representing the system state may manifest in various types and formats, such as images, signals, or tabular data. Disparities in data format and extension necessitate distinct characterizations and treatments.
Furthermore, our research proposes a novel set of application-related criteria, consisting of two sub-criteria. These criteria aim to evaluate the domain (e.g., manufacturing, medical, transportation) of the system depicted in the dataset, along with discerning the data source—whether it originates from a real-world application, a simulation, or a test bench.

3.2. PHM cycle modeling

In order to assign weights to each similarity criterion, we propose to, firstly, divide the studied PHM cycle into elementary processes. In fact, the PHM cycle is composed of seven elementary processes according to (Omri, Al Masry, Mairot, Giampiccolo, & Zerhouni, 2020), namely data acquisition, data processing, data assessment, diagnostic, prognostics, decision support, and HMI. From data acquisition to decision support and HMI, the importance of each of the established criteria depends on the process.

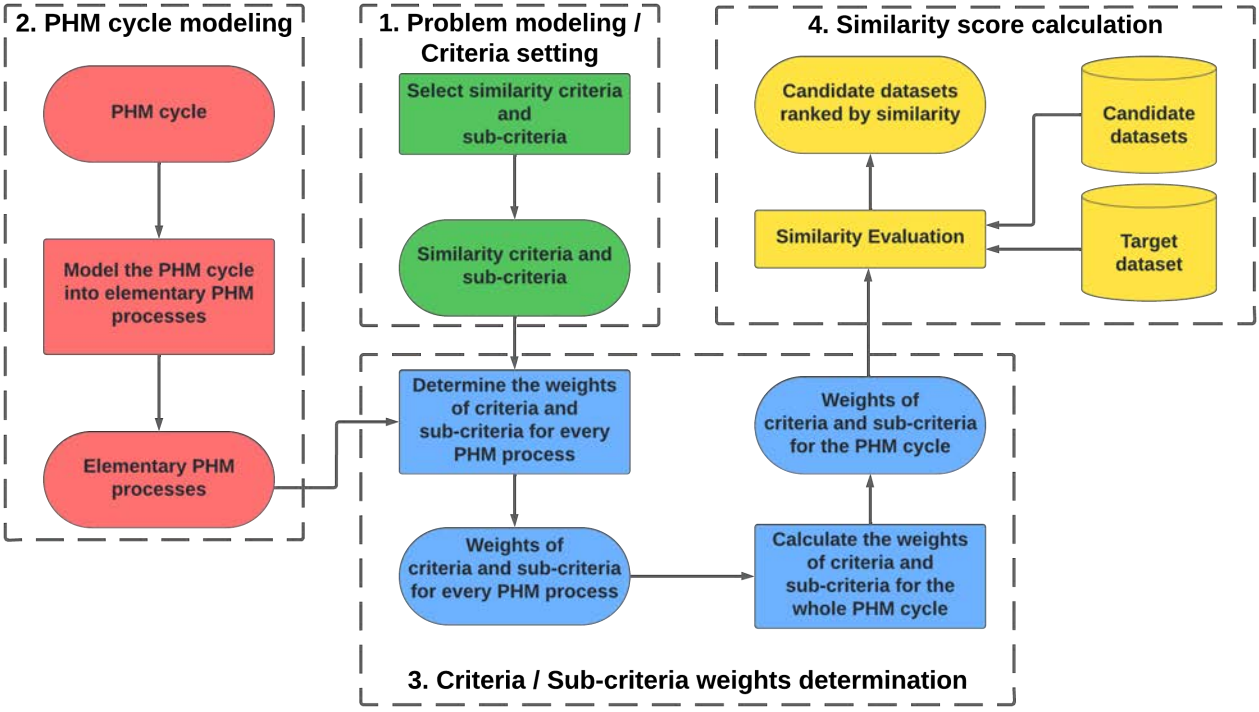

Figure 1. AHP based approach for datasets similarity evaluation

Table 1. Data similarity criteria

Criteria	Sub-criteria
Standard criteria	1. Number of attributes (Alelyani et al., 2011; Bhatt et al., 2012; Oreski et al., 2017) 2. Number of instances (Alelyani et al., 2011; Bhatt et al., 2012; Oreski et al., 2017) 3. Number of classes (Alelyani et al., 2011; Bhatt et al., 2012; Oreski et al., 2017) 4. Number of binary features (Bhatt et al., 2012) 5. Data format 6. Data extension
Statistical criteria	7. Data distribution (Alelyani et al., 2011) 8. Features correlation (Bhatt et al., 2012; Oreski et al., 2017) 9. Multivariate normality (Oreski et al., 2017) 10. Mean Kurtosis of attributes (Bhatt et al., 2012) 11. Mean skewness of attributes (Bhatt et al., 2012)
Data quality criteria	12. Accuracy (Omri et al., 2021; Redman, 1997) 13. Completeness (Omri et al., 2021; Oreski et al., 2017) 14. Consistency (Redman, 1997) 15. Timeliness (Redman, 1997)
Application related criteria	16. Field of application 17. Data source

For example, the data distribution a negligible impact on the data acquisition process. However, this characteristic is very important in the data processing and exploitation processes (diagnostic and prognostic). Thus, the importance of each of the criteria will be judged with respect to every PHM process separately.

3.3. Criteria / Sub-criteria weights determination

Notation:

- P_i : Elementary process i (i=1,..., L)
- D_h : Similar dataset h (h=1,..., Q)
- Cj : Criterion j (j=1,..., N)
- $X_{j,i}$: Weight of criterion j for process i
- SCk : Sub-criterion k (k=1,..., M)

- $Y_{k,i}$: Weight of sub-criterion k for process i
- W_k : Weight of sub-criterion k
- M_j : Number of sub-criterion related to the criterion j
- $Z_{h,k}$: Similarity score of the candidate dataset h with the target dataset with respect to the sub-criterion k
- R_h : Similarity score of the candidate dataset h with the target dataset.

In the AHP technique, a ratio scale is used to derive, two by two, the criteria's and sub-criteria's importance. This comparison, unlike techniques that use interval scales, requires no units (Ishizaka & Labib, 2011) and assures a more accurate decision than comparing all the criteria at once.
The pairwise comparison of criteria, and every group of sub-criteria, is realized using Saaty's 1-9 scale for pairwise comparison (Saaty, 2005) described in Table 2.

Table 2. Saaty's 1-9 scale for pairwise comparison

Intensity of importance	Definition
1	Equal importance
3	Moderate importance
5	Strong importance
7	Very strong importance
9	Extreme importance

To determine the weights of N criteria for the elemental process Pi, An NxN matrix is created, where $a_{j1,j2}$ describes the importance of criterion $Cj1$ over criterion $Cj2$. Therefore, for all j1 and j2, $a_{j1,j2}$ is the inverse of $a_{j2,j1}$ and $a_{j1,j1} = 1$.

$$\begin{bmatrix} 1 & a_{1,2} & .. & a_{1,N} \\ a_{2,1} & 1 & .. & a_{2,N} \\ .. & .. & .. & .. \\ a_{N,1} & .. & a_{N,N-1} & 1 \end{bmatrix} \quad (1)$$

This procedure is carried out to deduce the relative importance of the criteria by comparing them two by two using the fundamental scale of importance intensity. The weight $X_{j,i}$ of criterion Cj in relation to the process Pi is calculated using equation 2.

$$X_{j,i} = \frac{\sum_{j2=1}^{N} \left(\frac{a_{j1,j2}}{\sum_{j1=1}^{N} a_{j1,j2}}\right)}{N} \quad (2)$$

Similarly, the sub-criteria relating to each criterion are compared two by two, and the weight of each sub-criterion in relation to the Pi process is calculated using equation 4

$$\begin{bmatrix} 1 & b_{1,2} & .. & b_{1,Mj} \\ b_{2,1} & 1 & .. & b_{2,Mj} \\ .. & .. & .. & .. \\ b_{Mj,1} & .. & b_{Mj,Mj-1} & 1 \end{bmatrix} \quad (3)$$

$$Y_{k,i} = \frac{\sum_{k2=1}^{Mj} \left(\frac{b_{k1,k2}}{\sum_{k1=1}^{Mj} b_{k1,k2}}\right)}{Mj} \times X_{j,i} \quad (4)$$

At the end of this procedure, the weight of each criterion/sub-criterion is given, showing their importance for each elementary process of the PHM cycle.
In order to deduce the weight of a sub-criterion for the whole cycle, an average of these weights is calculated (equation 5).

$$W_k = \frac{\sum_{i=1}^{L} Y_{k,i}}{L} \quad (5)$$

3.4. Similarity score calculation

In this final step, the similarity $Z_{h,k}$ of every candidate dataset D_h with the studied dataset regarding each sub-criterion k is evaluated. The assessment is done using the fundamental scale of importance intensity (Table 2).
For quantitative criteria, an odd number between 1 and 9 is assigned, depending on the decision-maker's expertise. On the other hand, for qualitative criteria, only two possible values can be given, 9 for two data sets with similar attributes and 1 otherwise.
Finally, a normalized similarity score of each candidate dataset R_h is calculated using equation 6. The higher the similarity score, the more the concerned dataset is similar to the target dataset. A similarity score of 1 means that the two compared datasets have identical characteristics.

$$R_h = \frac{\sum_{k=1}^{M} Z_{h,k} \times W_k}{9} \quad (6)$$

4. ILLUSTRATIVE CASE STUDY

The proposed database similarity assessment methodology will be applied to a case study of bearing failure databases available online.
A bearing is a machine component that lessens friction between moving elements in mechanical engineering. It is frequently used in wheels or axles to support and guide a rotating or oscillating shaft. Bearings can be subject to various failures, manifested by cracks, wear marks, chips, and abnormal noises. These failures can significantly affect the mechanical and energy sectors' capacity to operate, level of safety, and financial aspect (Nectoux et al., 2012).
In the context of PHM applications for bearing condition prognosis, (Nectoux et al., 2012) provided a database for the IEEE PHM 2012 Prognostic Challenge. The experiments were car-

ried out on the PRONOSTIA platform at the Femto-ST Institute, and the results present 9 features relating to run-to-failure tests of 17 bearings.

4.1. Proposed criteria and PHM cycle modeling

For the application under consideration, based on the criteria summary table (Table 1), eleven sub-criteria split among three criteria were proposed. The sub-criteria relating to the standard criteria were retained, except for the number of classes. This selection is justified by the studied databases, which were not originally designed for classification purposes and lack class labels. In addition, the application-related criteria were also retained with the proposal of two additional criteria specific to this application, namely the number of operating conditions applied and the number of tested bearings. Moreover, two of the data quality sub-criteria were used in this case study. The completeness was evaluated as the ratio of non-empty cells over all available cells, and the accuracy was assessed as the presence or absence of noise.
For this application, the PHM cycle was simplified to 3 elementary processes, namely the data acquisition, the data preprocessing, and the prognostics processes.

4.2. Similar databases collection

A collection of four databases, available online, for the same applications, was carried out.
The first dataset (Kaggle, 2023) is provided by Quantum company in collaboration with Kharkiv Polytechnic Institute. It consists of 3-axis vibration measurements of 112 rotating bearings.
The second dataset (Qiu, Lee, Lin, & Yu, 2006) is a run-to-failure dataset of four bearings under one operating condition, provided by Qiu et al. Eight features related to the vibration and the temperature of the bearings were collected to study their health state.
The third data set (CWRU, .) is provided by Case Western Reserve University and presents ten statistical features related to measurements of 21 bearings under fixed operating conditions that manifested ten possible types of faults.
Finally, the fourth database presents recordings of the acceleration of a high-speed bearing used for wind turbines over 30 days (6 seconds daily). These recordings were made under two operating conditions.
Table 3 details the selected dataset characteristics in relation to the criteria and sub-criteria chosen for the study.

4.3. Criteria and sub-criteria weights calculation

As mentioned in section 3, and in order to determine the sub-criteria weights, a pairwise comparison of the importance of the criteria for every elementary PHM process was performed.
Table 4 details the process of comparing importance and calculating criteria weights for the data acquisition process.
The criteria weights were calculated using equation 2, after constructing the comparison matrix. The application criterion contributes the most to selecting a similar dataset for the data acquisition process. In addition, a similarity in the application criterion is strongly preferred to the quality criterion. In fact, a different application may require another data acquisition system. Moreover, as seen in Table 4, no two criteria are of equal importance for the acquisition process.
Table 5 compares the criteria importance and weights in the data preprocessing process. In contrast to the data acquisition process, the application criterion has an insignificant weight compared to standard and quality criteria, indicating a lower priority in this context. Conversely, the quality criterion holds the highest significance in selecting an appropriate dataset in the preprocessing process, holding nine times more importance than the application criterion and three times more significance than the standard criterion. These findings align with expectations, as the preprocessing process rarely depends on applications and focuses mainly on data quality and standard characteristics.
The weights of each family of sub-criteria were then determined for each elementary process of the PHM cycle. This is done by comparing them two by two using the 1-9 scale for pairwise comparison and then, by applying equation 4 to incorporate the weights of the associated criteria.
Table 6 shows the weights of the standard sub-criteria for the data acquisition process. The number of features is found to be the most important sub-criterion to assess the similarity between two datasets concerning the data acquisition process. In fact, features (variables) are collected using acquisition devices like sensors. These devices are costly and require studies to set them up and to ensure data acquisition. This sub-criterion is therefore the most important for this PHM process. The number of features sub-criterion is considered to be very strongly important than the number of instances, extremely important than the data extension sub-criterion, and moderately important than the data format sub-criterion.
The data format is the second most important standard sub-criterion to assess datasets similarity in relation to the data acquisition process. It is strongly more important than the number of instances and the number of binary features, and moderately more important than the data extension sub-criterion.
The Standard sub-criteria importance and weights for the prognostic process are described in Table 7. Similarly to the acquisition process, the number of features criterion is the most important factor in determining databases' similarity in relation to the prognostic process. Additionally, the data extension is the least impacting factor in both processes. The second most important standard sub-criterion is the number of binary features in this context. It is moderately more important than the number of instances and data format criterion and highly more important than the data extension criterion.
The final weights of all the considered sub-criteria for the

Table 3. Collected datasets characteristics

	Target dataset	**Candidate Dataset 1**	**Candidate Dataset 2**	**Candidate Dataset 3**	**Candidate Dataset 4**

Quality	3	9	1	**0,6486**

whole PHM cycle are detailed in Table 8.

The accuracy sub-criterion is found to be the most important. Since the scores are normalized, then a weight of 0,3603 means that this sub-criterion contributes by 36,03% to the final decision about datasets similarity. The following sub-criteria are the number of tested bearings, the number of operating conditions, and the number of collected features. These four sub-criteria contribute by more than 75% to the final decision.

4.4. Similarity score calculation and decision-making

In this final step, the similarity of every candidate dataset with the target dataset is evaluated with respect to every sub-criterion using the fundamental scale of importance intensity (Table 2).

Similarity based on qualitative criteria is assessed using the Saaty scale. In other words, if both datasets have the same attribute, a rating of 9 is assigned; otherwise, a rating of 1 is assigned.

For example, for the data format sub-criterion, two candidate datasets are of the same format as the target dataset, so they got a similarity score of 9. The other two datasets are of different formats (text and binary data container), leading to a weak similarity score of 1.

A score of similarity, according to every sub-criterion, between each candidate dataset and the target dataset is given. Afterward, the weights deducted in the previous step are used to get a similarity score for every candidate dataset 8.

The second dataset (Qiu et al., 2006) is found to be the most similar dataset to the target dataset (Nectoux et al., 2012) with a similarity score of 0,7143. However, the first candidate dataset (Kaggle, 2023) is the least similar dataset to the target dataset. This is mainly caused by the difference in the accuracy sub-criterion, the number of tested bearings and the number of features. These sub-criterion were found to be three of the four most important comparison sub-criteria. Therefore, a low score in these attributes leads to a weak overall similarity score.

If a simple normalized mean of the similarity scores is calculated, the first candidate dataset will obtain a higher score of 0,7172, meaning that it is the most similar dataset. This shows the importance of assigning weights to the comparison sub-criteria.

It is important to note that, although the fourth dataset is the only one originating from the real world, it was not selected. This decision stems from the fact that the 'data source' criterion is just one of several simulation criteria used in the selection process. Moreover, the target dataset itself is derived from a simulation, rendering dataset number 4 dissimilar in terms of data source. Our aim is to select the dataset that most closely resembles the target dataset, rather than simply identifying the best dataset.

5. DECISION RELIABILITY

The methodology outlined in this study hinges upon conducting pairwise comparisons of both criteria and sub-criteria to ascertain their respective weights. These comparisons are based on subjective judgments provided by the decision-maker. Consequently, it becomes important to assess the consistency of these judgments. Consistency, within the context of the

Analytic Hierarchy Process (AHP), denotes the extent to which the pairwise comparisons rendered by decision-makers exhibit logical coherence and absence of contradictions. Inconsistencies in judgments bear the risk of yielding unreliable weight assignments, thereby potentially skewing the subsequent similarity evaluations.

Several works have addressed the problem of consistency of AHP matrices. One way to deal with this is by determining the Consistency Ratio (CR) (Pant, Kumar, Ram, Klochkov, & Sharma, 2022; Franek & Kresta, 2014). First, the Consistency Index (CI) is computed according to equation 7:

$$CI = \frac{\lambda_{max} - N}{N - 1} \tag{7}$$

with λ_{max} representing the largest eigenvalue of the pairwise comparison matrix and N indicating the matrix size (number of criteria or sub-criteria).

Using pre-defined tables (Table 9), the Random Index (RI) corresponding to the matrix size is determined. The Consistency Ratio (CR) is then calculated by dividing CI by RI. A CR value below 0.1 signifies acceptable consistency in judgments, while values exceeding 0,1 may indicate potential inconsistencies requiring further scrutiny or adjustment.

As an example, the consistency ratio of the criteria pairwise comparison matrix is 0,03 for the data acquisition process and 0,07 for the preprocessing process. These results demonstrate that the weights of the resulting criteria are consistent and can be used to reliably determine criteria weights.

On the other hand, the consistency ratio of the standard sub-criteria matrix for the prognostic process is 0,11 meaning that the comparison need to be adjusted in order to get a consistent judgment of the sub-criteria weights.

6. CONCLUSION

In this work, a database comparison approach was proposed to find a solution to the problem of lack of data for PHM applications. Indeed, for this field of study, and in order to develop a data-driven PHM solution, datasets need to be available, containing all the variables describing the system under study and complying with quality standards. In reality, this is

Table 9. Random index for the AHP consistency ratio (Saaty, 1980)

Number of rows	1	2	3	4	5	6	7	8	9
RI	0	0	0,58	0,90	1,12	1,24	1,32	1,41	1,45

not always the case.

Therefore, we have proposed an approach for assessing the similarity between a target dataset and a set of datasets available online. A set of criteria has been proposed, based on data characteristics. As the criteria are not equally important for judging similarity, a weight for each criterion is determined using the analytical hierarchy process. The similarity of the datasets is then scored against each criterion, and a normalized score is calculated for each dataset.

The proposed approach has been applied to an illustrative case, where the similarity of four datasets with a bearing operating database has been evaluated. The application leads to calculating similarity scores for each dataset and selecting the most similar one.

This work presents a first step towards solving the problem of lack of data for PHM applications. It makes it possible to design a PHM solution for a given system without the need to use data directly from that system.

On the other hand, this proposal is limited by the subjectivity of the decision-maker. The latter, responsible for rating similarity and judging the importance of criteria, may be biased and lead to subjective decisions. We therefore recommend that weights and scores be allocated by several experts at the same time, in order to limit the subjectivity of decision-makers.

In addition, considering the limitations of our current methodology, future studies may employ fuzzy techniques to reduce the uncertainty of the decision. Furthermore, in this work, we proposed a non-exhaustive list of criteria, other criteria can also be used, namely the maturity of the data for example, which leads to the generalization of the approach to various fields and applications.

ABSTRACT

The paper focuses on PHM in the maritime industry, specifically on the maintenance of uncrewed vessels, in contrast to the more commonly discussed navigation. The paper examines the potential challenges of removing the maintenance crew and the potential benefits that can result from this major change in operations.
The removal of the primary maintenance team from a vessel necessitates an increase in monitoring and analysis that can be realised by the techniques of PHM. By looking from the perspective of stakeholders, the challenges and opportunities of PHM implementation become clearer. In comparing the challenges that faced other industries with the maritime industry, roadmaps and proposals can be drawn up for vessel owners. There is a correlation between the phased removal of the engineering crew and the increases in monitoring that is required. Current large vessels that do not carry passengers can operate with UMS (un-manned machinery space) for limited periods. To allow this a specific set of sensors referred to as E0 (Engineers-zero) must be established and maintained. This E0 sensor set forms the basis for what is needed to allow UMS for longer periods of time. The critical equipment, as deemed by class societies, is monitored by E0. Acquiring the data from the E0 sensor set and performing PHM analysis on the data allows remote engineers to accurately determine the current and future state of critical equipment. This equipment list needs to be expanded. Causality based risk modelling is employed to establish a data driven critical equipment list and minimum sensor set to cover the maximum amount of failure modes. This builds on the current required E0 sensor set.
With a conventional maintenance system onboard a vessel the crew are doing a lot of the sensing. The crew act as intermediaries between various systems, taking data from one system to help diagnose another system, making a change to one system to help improve another system. The maintenance crew must balance the interfaces of each system so that a harmony or equilibrium can be achieved. This balancing act is part of what makes a PHM study on a vessel so interesting. Many systems onboard a vessel have a sole purpose to support the crew. With the removal of the crew these support systems can also be removed, simplifying the overall engineering of the vessel.
The methodology that has been used to assess the above points is to create a framework for the design and deployment of PHM to marine assets. The framework relates to RAM (Reliability, Availability, Maintainability) and considers stakeholder points of view and their inputs' implications. In developing the framework, the stakeholder group is realised. The framework compares the 'As-Is' conventional method against the proposed PHM framework. The conclusions are that the E0 philosophy can be expanded upon to facilitate the integration of PHM. Also, the paper concludes that a PHM deployment framework gives the maritime industry a basis for using this modern technique for machinery health. Lastly, the paper shows that PHM is a vital element to uncrewed vessels.

1. INTRODUCTION

In this paper we will investigate a way to use the principles of RAM (Reliability Availability Maintainability) to facilitate uncrewed vessel operations. The focus of the paper is going to be only on the uncrewed Engineering operations, not on the Navigational operations.

The motivations for conducting this study are,

1. The maritime industries move to leverage modern technology to reduce environmental impacts of shipping is a major motivator for this study.
2. To offer a method for enabling remote engineering of uncrewed vessels both in terms of the RAM driven PHM system and organisational architecture.
3. To increase safety at sea by reducing the number of crew needed to locally operate the vessels.

To validate the decision to move to a RAM enabled PHM maintenance system, it is important to carry out a comparison between different maintenance systems. To do this, key performance indicators (KPI) need to be established to track and compare the differences in performance of each, also, standardizing resources needed into categories.

Table 1: Generic Maintenance System KPI's

KPI	Description
Availability	Actual and predicted availability are critical to commercial operations
Human reliance / human error	How reliant the system is on individual humans
Unplanned maintenance tasks	Quantity and frequency of unplanned maintenance tasks
Planned maintenance tasks	Quantity and frequency of planned maintenance tasks
Set up cost	Cost of setting up the maintenance system
Running costs	Cost of running the maintenance system
Maintenance Costs	Cost of maintaining the asset during its lifetime

Table 1 above shows a list of KPI's that can be used to compare maintenance systems. This is not a definitive list, but serves as a overarching view of a maintenance systems efficiency.
Each of the evolutions of the proposed maintenance systems will be compared on the above KPI's with results in the appendix of this paper.
Other metrics that can be considered are:

- Time
- Environmental
- Complexity
- Sustainability

The maintenance landscape in the maritime industries is due for an overhaul. Remote Engineering is becoming a factor. This paper aims to show a possible way forward

This paper uses a typical 70 – 100 meter length overall vessel designed to have an operational lifespan of 20 years as an example asset.

To recap on the evolution of maintenance so far, from 1920 to now we can see that cost and availability have always been the biggest drivers. As a high level over view the following is a view of these evolutions. Figure 1 shows how maintenance systems have progressed since "run to failure" where a machine was only repaired, rather than maintained. To Dynamic Maintenance, where failures are identified in a juvenile state, allowing operators to plan corrective action and impose mitigating actions to prolong the asset life prior to maintenance.

2. MAINTAINING A VESSEL

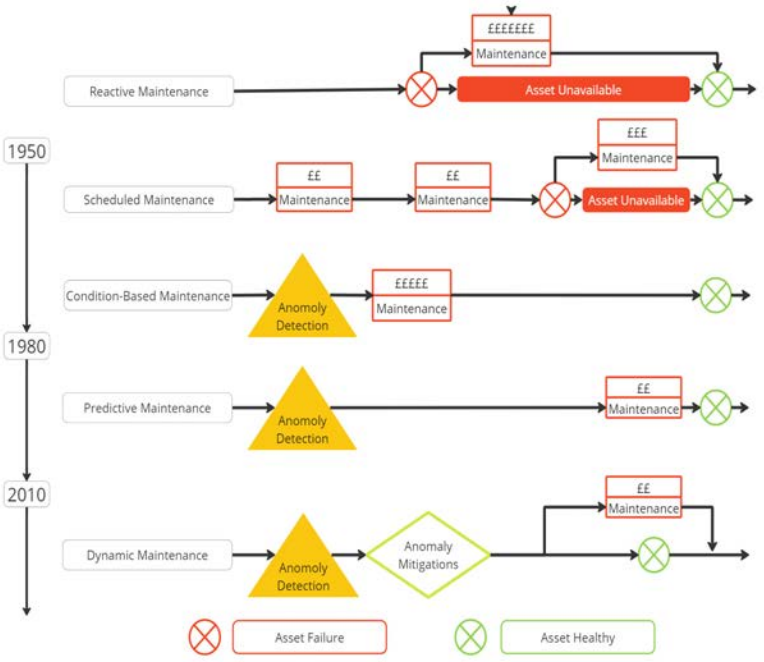

Figure 1. Evolution of Maintenance Systems

Figure 1 also shows that as the system evolves maintenance can be done at targeted times when it is most effective, this optimises the maintenance and improves asset availability. This optimisation culminates in a system that can mitigate the failure to prolong asset life so that maintenance intervals can be fixed.

Classification societies guide and ensure that ships are maintained to certain standards. For ships, classification societies provide classification services that involve assessing the structural integrity, safety, and performance of

vessels according to their rules and regulations. These services include:

- surveys at various stages of a ship's life, including during construction, after delivery, and during operation. these surveys verify that the ship complies with class rules and standards.
- regular surveys are conducted to ensure that the ship remains in compliance with class requirements throughout its operational life. these surveys cover aspects such as hull integrity, machinery, electrical systems, and safety equipment.
- guidelines and requirements for implementing maintenance management systems onboard ships are also provided by classification societies. these systems help shipowners and operators manage maintenance activities effectively to ensure the continued safe operation of the vessel.
- condition monitoring and predictive maintenance, allowing ship operators to identify potential issues before they lead to failures or downtime.
- assistance and support to shipowners in understanding and complying with relevant regulations and standards, including international conventions and flag state requirements.

2.1. Classification Society Methodology

Classification societies assist ship owners in improving maintenance to support increased safety. This starts by assigning critical equipment. Criticality assessment is carried out to comply with standards such as NORSOK Z-008 PSA, ISM code 10.3 and OVMSA. For the analysis, generally, all onboard maintainable items are included. A risk-based assessment is then carried out in terms of impact to health, environment, operation, property, MASS capability.

PHM is currently included in Class Society documentation, but there is little in the way of guidance. The generic view is that PHM can provide valuable information for corrective and preventative action, inclining operations adjustment (Shipping, 2018).

Paper based analysis is used (rather than model based) to risk assess equipment and deem it critical if needed. While RAM is not used in its entirety by classification societies, they are considering reliability and safety analysis as part of a certification process of a vessel.

Classification Societies also issue vessels with ‘notations’ which indicate to clients the level of quality or performance the vessel has achieved. DNV for example issue a Condition Monitoring System notation if the vessel can prove compliance to specific equipment health requirements. At time of writing there is no PHM notation.

3. UNMANNED MACHINERY SPACES (UMS)

Unmanned Machinery Spaces (UMS) are engine rooms or machinery spaces on ships that are designed and equipped to operate without the continuous presence of personnel. This means that machinery and systems are automated and monitored remotely from a control room, reducing the need for crew members to be physically present in these spaces. One of the classifications and notations associated with UMS is the E0 (Engineers Zero) notation.

3.1. Key Features of UMS with E0 Notation:

Advanced Automation: UMS with E0 notation feature advanced automation systems that control and monitor machinery and systems in the engine room. Redundant systems and fail-safe mechanisms are implemented to ensure continuous operation and minimize the risk of failure.

Machinery and systems are monitored remotely from control rooms or other locations onboard the ship. Automated alarm and alert systems notify onboard personnel or shore-based monitoring centres of any abnormalities or emergencies.

Emergency procedures and backup systems are in place to respond to emergencies or system failures, including the ability to remotely intervene or override automated systems if necessary.

Ships with UMS, including those with the E0 notation, must comply with relevant regulations and guidelines governing unmanned or partially unmanned operations, such as those issued by the International Maritime Organization (IMO) and flag state authorities.

4. ENGINEERS ZERO (E0)

For a typical vessel between 70 and 100 meters, the E0 monitoring and alarm list is a comprehensive set of internal alarms for various systems and components on a ship. These alarms are designed to monitor the status of critical machinery, systems, and equipment, and they provide alerts in case of abnormalities or failures. The following is a breakdown of the categories and some examples of alarms existent on UMS with E0 capability.

Internal Alarms: These alarms are related to the ship's internal systems and components.

Earth Failure Alarms: These alarms indicate a potential earth (ground) failure in specific components, such as controllers and power supplies.

Power Failure Alarms: These alarms notify of power failures in specific components, such as controllers and power supplies.

Fuel Oil System Alarms: These alarms monitor the fuel oil system, including tank levels, overflows, and pressure.

Main Propulsion Alarms (Port and Starboard): These alarms relate to the main propulsion systems, including power

supply failures, low oil pressure, high temperatures, and warnings regarding control systems.

Generator Set Alarms: These alarms monitor various parameters of generator sets, including fuel levels, water pressure, oil pressure, temperatures, overspeed, and abnormal conditions.

Lube Oil System Alarms: These alarms monitor the lube oil system, including separator alarms and overflow alarms.

Cooling System Alarms (Sea Water and Fresh Water): These alarms monitor the cooling systems, including low pressure alarms for sea water and freshwater systems and low-level alarms for expansion tanks.

Compressed Air System Alarms: These alarms monitor the compressed air system, including low-pressure alarms for starting air receivers and quick-closing cabinets.

Bilge System Alarms: These alarms monitor bilge levels in various compartments throughout the ship.

Main Switchboard Alarms: These alarms monitor the main switchboard for various failures and abnormalities in power supply and distribution.

Miscellaneous Alarms: These alarms cover a range of miscellaneous systems and components, including communication errors, black-out bus failures, and controller failures.

These alarms are crucial for maintaining the safe and efficient operation of the vessel by promptly alerting crew members to any issues that may arise within the ship's systems. Typical maintenance intervals are having a monthly occurrence for E0 alarms.

Overall, there will be approximately 450 alarms across the systems described above. With all these in place, a vessel can apply for E0 notation and operate with unmanned machinery spaces for certain periods of time. The rules around when a vessel can operate in UMS are also not described in this paper.

5. EXPANSION ON E0 FOR UNCREWED SHIPS

Having the E0 notation in place allows the engineering staff to rely on the automation system to alert them to critical issues onboard. Expanding on this principle can form a basis for much longer periods of UMS operation. To build upon this principle to facilitate uncrewed operations the maintenance and monitoring strategy of ships needs to be changed.

5.1. Dynamic Positioning

It is also worth mentioning dynamic position (DP) systems in the context of this investigation. DP is used to keep a vessel in location. There are 3 grades for the DP capability, as shown below.

Table 2: Dynamic Positioning Grades

DP1	Position Keeping
DP2	DP1 + any single component failure and vessel remains 100% capable of position keeping
DP3	DP2 + Any single compartment failure and vessel remains 100% capable of position keeping

It is worth mentioning the DP grades here because they require a certain level of redundancy. To be classed as a DP3 vessel the vessel must be designed in such a way that if any compartment is lost the vessel is still 100% capable. This could be a fire in an engine room for example. The philosophies on DP grade can also be expanded and contribute to a foundation for RAM of uncrewed vessels.

6. VESSEL MAINTENANCE

Vessel maintenance covers the vessel itself and the systems installed onboard. There are systems necessary for the vessel to operate, and to support the crew. The SFI coding system is used in most cases to group the maintenance tasks into the following parent categories. Table 3 below outlines the high level SFI categories and the average number of tasks in each.

Table 3: - tasks per vessel system category

Category	Average Number of Tasks
1. Ship General	20-50
2. Hull	150-200
3. Equipment for Cargo	10-50
4. Ship Equipment	200-600
5. Equipment for Crew and Passengers	300-500
6. Machinery Main Components	100-500
7. Systems for Machinery Main Components	300-600
8. Ship Common System	100-300
9. Payload Equipment.	Depends on Payload types.

7. CONVENTIONAL MAINTENANCE SYSTEMS

Here we look at the typical modern conventional method of maintaining a vessel.

A conventional vessel uses a combination of planned, preventative, corrective and breakdown maintenance strategies. The two primary sources of information are the PMS (Planned Maintenance System) and the Engineers observations. A general overview of this process is shown in figure 2 below.

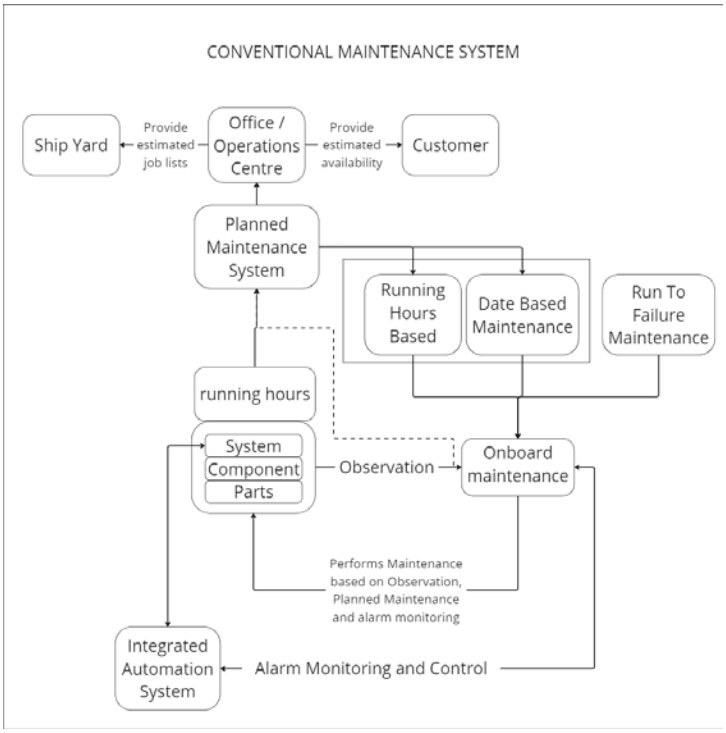

Figure 2. Conventional Maintenance System

7.1. Conventional Maintenance System Description

The system shown in figure 2 has the relationship between the onboard maintenance team and the asset to be maintained at the centre. Physical metrics of the asset are relayed to the engineers by an integrated automation system. This system also facilitates control of the asset. The assets running hours are maintained in the PMS which issues jobs to the onboard maintenance team. The team also react to faults and failures as they are observed. The PMS is linked to a shoreside system that assists the "office" in planning yard periods and vessel's availability to clients. The effectiveness of this system relies on the team onboard.

7.2. Method of Performing Maintenance

Maintenance is generally performed by an onboard team of engineers. If more extensive maintenance is needed specialists from OEM's are brought in. with this maintenance strategy there is a lot of reactive maintenance being done or planned maintenance that has no connection to the actual health of the asset.

Maintenance tasks are issued by the PMS and carried out by appropriate member of the engineering team. The onboard team monitor spares and consumable usage and submit orders when stock is running low. Certain items are classed as critical spares by a classification society to ensure that the safety critical equipment has spares onboard at all times.

Below is a summary of a typical maintenance team on a conventional vessel between 70 and 100 meters in length.

Table 4: Average Annual Cost of Engineering Team on Conventional Vessel

Position	Quantity	Qualification	Average annual cost
Motor Man	2	Marine Engineer operator license or similar	$70,000
Third Engineer	2	3 years college	$100,000
Second Engineer	2	4 years college	$150,000
Chief Engineer	2	5 years college	$210,000
Electro Technical Officer (ETO)	2	3 years college	$150,000

In Table 4. we can see that the total average cost of the onboard maintenance team, including flights and other travel is $680,000 over an anticipated life span of 20 years engineering crew costs amount to $13,600,000. This is one of the costs that uncrewed operations can mitigate.

A summary of the other resources required for a conventional maintenance system over a presumed 20 year life span.

Table 5: Example summary of average OPEX for conventional maintenance

Resource	Cost Over 20-year Asset Life Span
Engineering Crew Costs	$13,600,000
Dry Dock / docking	$2,000,000

Dry Dock specific Maintenance tasks	$6,000,000
OEM Maintenance	$10,000,000
General maintenance spares and consumables	$90,000,000
Total	$121,600,000

Table 5 shows average operational expenditure for maintenance of a typical lean crewed 70m-100m length overall vessel.

The yearly quantity of maintenance tasks varies through an assets lifetime, as can be seen in Figure 3 below.

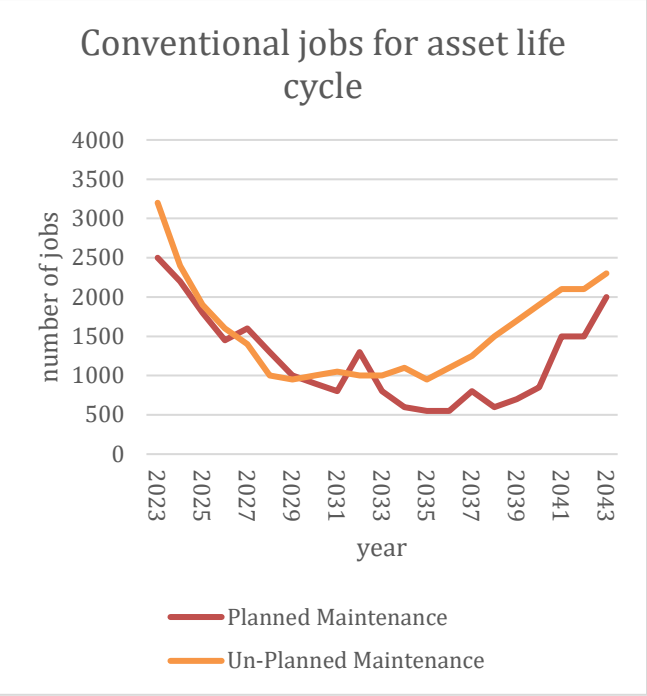

Figure 3. Number of maintenance tasks over asset lifespan

Figure 3 shows the average number of jobs for both planned and unplanned maintenance tasks. The scale is from first launch to end of life for the vessel, the vessel in the example is designed to have a 20 year life span. The general trend is a high number of jobs that decreases during the infancy of the asset, component failure during this period is often referred to as infant mortality. The trend flattens out after the first 2 to 3 years and then rises again as the asset starts to age. Figure 2 also shows some higher peaks in planned maintenance jobs, these are jobs that have been completed during the vessels 5 yearly dry docking, with this maintenance philosophy the 5 yearly dry docking is unavoidable down time, so grouping maintenance tasks to coincide with this improves efficiency.

With a conventional maintenance strategy as outlined in Figure 1 there is not much room to improve the efficiency of maintenance, there can be no reduction in spares, no extension of maintenance periods and no improvement in efficiency of systems for carbon footprint reduction. However, having a full complement of engineering staff onboard the asset means there is little need for maintenance management.

The data for number of planned jobs is taken from consolidation of OEM maintenance tasks that are recommended in the user manuals across all systems integrated to the vessel.

The data on unplanned maintenance tasks is obtained from historical entries in planned maintenance systems. Each task that is conducted onboard must be recorded in the planned maintenance system, whether it was a planned or unplanned task. Because of the nature of unplanned tasks the data is an average from historical data only.

7.3. Controls and Management

A conventional maintenance system is primarily managed by the chief engineer (CE) onboard the vessel. The CE keeps track of upcoming planned maintenance and ensures the correct spares will be available. The CE usually organises OEM maintenance also. There will be an office based team managing major planned maintenance intervals such as the 5 yearly dry docking, in cooperation with the onboard CE.

The controls that are in place to ensure maintenance is done correctly are mostly down to the CE onboard either checking the work or trusting the engineering team. Because the CE cannot check every single detail, they must be confident in the team. This is why the engineers onboard must have certificates of competency that are revalidated every 5 years, to ensure that they are still competent to perform the maintenance activities assigned to their role.

7.4. System Health Indicators and Key Performance Indicators

In a conventional maintenance system, the SHI are primarily observations by the crew. The Automation system can alert the crew to a parameter reaching a set point, for example if temperature increases to 50 degrees an alarm is triggered. The setpoints are controlled, especially for the E0 alarms. Once an alarm is triggered diagnosis is done by the maintenance crew using tools and human senses. Some trending is possible within the IAS on modern ships, although the majority of vessels operating may not be capable of trending a metric.

The SHI/KPI are selected following literature review and consolidating the metrics that are generally used. The values against each of the KPI/SHI are estimated based on achievements made by similar PHM implementation in other industries against historical data from vessel maintenance.

Table 6 below shows example KPI's / SHI's for a conventional maintenance system.

Table 6: Conventional Maintenance System Metrics

KPI / SHI	Description
Availability	292 days per year potential
Human reliance / human error	5 humans obtaining information for maintenance
Unplanned maintenance tasks	3200 tasks
Planned maintenance tasks	2500 tasks
Set up cost	$250,000 – one time cost
Running costs	$500,000 – yearly running costs
Maintenance Costs	$500, 000 – yearly spares / consumables

8. Conventional Condition Based or Reliability based maintenance System

The next step up from the maintenance system previously discussed starts to bring in condition monitoring. According to Lloyds Register only 17% of classed ships operate with an approved PMS, and only 12% of these use condition monitoring, leaving ~2% of classed ships with a condition monitoring system in place (Shorten, 2012). This means that as of 2012 only 12% of registered vessels operate using the Conventional Philosophy described in section 6.0 of this paper, and only 2% are using the system described in this section. This data is 14 years old at time of writing, so should be considered out of date, however this is the most recent formal data on the usage of CMS in the maritime industry.

Below is a generic example of including condition monitoring into the maintenance system of a vessel.

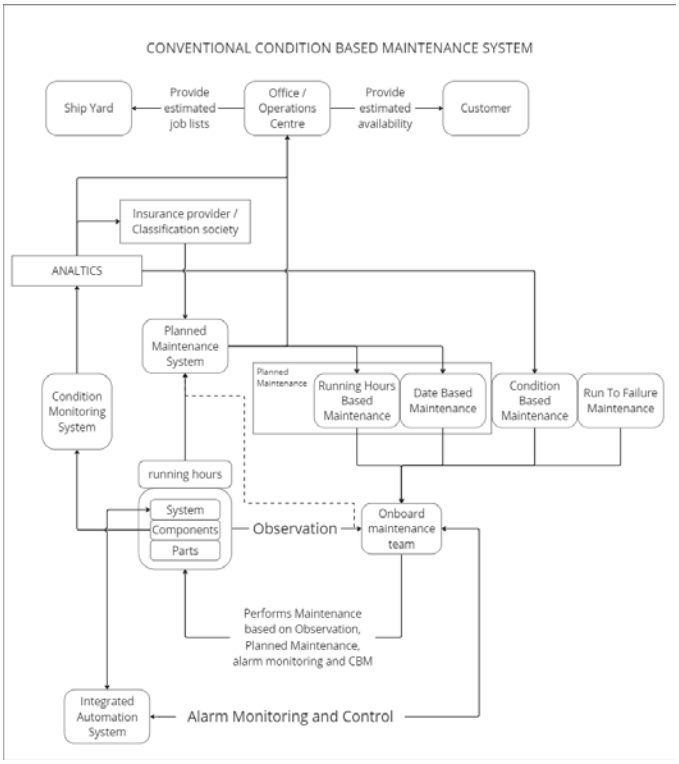

Figure 4. Conventional Condition Based Maintenance System layout

8.1. Conventional Condition Based Maintenance System Description

Building on the description in section 6.1, there is now the addition of a condition monitoring System (CMS) as can be seen in Figure 4. The output of the CMS is raw data that must be analysed. The "insights" that are generated from the analysis can be used to extend maintenance by sending to classification society and guiding the maintenance actions of the onboard team.

Correct application of CMS is vital for this maintenance system to work. Covering the asset with sensors is expensive and ineffective. The typical system of this type on vessels uses a vibration probe and measurements are taken at intervals. This method allows human error from the start as measurements are not always taken consistently with the asset in the same state. A RAM approach here delivers effective designs for CMS based on data driven reasons. Digital twins can be used for design of CMS for efficient sensor sets to cover the maximum amount of failure modes. Failure modes must be properly understood and categorized at this stage. Failure to properly design the CMS at this stage of evolution will increase costs and complexity of maintaining the asset. Typically, the CMS is applied to large rotating machines and vibration is the only sensing type.

8.2. Method of performing Maintenance.

Many CMS systems found in the maritime industry are not fixed, instead a portable sensor is used to take vibration readings. One of the maintenance crew is tasked with carrying out the measurement. This manual measurement introduces many human errors and means continuous monitoring is not possible. Once measurements are taken they are uploaded back to a land based office and then transferred to a 3rd party analytics provider. When potential faults are identified the company is informed who then inform the vessel and action can be taken. Due to the potential errors in measurement the results are often in accurate and so trust in the system does not develop. Often the system is abandoned and only the necessary readings are taken with little to no action from results.

8.3. System Health Indicators

As well as those mentioned in the previous iteration, this strategy can produce vibration health indicators.

Table 7: Conventional Condition Based Maintenance System Metrics

KPI / SHI	Description
Availability	292 days per year potential
Human reliance / human error	5 humans obtaining information for maintenance
Unplanned maintenance tasks	3000 tasks
Planned maintenance tasks	2800 tasks
Set up cost	$300,000 – one time cost
Running costs	$680,000 – yearly running costs
Maintenance Costs	$500, 000 – yearly spares / consumables

9. Prognostic Health Management maintenance System

In this section we look at the inclusion of prognostics in the maintenance strategy. It is important to note that this is where significant divergence occurs between a RAM enabled maintenance system and one that has not taken into account the nature of RAM.

Figure 5 below shows a general example layout of a PHMMS.

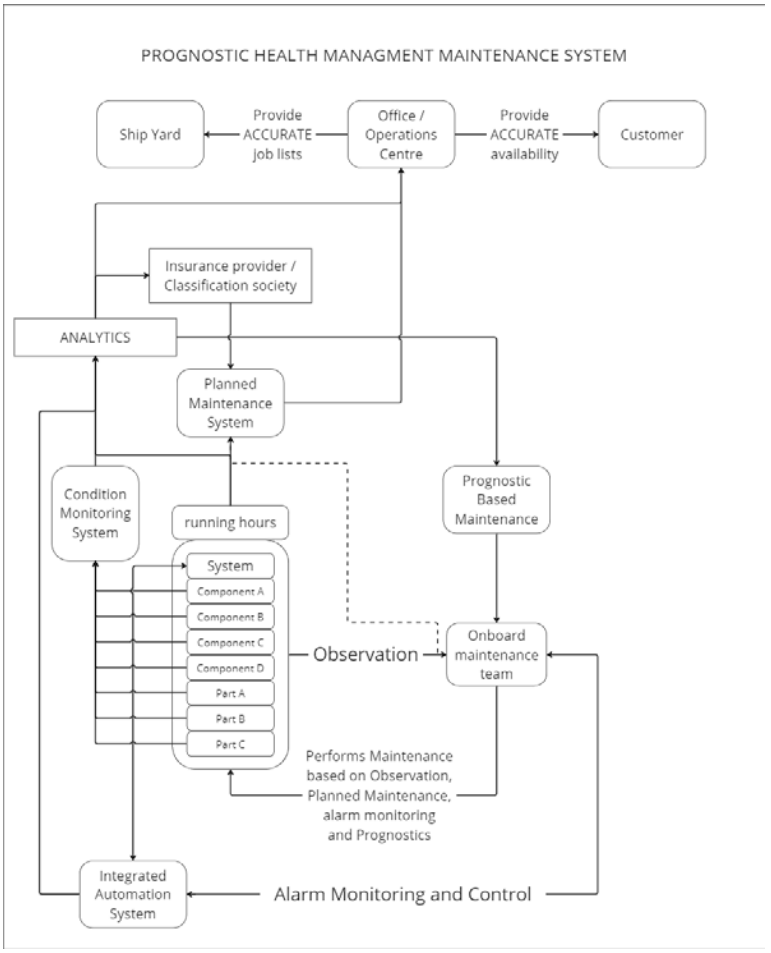

Figure 5 - Prognostic Health Management Maintenance System layout

9.1. Prognostic Health Management Maintenance System Description

We can see in figure 5 that the asset to be maintained is now broken into components and parts. Condition monitoring is applied to all components and parts. Covering the asset in monitoring sensors produces a lot of data. The monitoring system itself becomes complex and expensive. We can also see in figure 5 that the onboard maintenance team is relying on observations and prognostics only. Relying on total coverage for PHM eliminates the need for other maintenance strategies such as run to failure, but many failure modes, especially in the electronics domain, cannot be detected by readily available sensors.

9.2. Method of Performing Maintenance

As failure modes are detected action will be taken. In an ideal total PHM system all maintenance is done proactively and for data driven reasons

9.3. System Health Indicators

In this strategy the state of each failure mode for each system can be presented to the operator. For example, failure mode A may have not been detected, whereas failure mode B may be 10% of the way to critical failure of the system. As well as this the onboard team will use observations for system health indication.

Table 8: PHMMS metrics

KPI / SHI	Description
Availability	328 days per year potential
Human reliance / human error	5 humans obtaining information for maintenance
Unplanned maintenance tasks	2800 tasks
Planned maintenance tasks	2300 tasks
Set up cost	$1,000,000 – one time cost
Running costs	$680,000 – yearly running costs
Maintenance Costs	$500, 000 – yearly spares / consumables

Table 8 shows the average metrics for this maintenance system. For this particular strategy it is important to note the complexity of the monitoring system and the cost to set this up. At this level the monitoring system its self is likely to experience failures just due to the amount of sensors and the probability MTTF.

Due to complexity, cost, and the amount of time it would take to set this up.

10. RAM Enabled Predictive Maintenance System

We now look at the culmination or sweet spot system, a RAM enabled PHM system. The diagram below shows an example general layout of such a system.

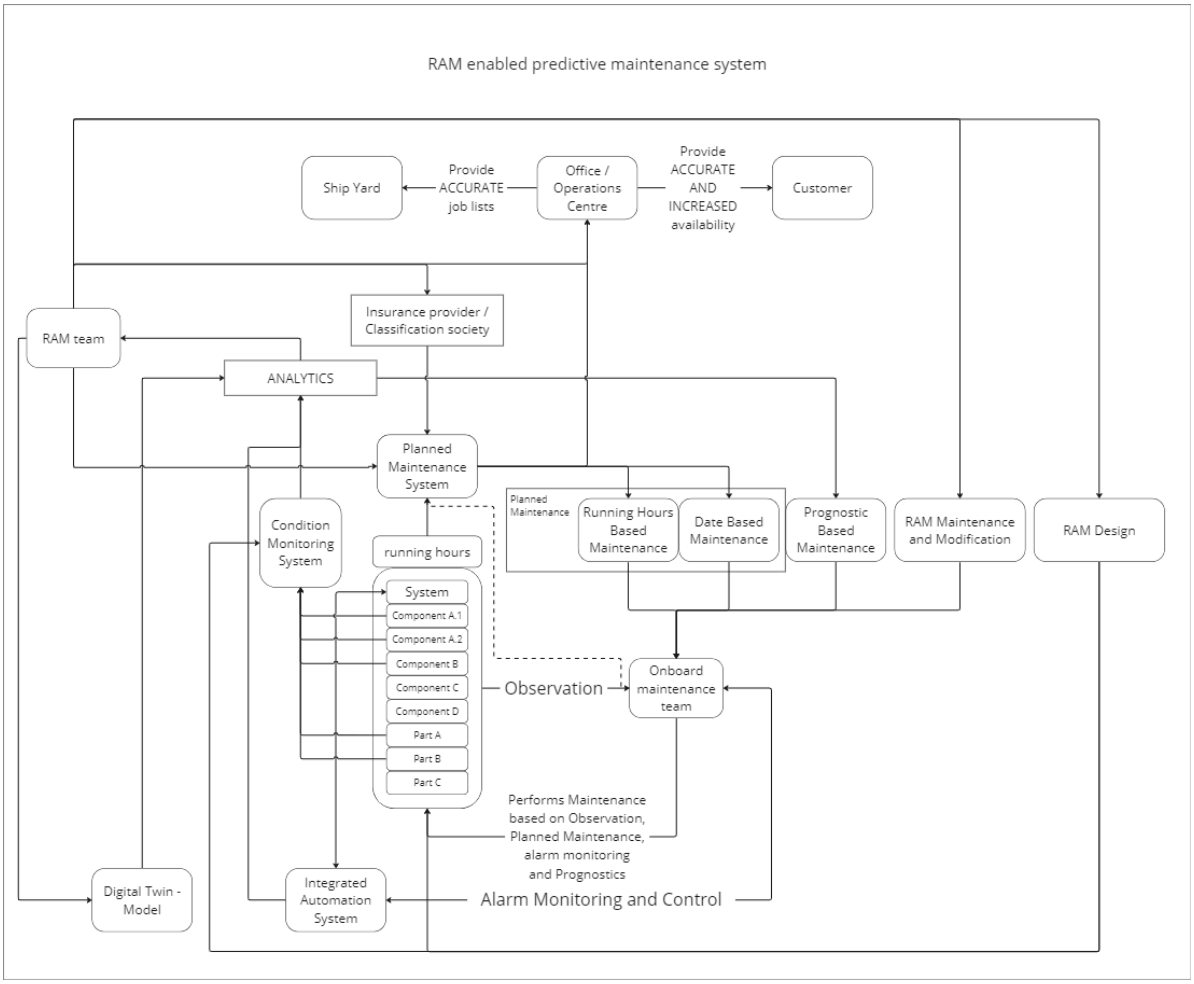

Figure 6. RAM enabled PHM Maintenance System layout

10.1. RAM Enabled Maintenance System Description

This system has many parts as can be seen in figure 6, but there is potential for harmony. The main difference between this and the previous system is in the design. Here targeting is done through RAM. No longer are we blanketing the asset in sensors, now we are using advanced design methods to create the minimum sensor set to cover the maximum failure modes. Digital risk and function twins are used to facilitate the sensor suit design and simulate effectiveness.

RAM shows us that certain components benefit from certain maintenance strategies depending on criticality, cost, redundancy and other factors.

10.1.1. Digital Twins

Following a concise RAM strategy generates details on the types of tools that can be used. Digital twins can play an important role in PHM design and assist in enabling effective PHM.

Digital twins are an aspect that is gaining momentum in the realms of PHM (Kammal Al-Kahwati, 2022) there are many advantages to using digital twins as part of machinery health management as Al-Kahwati explains There is an important point that is hinted at in Al-Kahwati's paper, that is availability. In order for the techniques in PHM to be given serious consideration by industry there must be a quantifiable gain. Availability of an asset is one such quantifiable metric, (the other two main areas being Reliability and Maintainability – RAM) Availability of a system is essential for a solid business case (Kammal Al-Kahwati, 2022). (Mulugeta Weldezgina Asres, 2022) AnoP is becoming increasingly linked to a concept known as Industry 4.0 (Mulugeta Weldezgina Asres, 2022) the ability to detect causal based anomalies of complex systems is critical to both the systems health and the quality of the system output. Using a multivariant causality-based anomaly prediction system as part of prognostic health management is about as advanced as system health prediction can get.

10.2. Method of Performing Maintenance

With this system the maintenance is still performed by the onboard maintenance team, however the maintenance is much more targeted. Spares holding can be reduced and potentially only ordered once degradation indicators are presented to the team. Systems and components deemed as non-critical and low cost are still replaced or repaired only when they fail, which in some cases is the most effective strategy. For example, light bulbs / tubes or LED's are run to failure items.

10.3. System Health Indicators

The health indicators are tuned per system. One system may only present human observable indicators, while another may present complete failure mode status through additional sensor sets. The indicators across the system of systems that is a vessel are optimised.

Table 9: RAM Enabled Predictive Maintenance System Metrics

KPI / SHI	Description
Availability	347 days per year potential
Human reliance / human error	<4 humans obtaining information for maintenance
Unplanned maintenance tasks	1000 tasks
Planned maintenance tasks	3000 tasks
Set up cost	$500,000 – one time cost
Running costs	$610,000 – yearly running costs
Maintenance Costs	$400, 000 – yearly spares / consumables

11. RAM / PHM Maintenance System For Lean / Uncrewed Vessels (MASS)

The last iteration of this maintenance system evolution is to tie the lean / uncrewed operational model to the RAM / PHM model.

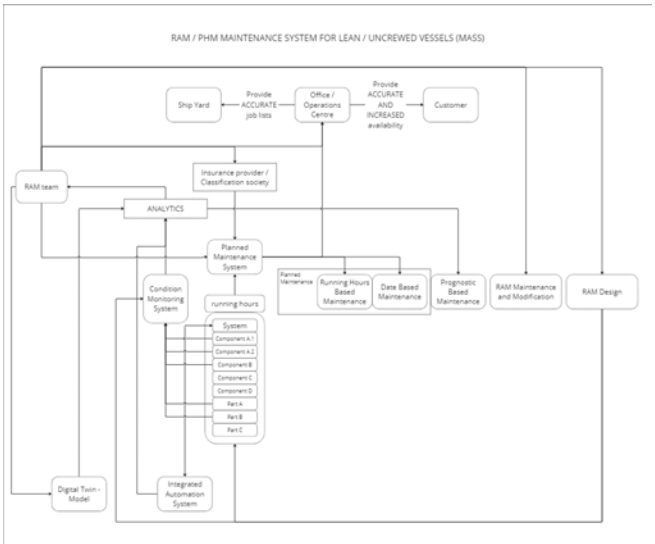

Figure 7. RAM / PHM system for MASS with onboard maintenance team removed

Figure 7 above shows the removal of the humans. Despite the sophisticated technology this removal leaves a gap between information and action. Figure 8 shows an example of how this gap may be filled by remote operations.

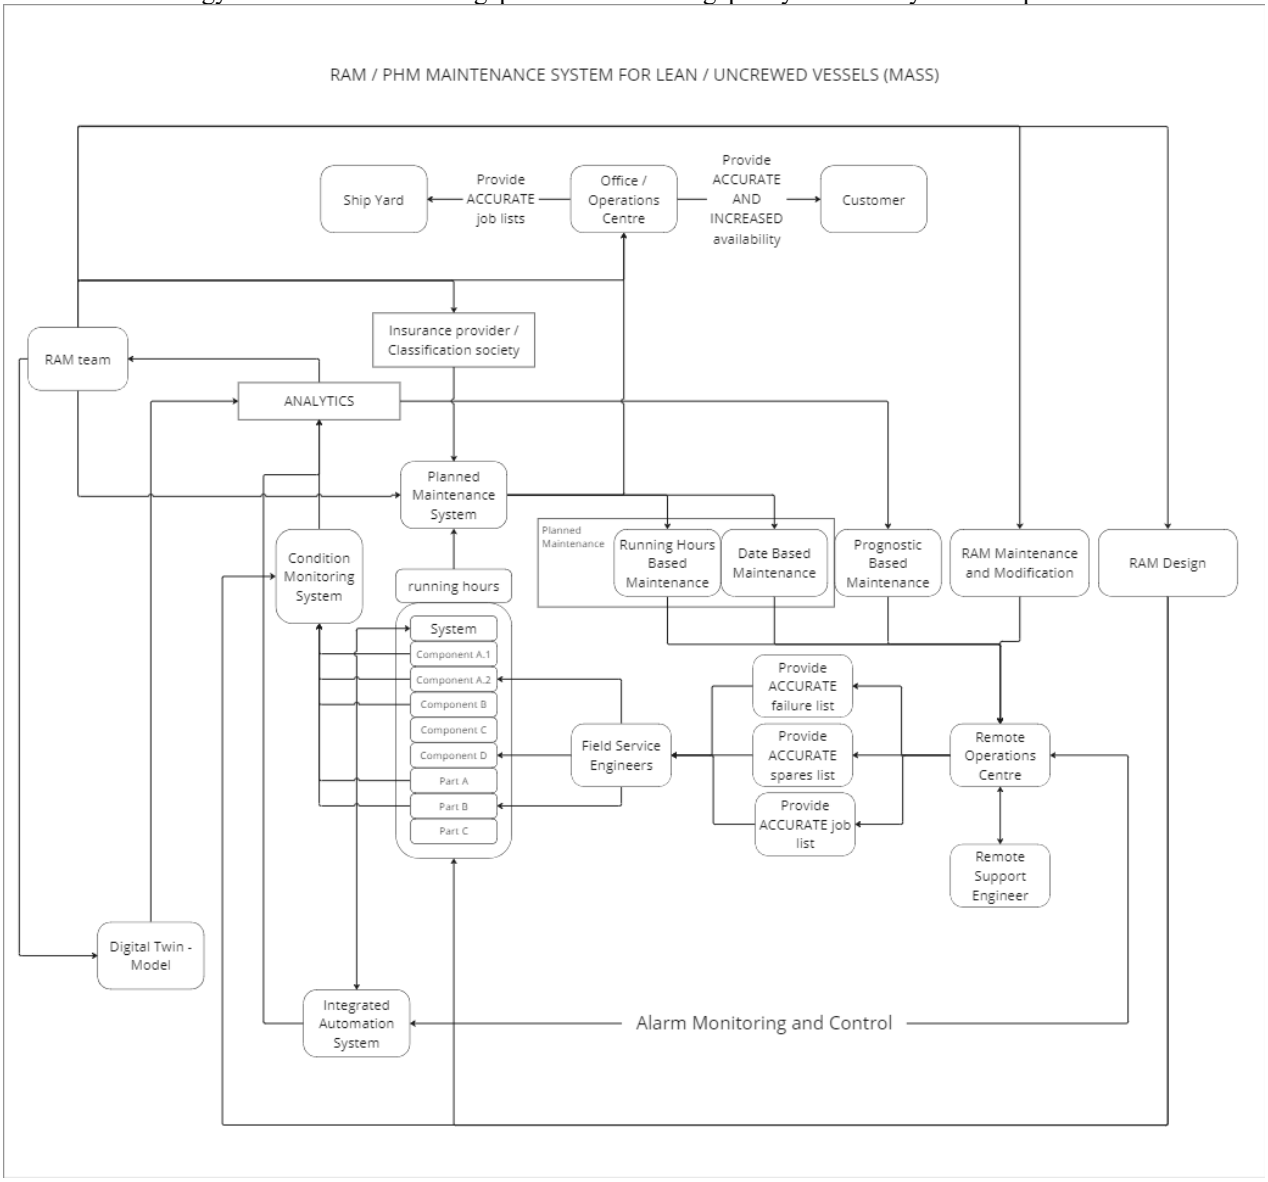

Figure 8. RAM / PHM system for MASS with onboard maintenance team replaced by remote operations

11.1. RAM / PHM Maintenance System For Lean / uncrewed Vessels (MASS) system description

The system its self is the same as the previous system, however the decision making has been moved to a shore based facility and the maintenance actions are now being performed by a specialist team that are only onboard when the vessel is in port. Figures 7 and 8 show that a RAM enabled PHM system facilitates lean / uncrewed operations while the need for lean / uncrewed operations validates the use of a RAM enabled PHM maintenance system.

11.2. Method of Performing Maintenance

With this system a shore side team are given instructions on what maintenance actions need to be done prior to joining the vessel. The list is completed and the team leave the vessel prior to her leaving port. These actions include those described with the previous system in section 10.

11.3. System Health Indicators

The same indicators are generated as in section 10 but without the human observations. Summary can be seen in table 10 below.

Table 10 : RAM / PHM Maintenance System for Lean / Uncrewed Vessels (MASS))

KPI / SHI	Description
Availability	356 days per year potential
Human reliance / human error	Potentially 0 humans obtaining information for maintenance
Unplanned maintenance tasks	Potentially 0 tasks
Planned maintenance tasks	3000 tasks
Set up cost	$600,000 – one time cost
Running costs	$360,000 – yearly running costs
Maintenance Costs	$300, 000 – yearly spares / consumables

12. DISCUSSIONS

A conventional Maintenance system is reliant on the maintenance crew onboard the vessel. The cost of the crew is high, and including the systems to support the crew onboard adds size and cost to the vessel. Diagnostics can be time consuming and there is a high amount of reactive maintenance. Having such a highly qualified maintenance crew onboard the vessel means the maintenance is self-managed onboard.

The general coverage of CMS and acceptance of PHM is a subject that can be heavily discussed. The latest numbers on CMS coverage are 14 years old, publications such as DNV's titled Beyond Condition Monitoring in the Maritime Industry is a fantastic snap shot of the state of CMS coverage around the same time as the coverage survey was conducted by Lloyds (Knut Erik Knutsen, 2014) does this suggest a new survey is needed?

It is also worth discussing the practical and theoretical implications to an asset and to an organisation if a RAM enabled PHM driven Maintenance system is employed. Practically for the asset there will be component changes to conform to the RAM strategy, spares holdings will change and additional sensor sets will be added. Systems that are not normally integrated may need to be integrated under a RAM / PHM maintenance system.

For the organisation there will need to be adjustments, both in the personnel skills and in the connections between departments. A new way of handling services will need to be developed including department and logistics handling to create the enhanced service team required to service an uncrewed vessel.

In theory, the gaps that an organisation faces and the gaps that the asset faces can be realised by proper assessment that takes into account RAM. This assessment must be carried out with appropriate subject matter experts in order to ensure the asset and the organisation are ready for the adoption of this new maintenance / operations aware design approach.

Table 11 below aims to summarize the KPI's and impact on them by the difference maintenance strategies. Taking into account the details from the processes presented in the previous sections. The cost figures associated with these KPI's were averaged from typical industry quotes related to maintenance upgrades and new build design. The costs will vary dependent on the vessel class, its anticipated modes of operation, and the age of the vessel if considering retro fit.

Table 11 : KPI / SHI summary

KPI	Metric / Unit	Conventional Maintenance System	Conventional Condition Based Maintenance System	Prognostic Health Management Maintenance System	RAM Enabled Predictive Maintenance System	RAM / PHM Maintenance System for Lean / Uncrewed Vessels (MASS)	Trend
Availability	days availability per year	325	325	350	350	358	
Human reliance / human error	maintenance staff needed onboard	5	5	5	4	0	
Unplanned maintenance tasks	average number of tasks per year	3200	3000	2800	1000	0	
Planned maintenance tasks	average number of tasks per year	2500	2800	2300	3000	3000	
Set up cost	average dollars one time cost	250000	300000	1000000	500000	600000	
Running costs	average dollars per year	680000	680000	680000	610000	360000	
Maintenance Costs	average dollars per year	500000	500000	500000	400000	300000	

Below are 3 consolidated graphs showing the general trend across the

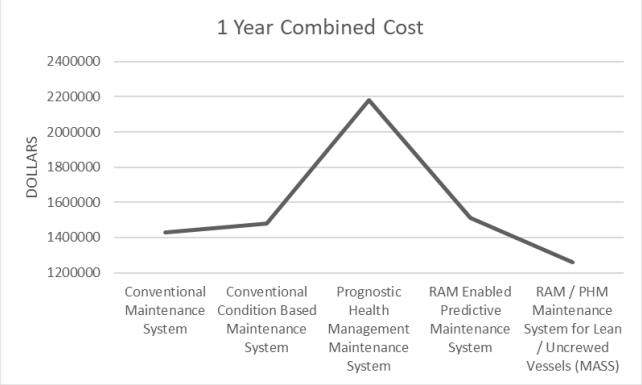

Figure 9. combined cost of each evolution over 1 year

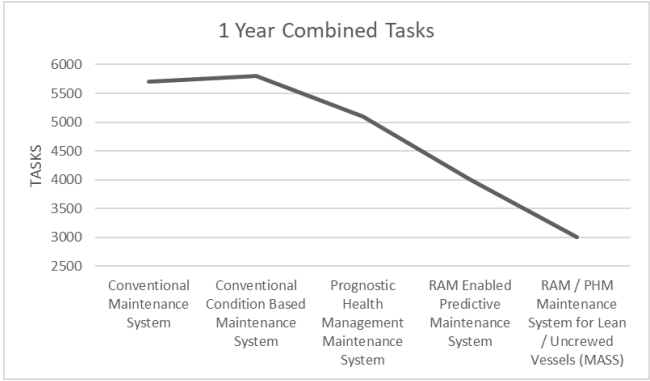

Figure 10. Combined tasks of each evolution over 1 year

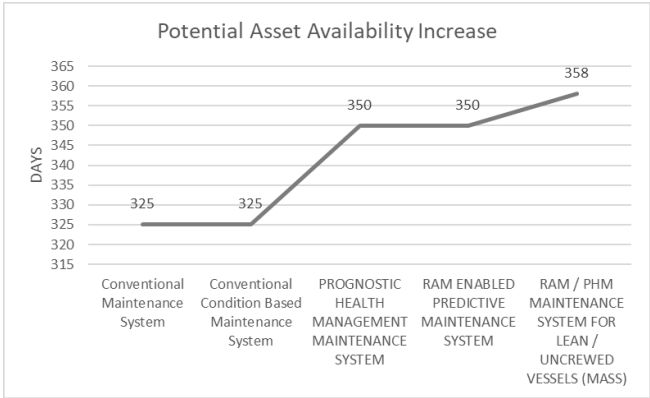

Figure 11. Potential asset availability using each evolution over 1 year

Figure 9 assists in demonstrating that a ROI is only feasible if RAM is included in PHM design.

Not using RAM could be a contributor to advanced monitoring system utilization being abandoned in many cases in the maritime industry due to a negative ROI

Figure 11 lets us consider the worth of an average day rate for the vessel. For example, take a day rate of $20,000, this gives a maximum of $7.3M generation. The income potential difference between a conventional maintenance system and a RAM enabled PHM maintenance system can be 10% which in this example equates to $660,000 per year additional potential income. If we take a conservative look at this and realise only 5% additional availability, the additional income will offset the cost of setting up a RAM enabled PHM system in 2 years. In addition to increased income potential there are decreases in costs that can be maximised by designing the vessel to be lean / uncrewed. There is also the increased reliability of the asset and increased availability prediction accuracy that can have major impacts on reputation.

While a RAM enabled PHM system is most effective when combined with the lean / uncrewed option it also enables the lean / uncrewed option and so these two technologies combined with their associated philosophies are bound together and are mutually beneficial.

When looking at the setup costs for PHM the following must be considered.

The PHM approach without using RAM is fraught with danger leading to high costs, high amounts of data. The extreme nature of this strategy could mean that components that were traditionally low cost run to failure items are now being monitored by an expensive and complex system. In this case maintenance / replacement costs will increase.

The design approach is another point of discussion, using digital twins and how to combine the data driven approach with subject matter experts to perfect the design. Extensive “tuning” must be done to ensure the best fit for each system onboard the vessel, this can be done much faster using digital twin technology.

Below is a generalised list of considerations for implementing a PHM system on any system onboard a vessel.

Table 3: PHM system components

SYSTEM	COMPONANT
Analysis	Software
Analysis	Engineer
Analysis	Training
Analysis	Computer
Analysis	Modelling
Data Acquisition	Sensors

Data Analytics	Engineer
Data Analytics	Storage

Table 11 shows an example of the components required to set up the proposed system, in addition the company itself must be setup to handle prognostics.

12.1. Implementation Examples

The proposed move to a RAM enabled PHM maintenance system should be employed if shipping owners have a need to increase asset availability. An implementation example would be a shipping company that is renewing / replacing vessels and wants the new vessels to have higher availability, reduced running costs, and remote capability, either lean or uncrewed.

Another example would be a vessel owner seeking to build more advanced uncrewed vessels and requiring a maintenance system that can facilitate the nature of uncrewed vessels.

12.2. Next Steps

The proposed move to RAM enabled maintenance systems can have wide reaching implications for the maritime industry, from ship builders and operators, to crew and service technicians, and then to assurance and insurance providers.

Ship builders can benefit from RAM enabled designs by offering increased reliability, operators share the same benefit. The crews serving onboard will be conducting maintenance in different ways. Assurance and insurance providers can benefit from the machinery health on demand that is achievable with the data produced by a RAM enabled PHM maintenance System. The future implications of the proposed system warrant extensive discussion in order to maximise the benefit to all stakeholders.

13. CONCLUSIONS

This paper describes a possible model for an advanced maintenance system that enables lean / uncrewed vessel operations. It also describes the evolutionary steps that have occurred to reach the proposed system.

Contributions to this paper are:

1. Articulation of maintenance strategies typically found in the maritime industry sector (including mapping of typical actives by stakeholders).
2. A snapshot of a generalised PHM value model targeted at the maritime industry sector.

One conclusion that can be seen is that a pure PHM approach is not effective and should be avoided. We can also conclude that the maritime industry is due for CMS coverage / utilisation / acceptance surveys, including acceptance of PHM from both engineering and cultural perspectives. The third conclusion from this paper is that there is a sweet spot for maintenance that can only be achieved by design, and that a concise RAM philosophy is an appropriate tool for assisting in the design and enabling a PHM system for vessels.

We can also conclude that there are existing elements onboard the vessel to build upon to facilitate lean / uncrewed operations, such as E0 and UMS notations.

The last conclusion is that a RAM enabled PHM maintenance system both supports and is validated by lean / uncrewed vessel operations and is a major contributor to asset availability increase.

ABSTRACT

System overheating is a common problem in electric equipment, as degradation of contacts lead to an increase in Ohmic resistance and increased thermal losses. Temperature measurements are widely employed to monitor a device's health status, to estimate its remaining useful life, and to inform maintenance strategies. An issue that is special to electrical distribution networks is the varying heating power, which is in turn due to changes in the current. This results in varying temperatures, which in addition can often be delayed compared to the currents. Simple threshold-based diagnostics approaches are therefore not reliable for detecting faults in contacts. It is common to analyze the thermal behavior of electric devices using thermal networks, for both design and diagnostic purposes. Unfortunately, identifying the parameters of thermal networks from measured temperature data is a challenging problem, mainly due to identifiability issues and to numerical instabilities in parameter estimation. We propose an alternative data-driven strategy to compute the state-of-health of electrical devices which does not resort to thermal networks. Our approach consists in informing physics-based reduced models of the thermal response with sensor data. We show that our method is linked to the thermal network approach but avoids the full identification of the system, leading to better stability as well as less computational effort in the determination of its parameters. Rigorous testing with synthetic and experimental data confirms the efficacy of our methodology.

1. INTRODUCTION

The effective monitoring of the operational health of electric devices is of utmost importance to guarantee the secure and steady functioning of industrial facilities (Hoffmann et al., 2020). Among the vulnerabilities encountered by these devices, the issue of overheating due to Joule's effect stands out prominently. A significant portion of the heat generated within these devices comes from electric contacts. The deterioration of contacts results in an increase in their electrical contact resistance (ECR), which, in turn, triggers pronounced overheating. Such overheating not only disrupts operational stability but also exposes the devices to the imminent risk of irreparable harm.

With the rise in connectivity of industrial devices – the industrial internet of things – the potential of monitoring algorithms for predictive maintenance has grown considerably. In the present context, temperature data can be leveraged to prevent excessive overheating and monitor the health state of devices. While simple algorithms monitor the temperature and raise alerts based on critical levels, the dynamic nature of the thermal response to time-dependent current loads yields more insight into the root cause of the problem.

The method we propose in this report is computationally light and memory-efficient (in contrast to numerical solvers of partial differential equations), and is robust when confronted with real data (unlike thermal networks). Despite its simplicity, we believe this method can be effectively used for making thermal predictions and detect anomalous behavior for a wide range of electric devices.

Thermal networks can be cumbersome to set up and train (O. M. Brastein et al., 2019; O. Brastein et al., 2020; Boodi et al., 2022), but they are nevertheless a flexible tool to model the temperature response of the device. Conversely, the method which we propose here does not allow to predict temperatures away from the sensor and requires some dedicated training of the response of each device using a specific current profile. Memory-wise, the method also requires some limited storage of past current values. Finding a mathematical equivalence of thermal networks and the proposed method may therefore lead to the development of a method that combines the two approaches and retains the advantages of both.

The remainder of this article is as follows. In Section 2 we introduce the thermal kernel method, focusing on how to cope with noise in the data, and on how to infer variations in the ECR values. The equivalence of the kernel method and the thermal network approach is then discussed in Section 3. In Section 4 we test the method against synthetic data, checking the accuracy of the method as well as its robustness against model misspecification and noise in temperature data. Finally, in Section 5 we draw our conclusions and propose an outlook for future work.

2. THE THERMAL KERNEL METHOD

We consider an electric device which is equipped for simplicity with a single temperature sensor (see Section 2.4 below for the case of multiple sensors). We model the over-temperature T at the sensor location for a new and healthy device as

$$T(t) = \int_0^t k_0(t-s)\, I^2(s)\, \mathrm{d}s, \tag{1}$$

where k_0 is an unknown kernel function, and where I denotes the electric current, which we assume to satisfy $I(t) = 0$ for all $t \leq 0$. Note that k_0 can be seen as a Green function of the thermal problem, and I^2 is proportional to the thermal input due to Joule's law of heating. The kernel k_0 captures all linear thermal influences on the temperature measured by the sensor, and in particular the heat generated both by bulk conductors (e.g., busbars in electric devices) and the heat generated at imperfect contacts, which are both proportional to I^2. The existence of such a kernel function is guaranteed if we assume that the system is linear both with respect to the heat flow and the dependency on I^2.

Let N be the number of electrical contacts in the device, and denote by ΔR_i the variation (typically an increase) of the ECR in the i-th contact for $i = 1, \ldots, N$. Then, we assume that there exist kernels k_i for all $i = 0, 1, \ldots, N$ such that the temperature at the sensor location reads

$$\begin{aligned} T(t) = &\int_0^t k_0(t-s) I^2(s)\, \mathrm{d}s \\ &+ \sum_{i=1}^{N} \Delta R_i \int_0^t k_i(t-s) I^2(s)\, \mathrm{d}s. \end{aligned} \tag{2}$$

With the formula in Eq. (2), we assume that the thermal response at the sensor location of the device after contact degradation is encoded by the kernel

$$k_\Delta(t) = k_0(t) + \sum_{i=1}^{N} \Delta R_i k_i(t), \tag{3}$$

where the kernels $k_i(t)$ model the thermal response due to a change of resistance at contact i. The kernel functions k_i for $i = 0, 1, \ldots, N$ are unknown and depend on the device geometry, on how heat is exchanged with the surrounding environment, and on the thermal interconnections of the device components.

2.1. Determination of the kernel functions

In order to determine the kernel functions we use the response of the system to a step excitation, i.e., by imposing a constant current $I(t) = I_0$ for all $t \geq 0$. First, we fix $\Delta R_i = 0$ for all i and derive both sides of Eq. (1) with respect to t to obtain

$$k_0(t) = \frac{\dot{T}(t)}{I_0^2}. \tag{4}$$

Note that the temperature derivative $\dot{T}$ may not be available from sensor data, but can easily be reconstructed in practice by means of a finite difference formula from the measured temperature T. Note that numerical differentiation may amplify noise on the signal. We tackle this issue in Section 2.2 below. Given k_0 we can then determine the remaining N kernels by increasing the ECRs by a known quantity one by one. Indeed, if it holds $I(t) = I_0$ and $\Delta R_j = 0$ for all $j \neq i$ for a fixed index i, we have from Eq. (2)

$$\dot{T}(t) = \left(k_0(t) + \Delta R_i k_i(t)\right) I_0^2.$$

If the ECR increase ΔR_i is known and we measure the corresponding temperature T, then the kernel k_i is given by

$$k_i(t) = \frac{1}{I_0^2 \Delta R_i} \left(\dot{T}(t) - I_0^2 k_0(t)\right). \tag{5}$$

It might be unpractical or impossible in some scenarios to increase the ECR by a known quantity. Determining kernel functions may then involve data generation through a high fidelity simulation.

2.2. Noisy or short temperature data: Exponential fit

Let us assume that the temperature T is observed for a finite time interval $0 \leq t \leq t_{\mathrm{end}}$ and that observations are subject to measurement noise. In this case, the kernel k_0 given by Eq. (4) (and similarly the kernels k_i, $i = 1, \ldots, N$) should be post-processed to obtain a smooth kernel that can also be evaluated for times $t > t_{\mathrm{end}}$. For this purpose, we can introduce the natural assumption that k_0 is given by an infinite sum of negative exponential functions, as in

$$k_0(t) = \sum_{j=1}^{\infty} a_j \exp(-\lambda_j t),$$

where $a_j \in \mathbb{R}$, $\lambda_j \in \mathbb{R}^+$ for all $j = 1, 2, \ldots$. We then truncate the sum to an integer number N_{exp} of exponential functions and write

$$\widetilde{k}_0(t) = \sum_{j=1}^{N_{\mathrm{exp}}} a_j \exp(-\lambda_j t).$$

A suitable value $N_{\exp}$ can be chosen with a model selection algorithm. Finally, we determine a_j and λ_j by maximizing the likelihood of the noisy kernel k_0 given by Eq. (4) applied with the data sequence T. This ansatz can be motivated by the equivalence between thermal networks and kernels (or more in general by any finite-dimensional approximation of the full heat problem). More details can be found in Section 3.

The approach of fitting exponential functions to k_0 could be problematic in case temperature data are corrupted by noise. Indeed, noise is amplified when computing the time derivative $\dot{T}$ of the temperature. In this case, it is more robust to fit directly the temperature data T, which under the assumption above is approximated by

$$\widetilde{T}(t) = I_0^2 \sum_{j=1}^{N_{\exp}} \frac{a_j}{\lambda_j} \left(1 - \exp(-\lambda_j t)\right).$$

We can therefore fit the curve above directly to the temperature data and determine the values of a_j and λ_j which fully define the kernel function k_0.

We can repeat the same reasoning for the kernels $\{k_i\}_{i=1}^N$ modeling the thermal response at the sensor location due to (additional) heat generated at the contacts. We make the guess that for all $i = 1, \dots, N$ it holds

$$k_i(t) = \sum_{j=1}^{N_{\exp}} a_{ij} \exp(-\lambda_{ij} t).$$

Manipulating Eq. (5) with similar calculations as above we obtain

$$T(t) - I_0^2 \int_0^t k_0(t-s)\,\mathrm{d}s = I_0^2 \Delta R_i \sum_{j=1}^{N_{\exp}} \frac{a_{ij}}{\lambda_{ij}} \left(1 - \exp(-\lambda_{ij} t)\right).$$

The left-hand side of this equation is known. Fitting the coefficients a_{ij} and λ_{ij} to data then defines the kernel k_i. Note that this approach assumes that the coefficients λ are independent of each other for k_0 and each k_i. Since the thermal time scales should be the same for the nominal value of the resistance and increased resistances by linearity, the values λ_{ij} should be shared by the fit to k_0. A more robust approach, which we do not investigate here, would therefore consist in fitting the kernel functions simultaneously.

2.3. Inference of the resistance variations

In this section, we describe how knowledge of the kernel functions can be combined with temperature data to infer online a variation of the ECR of the N contacts, and consequently deduce their health status. Assume that all the kernels k_i have been determined and denote for $i = 0, \dots, N$ by K_i the integrated quantity

$$K_i(t) = \int_0^t k_i(t-s) I^2(s)\,\mathrm{d}s,$$

where I is the measured current. Then, we can rewrite Eq. (2) as

$$T(t) = K_0(t) + \sum_{i=1}^{N} \Delta R_i K_i(t). \tag{6}$$

Assume that the current and the temperature at the sensor have been measured on a set of times $\mathbf{t} = (t_0, t_1, \dots, t_M)$, where $t_j = t_s \cdot j$ and t_s is the sampling time. We can then assemble M-dimensional vectors

$$\mathbf{T} = T(\mathbf{t}), \qquad \mathbf{K}_i = K_i(\mathbf{t}),$$

where $T(\mathbf{t}) = (T(t_0), T(t_1), \dots, T(t_M))^\top$. Using the vectorial notation, the discrete version of Eq. (6) is

$$\mathbf{T} = \mathbf{K}_0 + \sum_{i=1}^{N} \Delta R_i \mathbf{K}_i.$$

An estimator $\widehat{\Delta R} \in \mathbb{R}^N$ of the vector of ECRs can be defined as the least square estimator

$$\widehat{\Delta R} = \arg\min_{\Delta R} \left\| \mathbf{K}\Delta R - (\mathbf{T} - \mathbf{K}_0) \right\|, \tag{7}$$

where $\mathbf{K}$ is the $M \times N$ matrix with columns $\mathbf{K}_i$ for $i = 1, \dots, N$. The minimization problem is overdetermined whenever $M \geq N$, i.e., the number of time instants for the measurements exceeds the number of contacts in the system, which is most likely verified. Hence, the estimator in Eq. (7) should be determined as the solution of the $N \times N$ linear system

$$\mathbf{K}^\top \mathbf{K} \widehat{\Delta R} = \mathbf{K}^\top (\mathbf{T} - \mathbf{K}_0).$$

Note that in real applications we expect the values of ΔR_i to increase rather than decrease due to contact degradation. A physically meaningful solution could therefore be enforced by using the constrained minimizer

$$\widehat{\Delta R} = \arg\min_{\Delta R \geq 0} \left\| \mathbf{K}\Delta R - (\mathbf{T} - \mathbf{K}_0) \right\|,$$

where the symbol $\geq$ is meant component-wise.

2.4. Multiple temperature sensors

We now consider a device which is equipped with multiple temperature sensors, and explain how more information can be leveraged to obtain a possibly more precise estimation of variations in the ECRs.

Assume that we have J temperature sensors. The temperature

of each sensor $j = 1, \dots, J$ can be expressed as

$$T^j(t) = \int_0^t k_0^j(t-s)I^2(s)\,\mathrm{d}s + \sum_{i=1}^{N} \Delta R_i \int_0^t k_i^j(t-s)I^2(s)\,\mathrm{d}s.$$

Note that the resistance increase ΔR_i is common for all sensors, as contacts are the same. Conversely, the temperature response is different across sensors, hence typically $k_i^{j_1} \neq k_i^{j_2}$ for $j_1 \neq j_2$. Kernels k_i^j can be determined as outlined in Section 2.1 for each $i = 0, \dots, N$ and $j = 1, \dots, J$. Similarly to Section 2.3, we then write $\mathbf{T}^j = T^j(\mathbf{t})$ and $\mathbf{K}_i^j = K_i^j(\mathbf{t})$ where

$$K_i^j(t) = \int_0^t k_i^j(t-s)I^2(s)\,\mathrm{d}s.$$

Calling $\mathbf{K}^j$ the $N \times M$ matrix whose columns are the vectors $\mathbf{K}_i^j$ for $i = 1, \dots, N$, we have J linear equations for ΔR

$$\mathbf{K}^j \Delta R = \mathbf{T}^j - \mathbf{K}_0^j, \qquad j = 1, \dots, J.$$

In order to compute the least square solution $\widehat{\Delta R}$ we assemble a $NJ \times M$ matrix $\mathbf{K}$ and NJ vectors $\mathbf{T}$ and $\mathbf{K}_0$ by stacking vertically the J equations as

$$\mathbf{K} = \begin{pmatrix} \mathbf{K}^1 \\ \mathbf{K}^2 \\ \vdots \\ \mathbf{K}^J \end{pmatrix}, \quad \mathbf{T} = \begin{pmatrix} \mathbf{T}^1 \\ \mathbf{T}^2 \\ \vdots \\ \mathbf{T}^J \end{pmatrix}, \quad \mathbf{K}_0 = \begin{pmatrix} \mathbf{K}_0^1 \\ \mathbf{K}_0^2 \\ \vdots \\ \mathbf{K}_0^J \end{pmatrix}.$$

The least square estimate $\widehat{\Delta R}$ is then the solution of the $N \times N$ linear system

$$\mathbf{K}^\top \mathbf{K} \widehat{\Delta R} = \mathbf{K}^\top (\mathbf{T} - \mathbf{K}_0),$$

and similarly to the single-sensor case a non-negative constraint can be imposed to the least-square solution. We note that in this case we expect an improvement by enforcing the time scale parameters to be the same across resistances when performing an exponential fit as in Section 2.2.

3. Equivalence with thermal networks

Thermal networks have been used to model the temperature of electric devices, and to infer health status given temperature measurements (Stosur et al., 2016). In this section, we describe how our approach simplifies thermal networks, whose parameters are notoriously difficult to estimate from data (O. M. Brastein et al., 2019; O. Brastein et al., 2020; Boodi et al., 2022). For a general discussion on identifiability of linear models, we refer the reader to (Raue et al., 2014).

We call thermal network a model which splits the device into an integer number N_c of compartments, whose temperature is assumed to be sufficiently homogeneous to be described by a single over-temperature T_i, for $i = 1, \dots, N_c$. We assume that the i-th compartment has a heat capacity C_i for $i = 1, \dots, N_c$. The compartments are thermally interconnected so that the heat flowing between the compartments indexed by i and j is proportional to their temperature difference with a constant h_{ij}. If two compartments are not directly connected thermally, we trivially set $h_{ij} = 0$. Moreover, we assume that the heat flowing towards the environment is proportional to the over-temperature T_i with a constant α_i. Finally, we assume that all elements in the network represent parts of the device which are subject to an electrical current $I = I(t)$, so that the thermal input to the i-th element is given by $u_i(t) = R_i I^2(t)$ by Ohmic heating. Under these assumptions, the over-temperature T_i of the i-th compartment of the network, for $i = 1, \dots, N_c$, satisfies the ordinary differential equation (ODE)

$$C_i \dot{T}_i(t) = \sum_{j=1, j\neq i}^{N_c} h_{ij}(T_j - T_i) - \alpha_i T_i + u_i(t). \tag{8}$$

In this section, we show how the temperature evolution of each compartment in a thermal network satisfies Eq. (1), i.e., there exist kernels k_0^i such that

$$T_i(t) = \int_0^t k_0^i(t-s)I^2(s)\,\mathrm{d}s, \tag{9}$$

for each $i = 1, \dots, N_c$, and that the kernel function can be written as a sum of exponential functions as in Section 2.2. Hence, a system whose thermal response can be described accurately by a thermal network can also be described by thermal kernels, with the advantage that in the kernel approach less parameters need to be determined from temperature measurements.

To start the derivation, we notice that the ODE system Eq. (8) can be written in matrix form as

$$\mathbf{C}\dot{\mathbf{T}}(t) = \mathbf{H}\mathbf{T}(t) + \mathbf{R}I^2(t), \tag{10}$$

where $\mathbf{T}$ is a vector with the temperatures of all compartments, where $\mathbf{R}$ is a N_c-dimensional vector containing the values of the resistances, and where $\mathbf{C}$ and $\mathbf{H}$ are appropriate matrices containing the values of the coefficients h, α and C. Let us rewrite Eq. (10) as the generic linear system

$$\dot{\mathbf{T}}(t) = -\mathbf{A}\mathbf{T}(t) + \mathbf{F}(t), \tag{11}$$

where $\mathbf{A} = -\mathbf{C}^{-1}\mathbf{H}$ and $\mathbf{F}(t) = \mathbf{C}^{-1}\mathbf{R}I^2(t)$. Let $\mathbf{T}(0) = \mathbf{T}_0$ be a known initial condition. It is simple to verify by differentiation that the solution of Eq. (11) is given by

$$\mathbf{T}(t) = \mathbf{e}^{-\mathbf{A}t}\mathbf{T}_0 + \int_0^t \mathbf{e}^{-\mathbf{A}(t-s)}\mathbf{F}(s)\,\mathrm{d}s, \tag{12}$$

where we denote by $\mathbf{e}^{-\mathbf{A}t}$ the matrix exponential to distin-

guish it from the scalar exponential (e.g., e^t).

The matrix $\mathbf{A}$ is not symmetric but it is diagonalizable with real eigenpairs.[1] Recall that for any diagonalizable matrix $\mathbf{A} = \mathbf{V}\mathbf{\Lambda}\mathbf{V}^{-1}$, where $\mathbf{V}$ is the matrix with the eigenvectors $\{\mathbf{v}_j\}_{j=1}^{N_c}$ of $\mathbf{A}$ as columns, and $\mathbf{\Lambda} = \mathrm{diag}(\lambda_1, \dots, \lambda_{N_c})$ is the matrix of the eigenvalues, it holds

$$\mathbf{e}^{-\mathbf{A}t} = \mathbf{V}\mathbf{e}^{-\mathbf{\Lambda}t}\mathbf{V}^{-1} = \mathbf{V}\mathrm{diag}\left(e^{-\lambda_1 t}, \dots, e^{-\lambda_{N_c} t}\right)\mathbf{V}^{-1}.$$

This implies that if (λ, v) is an eigenpair of $\mathbf{A}$, then $(e^{-\lambda t}, v)$ is an eigenpair of $\mathbf{e}^{-\mathbf{A}t}$. Let $\mathbf{w}$ be an arbitrary vector in $\mathbb{R}^{N_c}$ and let $\{c_j = (\mathbf{V}^{-1}\mathbf{w})_j\}_{j=1}^{N_c}$ be the components[2] of $\mathbf{w}$ in the basis formed by the eigenvectors of $\mathbf{A}$, i.e., the scalars such that

$$\mathbf{w} = \sum_{j=1}^{N_c} c_j \mathbf{v}_j.$$

Hence, applying $\mathbf{e}^{-\mathbf{A}t}$ to $\mathbf{w}$ gives

$$\mathbf{e}^{-\mathbf{A}t}\mathbf{w} = \sum_{j=1}^{N_c} c_j \mathbf{e}^{-\mathbf{A}t}\mathbf{v}_j = \sum_{j=1}^{N_c} c_j e^{-\lambda_j t}\mathbf{v}_j.$$

Assume for simplicity and without loss of generality that $\mathbf{T}_0 = 0$. Replacing the decomposition above into Eq. (12) with $\mathbf{w} = \mathbf{C}^{-1}\mathbf{R}I^2(s)$ shows that

$$\mathbf{T}(t) = \int_0^t \sum_{j=1}^{N_c} c_j \mathbf{v}_j e^{-\lambda_j (t-s)} I^2(s)\,\mathrm{d}s,$$

where $c_j = (\mathbf{V}^{-1}\mathbf{C}^{-1}\mathbf{R})_j$. Hence, the temperature of the i-th compartment satisfies

$$T_i(t) = \int_0^t \sum_{j=1}^{N_c} \alpha_{ij} e^{-\lambda_j (t-s)} I^2(s)\,\mathrm{d}s,$$

where $\alpha_{ij} = \mathbf{V}_{ij} c_j$. This shows that the temperature of the i-th compartment can be indeed written as in Eq. (9) for

$$k_0^i(t) = \sum_{j=1}^{N_c} \alpha_{ij} e^{-\lambda_j t},$$

which is a sum of exponential functions as the approximations we employ in Section 2.2. Consider now that for each $k = 1, \dots, N_c$ the resistance of the k-th compartment increases by a quantity ΔR_k. We can write the overall kernel defining the temperature of the i-th compartment as

$$k^i(t) = \sum_{j,k=1}^{N_c} \mathbf{V}_{ij}\left(\mathbf{V}^{-1}\mathbf{C}^{-1}\right)_{jk} R_k e^{-\lambda_j t} + \sum_{j,k=1}^{N_c} \mathbf{V}_{ij}\left(\mathbf{V}^{-1}\mathbf{C}^{-1}\right)_{jk} \Delta R_k e^{-\lambda_j t}.$$

We see that k^i has the form of the kernel of Eq. (3) with

$$k_k^i(t) \coloneqq \sum_{j=1}^{N_c} \mathbf{V}_{ij}\left(\mathbf{V}^{-1}\right)_{jk} e^{-\lambda_j t},$$

which is the kernel associated to an increase in the k-th resistance as seen by the i-th element of the thermal network. Note that since the resistances do not appear in the expression of the system matrix $\mathbf{A} = -\mathbf{C}^{-1}\mathbf{H}$, the time scales λ_j in the kernels k_k^i are the same as the ones of the original kernel.

3.1. Generalization: kernel structure of thermal problems

The considerations above for thermal networks and the kernel structure of their solution applies more widely. In a linear approximation, heat transfer can be described by

$$\mathbf{C}\dot{\mathbf{T}} = \mathbf{L}\mathbf{T} + u, \tag{13}$$

where $\mathbf{L}$ is an operator describing both heat conduction $\mathbf{H}$ and coupling to the ambient α, and u is the heat injected in the system. In the specific case of a thermal network, the temperatures are vectors and the operators (finite dimensional) matrices. However, this equation may also describe a temperature field with a partial differential operator describing heat conduction on a physical domain Ω. For $x \in \Omega$, the local operator $\mathbf{C} = \mathbf{C}(x)$ is the specific heat capacity and the differential operator $\mathbf{L}(x) = -\nabla k(x) \cdot \nabla - k(x)\Delta$ describes heat conduction with a space-dependent heat conductivity k defined on Ω.

Note that Eq. (13) is linear in temperature, the operator $\mathbf{L}$ is self adjoint due to the symmetric nature of heat diffusion, and the field $\mathbf{C}$ is a (local) positive scalar. Normalizing the temperature $\widetilde{\mathbf{T}} = \mathbf{C}^{1/2}\mathbf{T}$ and multiplying Eq. (13) by $\mathbf{C}^{-1/2}$, we see that the operator occurring on the right hand side of the equation for $\widetilde{\mathbf{T}}$ ($\mathbf{C}^{-1/2}\mathbf{L}\mathbf{C}^{-1/2}$) is also self-adjoint. The spectral theorem then guarantees that this operator has real eigenvalues and orthogonal eigenfunctions that span the full space. Formally, the solution can be expressed in terms of the exponential operator $\mathbf{e}^{\mathbf{L}t}$ as

$$\widetilde{\mathbf{T}} = \int_0^t \mathbf{e}^{\mathbf{L}(t-s)}\widetilde{u}(s)\,\mathrm{d}s, \tag{14}$$

[1] Since $\mathbf{A} = -\mathbf{C}^{-1}\mathbf{H}$, with $\mathbf{H}$ symmetric and $\mathbf{C}$ diagonal and positive definite, we can write

$$\mathbf{A} = \mathbf{C}^{-1/2}\widetilde{\mathbf{A}}\mathbf{C}^{1/2},$$

where $\widetilde{\mathbf{A}} = -\mathbf{C}^{-1/2}\mathbf{H}\mathbf{C}^{-1/2}$. The matrix $\widetilde{\mathbf{A}}$ is real and symmetric, and hence can be diagonalized with real eigenpairs, which in turn implies that $\mathbf{A}$ is diagonalizable with real eigenpairs.

[2] Since the matrix $\mathbf{A}$ is in general not symmetric, the vectors $\mathbf{V}$ do not form a orthonormal basis of $\mathbb{R}^{N_c}$. If $\mathbf{A}$ is symmetric, it holds $\mathbf{V}^{-1} = \mathbf{V}^\top$ and

$$c_j = (\mathbf{V}^{-1}\mathbf{w})_j = \sum_{i=1}^{N_c} (\mathbf{V}^\top)_{ji}\mathbf{w}_i = \sum_{i=1}^{N_c} \mathbf{V}_{ij}\mathbf{w}_i = \langle \mathbf{v}_j, \mathbf{w}\rangle,$$

where $\langle\cdot,\cdot\rangle$ is the Euclidean scalar product, which gives the more recognizable decomposition on a basis of orthonormal eigenvectors.

where $\widetilde{u} = \mathbf{C}^{-1/2}u$. For practical calculations, one has to expand in the eigenvectors as shown in the explicit example above. The general solution (14) has the same structure as the thermal kernels (1), which is hence a generic form for this type of linear heat diffusion problems. Therefore the exponential form of the kernel function can be derived independent of the assumption of an underlying thermal network as an approximation taking the dominant eigenmodes of $\mathbf{L}$ into account.

4. Numerical Experiments

In this section, we present a series of numerical experiments demonstrating the usefulness, accuracy, and robustness of our approach.

4.1. Scenario 1: Simple network

The first test setup we employ in experiments is represented schematically in Fig. 1(a). We consider an electrical device, e.g., a power protection device such as a breaker or a switch, which protects an electrical installation. The device connects the installation to a power source (e.g., the grid) with two electric contacts between busbars, one per side of the device. We assume that the device is equipped with a temperature sensor. We consider the problem of monitoring the ECR of the two contacts using the temperature sensor of the device.

In order to simulate this scenario, we use a three-compartments thermal network as shown in Fig. 1(b). In the network, the center element represents the device, and the lateral elements the two contacts. We suppose that the three compartments are exposed to the same ambient temperature T_{amb}, which we assume without loss of generality to be equal to zero.

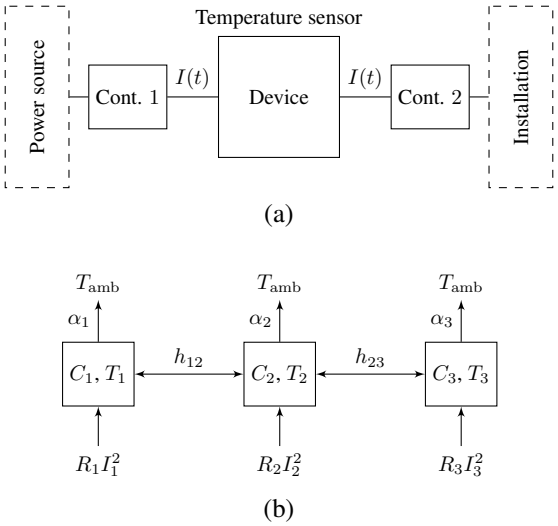

Figure 1. Setup for numerical experiments. (a) Schematic representation of a power protection device connecting an installation to a power source with two electric contacts. (b) Thermal network used to simulate the scenario.

The values of the coefficients C_i, α_i, R_i for $i = 1, \ldots, 3$, as well as of the h_{ij} for $(i, j) \in \{(1, 2), (2, 3)\}$, given in Table 1, are fixed to values which are realistic for a typical electric device. We determine the base kernel k_0 associated with the temperature sensor placed on the device fixing $I = 1\,\mathrm{kA}$ and simulating the network temperatures for $0 \leq t \leq 5\,\mathrm{h}$. Simulated data are obtained with an implicit numerical discretization of Eq. (10) on a time grid with time step equal to $1\,\mathrm{min}$. We then extract the device temperature T_2 and compute k_0 using Eq. (4), where $\dot{T}_2$ is computed by finite differences. We determine the kernels k_1 and k_3 associated to an increase of R_1 and R_3 following the procedure outlined in Section 2.1 with $\Delta R_i = R_i$, i.e., we double the ECR value to determine the kernel associated to a fault in the i-th contact.

Table 1. Coefficients of the thermal network in Fig. 1.

	$\alpha\,[\mathrm{W\,K^{-1}}]$	$R\,[\mu\Omega]$	$C\,[\mathrm{J\,K^{-1}}]$	$h\,[\mathrm{W\,K^{-1}}]$
1	1.0	100	3500	–
2	2.0	50	3500	–
3	3.0	100	3500	–
12	–	–	–	0.75
23	–	–	–	0.55

We measure the error on the i-th resistance as

$$\mathrm{err}_i = \frac{\left|\widehat{\Delta R}_i - \Delta R_i\right|}{R_i + \Delta R_i}, \tag{15}$$

where $\widehat{\Delta R}_i$ is the inferred increase in resistance and R_i is the nominal value of the i-th resistance (i.e., before increase). Note that the numerator in the right-hand side of Eq. (15) is equal to $|R_i + \widehat{\Delta R}_i - (R_i + \Delta R_i)|$, i.e., the absolute difference between the increased resistance and its inferred value. Hence, the error metric above is a relative error between the inferred and the true values of the increased *resistance*, rather than the resistance increase.

We generate 200 values of resistance increases $(\Delta R_1, \Delta R_3)$ randomly as $\Delta R_i \sim \mathcal{U}(0, R_i)$, independently for $i = 1, 3$. This means that the ECR degrades in all experiments, with values up to twice the original. For each pair of increases in the resistances, we generate 12 hours of temperature T_2 with sampling time $1\,\mathrm{min}$, always with the same current I defined by

$$I(t) = \begin{cases} 1\,\mathrm{kA}, & t \leq 1\,\mathrm{h}, \\ 0\,\mathrm{kA}, & 2\,\mathrm{h} < t \leq 5\,\mathrm{h}, \\ 0.7\,\mathrm{kA}, & 5\,\mathrm{h} < t \leq 9\,\mathrm{h}, \\ 0.3\,\mathrm{kA}, & t > 9\,\mathrm{h}. \end{cases} \tag{16}$$

The error in the estimation procedure, computed using Eq. (15), is summarized with boxplots in Fig. 2(a). We see that both resistances are estimated very accurately over the whole dataset of 200 experiments. Specifically, the error on R_1 never exceeds 0.1%, and the error on R_3 never exceeds 1%.

We repeat the same experiment but increase either R_1 or R_3 while keeping the other resistance to its nominal value. We repeat the inference 200 times per resistance with random increments as above. This experiment is relevant for applications, as the ECR of one contact only could undergo a rapid degradation, while all others could stay constant. Results, given in Figs. 2(b) and 2(c), demonstrates that also in this case the inference procedure is very accurate in determining the increased resistance values.

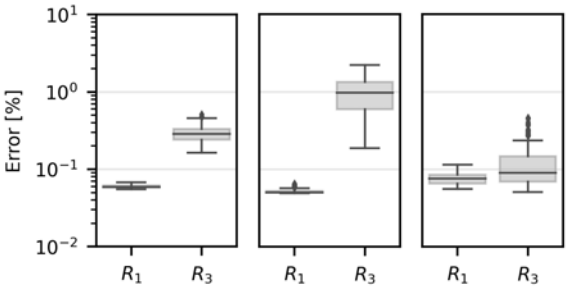

Figure 2. Percentage relative error in inference of two increased resistances given one temperature sensor. (a) Simultaneous increase of R_1 and R_3. (b) Only R_1 is increased. (c) Only R_3 is increased. Model configurations given in Fig. 1, test setup given in Section 4.1. Box-plot whiskers indicate 1.5 times the interquartile range, dots indicate outliers.

4.2. Scenario 2: The impact of adding a sensor

We consider a more complex configuration consisting of a thermal network with 6 compartments connected on a line, i.e., such that $h_{ij} = 0$ if $j \notin \{i-1, i+1\}$ for $i, j = 1, \dots, 6$. We assume that all parameters appearing in Eq. (8) are known, including nominal resistance values. Nominal parameter values are of the same magnitude as those of Table 1. Similarly to Section 4.1, we then increase randomly the resistances up to double their value and infer the increase increase with the procedure described in Section 2.3. The current used to excite the network with increased resistances is given in Eq. (16). We compare results obtained observing one temperature of the network only, T_2, and with two temperatures, T_2 and T_6. Note that when we observe one temperature we have one kernel k_0 and 6 additional kernels for the increase of R_i, $i = 1, \dots, 6$. When we observe two temperatures, we have one base kernel per sensor, and 6 additional kernels corresponding to an increase in resistance per sensor, for a total of 14 kernel functions. We recall that the method to infer the resistance increase with multiple sensors is described in Section 2.4.

Results, given in Fig. 3, demonstrate that errors can be as high as 60% on the fifth and sixth resistance (using the metric of Eq. (15)) when only the temperature R_2 is measured. This is because the thermal impact of the sixth compartment on the second is weak, and diluted by heat diffusion through the network. If we observe both T_2 and T_6, the error on all resistances is extremely low in most cases (below 0.01%), except of some outliers for which the error is above 50% error on R_6. This experiment nevertheless shows the benefit of equipping an electric device with an additional temperature sensor, especially if the device consists of many components that are thermally interconnected.

4.3. Scenario 3: Model misspecification

The method we present in this report to determine contact resistances relies on accurate determination of the kernel functions k_0 and k_i for $i = 1, \dots, N$. In a realistic setting, the kernel k_0 can be simply determined by applying a step current and measuring the temperature increase, or with any other system identification approach using data measured on the real device. For the kernels k_i, instead, we would need to increase artificially each resistance by a known quantity before applying a step current. It could be difficult, or unfeasible, to obtain such a controlled increase in practice, especially in a device-specific fashion. We could instead determine kernels that fit an entire fleet of devices, modulo the variability due to different installations. Specifically, we could use an experimental or simulated setup to determine universal resistance kernels $\widetilde{k}_i$ that are common to a whole fleet of devices, maintaining a base kernel k_0 that is specific to an individual installed device. The inferred resistances are then obtained as the solution to the linear system

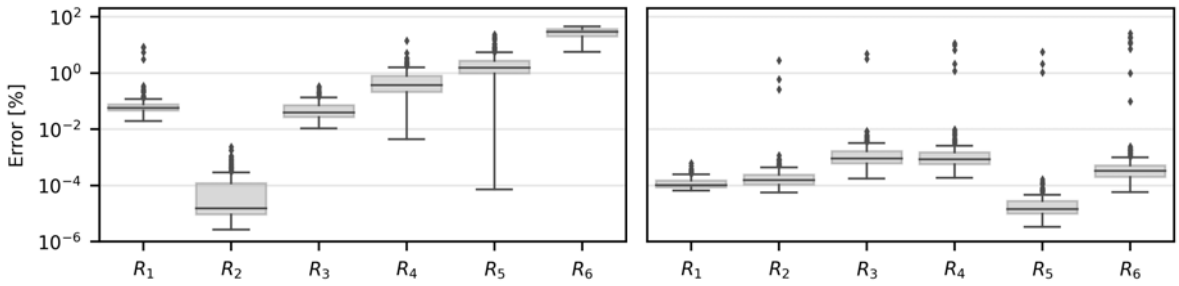
$$\widetilde{\mathbf{K}}^\top \widetilde{\mathbf{K}} \widehat{\Delta R} = \widetilde{\mathbf{K}}^\top (\mathbf{T} - \mathbf{K}_0), \tag{17}$$

where $\widetilde{\mathbf{K}}$ is built as in Section 2.3 using the fixed, universal kernels $\widetilde{k}_i$. The major concern with this approach is the misspecification between the real kernel function k_0 and the universal ones k_i, especially in terms of incompatible time scales.

Summarizing, the procedure that we propose to deal with installation specificity would consist of the following steps:

- Determine a universal base kernel $\widetilde{k}_0$ in an experimental or simulated setup;
- Use $\widetilde{k}_0$ to determine universal kernels $\widetilde{k}_i$ for each resistance that needs to be monitored;
- For each installation of the device, redetermine device-specific base kernel k_0 applying constant current load;
- When needed, infer an increase in resistances using Eq. (17).

We test the procedure above using the three-compartment network of Fig. 1, with coefficients given in Table 1. In order to simulate installation-specific conditions, we modify multiple times the value of the coefficients α_i as $\widetilde{\alpha}_i \sim \log \mathcal{N}(\alpha_i, \sigma)$, for $i = 1, \dots, 3$, where a large value of σ mimics devices that are very sensitive to different installations. We consider



(a) Compartment 2 sensed (b) Compartments 2 and 5 sensed

Figure 3. Inference of five resistances varied simultaneously in a six-compartment network. (a) One temperature sensor. (b) Two temperature sensors. Test setup given in Section 4.2. Box-plot whiskers indicate 1.5 times the interquartile range, and dots indicate outliers.

$\sigma = 0.4, 0.2, 0.1, 0.05$, and for each of these values we generate 200 values at random of the coefficients α to simulate 200 installations of the same device. Then, we infer the resistances R_1 and R_3 using Eq. (17). Note that we do not apply a resistance increase in this case, and just attempt to infer how impactful is a change of the nominal conditions onto the kernels.

Results, given in Fig. 4, demonstrate that re-calibrating only the base kernel k_0 for each installation is sufficient for keeping good accuracy in the inference of the resistances. Moreover, we see that a good inference result (below 1% except some outliers) can be achieved even for devices that are subject to high variability when installed (see the spread in temperature development in case $\sigma = 0.4$). We note that lower installation specificity results in smaller variability in the inferred resistances (see the width of the box-plots in case $\sigma = 0.05$).

4.4. Scenario 4: Noisy data

In all experiments above, we employed noiseless data for determining the kernel functions and for estimating the resistances in the model. In this section, we assess the impact of these two sources of noise on the estimation variability. We consider the simple three-element network of Fig. 1 with parameters as in the experiments above. We compute the base kernel k_0 and the kernels k_i associated to resistances $i = 1, 3$ by perturbing the temperature response to a step current with a Gaussian source of noise $\eta_k \sim \mathcal{N}(0, \sigma_k^2)$, where $\sigma_k > 0$. Then, we excite the system with the current profile of Eq. (16) and perturb the temperature response with a Gaussian source of noise $\eta_d \sim \mathcal{N}(0, \sigma_d^2)$, where $\sigma_d > 0$. We then infer the resistance increase without changing its value in the model, i.e., data is generated by imposing $\Delta R_i = 0$. We repeat the experiment for noise scales σ_d and σ_k ranging between 10^{-4} and 10^{-1}, and for each combination of σ_k and σ_d we repeat the experiment $M = 50$ times. At each j-th repetition, we record the estimated resistance variations $\widehat{\Delta R}_1^{(j)}$ and $\widehat{\Delta R}_3^{(j)}$. We measure variability in the estimation as the sum of the population standard deviations of the two estimated resistance increases, i.e.,

$$\text{variability} = \text{std}\left(\left\{\widehat{\Delta R}_1^{(j)}\right\}_{j=1}^{M}\right) + \text{std}\left(\left\{\widehat{\Delta R}_3^{(j)}\right\}_{j=1}^{M}\right),$$

where $\text{std}(\cdot)$ denotes population standard deviation. We repeat the estimation twice: once with raw kernel functions computed with Eqs. (4) and (5), and once by fitting exponential functions as explained in Section 4.4

Results, given in Fig. 5, demonstrate that the method we develop here is robust with respect to random sources of noise. As expected, the variability is a growing function of both σ_k and σ_d. We remark that fitting exponential functions to the kernels has a beneficial effect on the inference accuracy. Indeed, it can be noticed in Fig. 5 that the variability is slightly lower when thermal kernels are fitted with exponential functions.

5. Conclusion

We introduced a novel method based on thermal kernels to monitor the condition of an electric device given temperature measurements. This method allows the calculation of temperatures at specific locations for general linear heat diffusion problems including thermal networks, for which we demonstrated an equivalence analytically.

Thermal kernels are simple to fit to data due to their non-parametric nature, which prevents issues of poor identifiability. Indeed, the parameters of thermal networks as simple as the one of Fig. 1 can be cumbersome or even impossible to determine if only one of the compartments equips a temperature sensor, unless good priors on the parameters are available due to physical considerations or from the results of high-fidelity and high-cost simulations. This issue is completely circumvented by thermal networks, which absorb the effects of all the parameters of an equivalent network approach into

a simple data-driven linear transfer function.

We believe that thermal kernels should be preferred to thermal networks to monitor the linear heat sources (e.g., electrical resistances) of devices that are not equipped with a multitude of sensors, which would be required to fit the parameters of the network.

We suggest that future investigation may exploit the equivalence of thermal kernels and networks, e.g., to study whether knowing the former can be beneficial to improve the identifiability of the latter.

ABSTRACT

There are high expectations for the use of Machine Learning algorithms in Engine Health Management, but the practical application for use with turbofan engines is often hindered by small sample sizes and noisy data. This paper discusses a case in which Machine Learning techniques were combined with domain expertise to develop a classifier called Non-seal Erratic Oil Pressure (NEOP). This classifier is used as an engineering tool to support manual review of engines flagged with Honeywell's OPX (Oil Pressure Transducer) algorithm. The purpose of the classifier is to assist a human in analyzing engine trend data from the HTF7000 turbofan engine, when the OPX algorithm identifies an engine with erratic oil pressure. The NEOP history provides an additional data source when deciding if aft sump maintenance is needed to replace a worn carbon seal, or if the erratic signal is associated with some other cause. The OPX algorithm has enabled the prevention and avoidance of costly unscheduled engine failures resulting in millions of dollars in documented savings, and the NEOP algorithm helps to ensure that the conclusions from the OPX process continue to result in the appropriate engines being identified for maintenance inspection and corrective action.

1. INTRODUCTION

Data science and machine learning techniques hold great promise in the realm of proactive engine health monitoring, but currently there is a considerable gap between the conceptual possibilities and real-world results. This paper discusses an example where machine learning techniques, guided by domain expertise, were successfully utilized to produce an algorithm with real value.

Honeywell Aerospace manufactures the HTF7000 turbofan engine that powers several super-mid-size (SMS) business jets. Honeywell also develops Engine Health Monitoring algorithms to detect anomalies in the trends for those engines, indicating the presence of an incipient fault. These algorithms provide business jet operators with the ability to perform maintenance before the incipient fault progresses into a disruption to flight operations. A good example of these algorithms is the Carbon Seal Bimodality algorithm from OPX (Oil Pressure Transducer). Previous work (Hickenbottom, 2022) showed that this algorithm has proven very effective at detecting accelerated wear in the carbon seal near the number 4 bearing in the turbine section. It has correctly identified hundreds of engines with excessive carbon seal wear and allowed thousands of others to remain in service given evidence of healthy seals.

Once the Carbon Seal Bimodality algorithm and support process matured to the point that it can detect very small levels of seal wear, it became more prone to pick up other causes which present similar symptoms. After identifying a few false positive indications of carbon seal wear, a machine learning algorithm was developed to classify variability in oil pressure residual signature as either caused by Seal Wear, or Other Cause.

2. HISTORY OF CARBON SEAL BIMODALITY

The Carbon Seal Bimodality algorithm initially came into existence because of a need to detect incipient faults in the Oil Pressure Transducer (i.e., OPX). The first step was to correct the measured oil pressure because the measured pressure varies greatly with the oil temperature and engine operating regime. These normal variations can mask changes in oil pressure which are the symptoms of engine faults. The objective when developing the oil pressure correction logic was to use data science methods to analyze field data and identify the primary drivers of variation in the measured oil pressure. Once we determined the most 'correctable'

operating regime and we accounted for variations due to environmental conditions, we derived a model from field data. Comparing each oil pressure measurement to this model resulted in the Oil Pressure/Temperature Residual (OilPT Residual) CI, which is trended over time, with the initial intent of detecting incipient faults in the oil pressure transducer. By analyzing a handful of known OPX sensor failures we determined that a faulted sensor will often cause a shift or drift in OilPT Residual before the sensor fault progresses to the level detectable by the engine controller. Figure 1 is an example of the signature for a faulted oil pressure sensor.

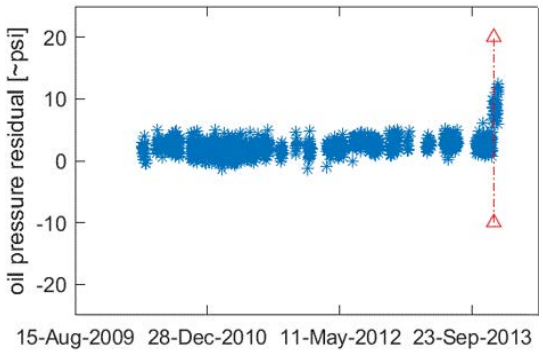

Figure 1. Trend of OilPT Residual with faulted oil pressure sensor

As we analyzed fleetwide trends of the OilPT Residual CI, we started to notice a unique pattern, where over time the CI would start to split into two separate populations, which would continue to diverge. Figure 2 is an example of an OilPT Residual trend with a bimodal distribution. The term bimodal refers to the two distinct peaks in the probability density function on the right side of the figure.

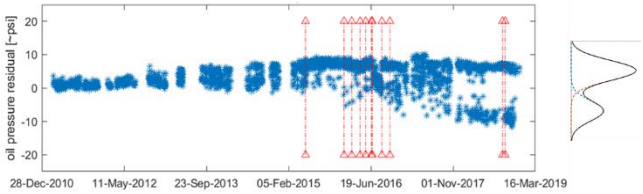

Figure 2. Bimodal distribution of OilPT Residual

As we searched for an explanation for this signature, we started thinking about the fact that the measured oil pressure is not an absolute measurement but is in fact a delta-pressure relative to the aft sump pressure. This implies that a perceived drop in oil supply pressure could be the result of an increase in the aft sump pressure. Next, we investigated the hypothesis that whatever might be causing the higher sump pressure would return to normal after hot section maintenance. To test this, we did a fleet run and identified several engines that had high bimodality at some point, which then went away abruptly. We then investigated the maintenance records for those engines and confirmed that the disappearance of bimodality correlated with the timing of hot section maintenance. This represented significant evidence to support the hypothesis that an increase in aft sump pressure is the cause of bimodality.

Once it became clear that hot section maintenance was causing the bimodality to reset, we started looking more closely at a carbon seal in the aft sump. An opportunity to inspect an engine with high bimodality presented itself and the condition of the carbon seal unlocked the mystery of OilPT Residual bimodality. Figure 3 shows the first carbon seal removed proactively based on bimodality in the OilPT Residual trend. Note that the pressure balance features seen on the top half of the picture on the right were originally present in the bottom half as well.

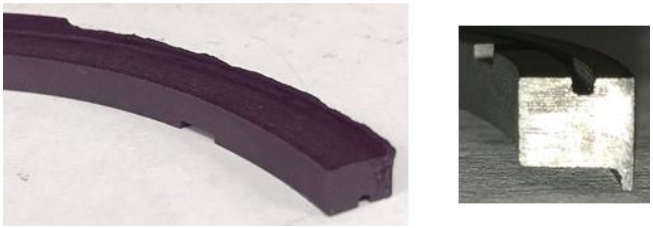

Figure 3. Worn carbon seal

With this new understanding of the correlation between bimodality and carbon seal wear, we conducted a fleet run and identified engines with varying degrees of carbon seal wear. As more engines with bimodality were inspected, the relationship between bimodality and carbon seal wear became even clearer. The strong correlation between bimodality and seal wear allowed the Service Related Difficulty investigation to focus on the engines with the highest level of wear, avoiding a fleetwide campaign of all fielded engines to replace the carbon seals with a new design. We began proactively removing carbon seals, which provided additional details to assess seal wear progression. Increased seal wear may result in secondary damage to the LP stub shaft (see Figure 4), which can increase maintenance costs. Being able to detect wear and replace the seal prior to this secondary damage results in significant maintenance cost savings. Since the operator can replace the seal while the engine is on the aircraft and wear occurs over hundreds of hours of operation, early detection also allows operators to address the issue without affecting their flight operations. The opportunistic maintenance from these alerts has resulted in millions of dollars in cost avoidance and improved aircraft uptime and availability.

Figure 4. Expensive secondary damage to stub shaft

3. NEED FOR NEOP ALGORITHM

At first, only those engines with the most severe seal wear were flagged to have their carbon seals replaced. As the improved-design carbon seals became more readily available, the bimodality threshold was gradually made more sensitive, such that more carbon seals were replaced earlier in their wear progression. This increased sensitivity means that variability in the data due to causes other than carbon seal wear can drive the bimodality measurement over the threshold.

Figure 5 is an example where an OilPT Residual trend is bimodal, but the bimodality is driven by a cause other than carbon seal wear. In this case, an alert was generated based on a very conservative assessment of the trend. Even though the review team felt it was unlikely that carbon seal wear was causing the bimodality on an engine with so few hours, the decision was made to enter the engine to inspect the carbon seal. This inspection revealed a healthy carbon seal, meaning that the alert was a False Positive.

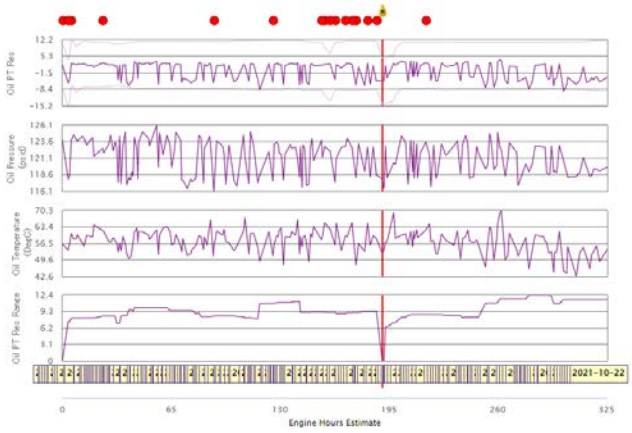

Figure 5. Bimodality driven by non-seal ("Other") cause

Prior to this case, the carbon seal bimodality algorithm had not resulted in any False Positive alerts to the aircraft operators. There were other examples of OilPT Residual trends with high variability, but they were visually determined to not fit the signature of carbon seal wear. Figure 6 is an example of a trend which was flagged by the algorithm, but manually overridden based on visual review by a domain expert.

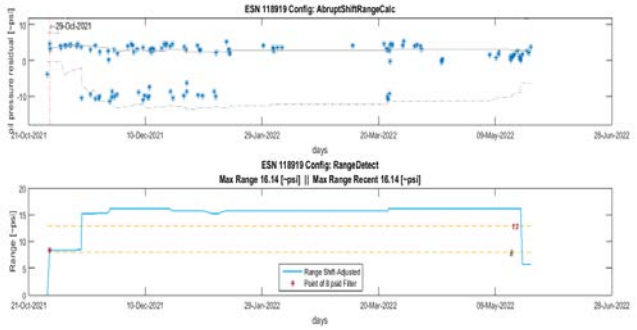

Figure 6. Expert determined bimodality not driven by seal wear

In some cases, it was easy for the review team to conclude that the variability in OilPT Residual was not caused by carbon seal wear, but in other cases it was not as clear. Figure 7 shows an example where visual review of the data did not result in an obvious conclusion. Because of the earlier False Positive, and the increasing number of cases where visual review of the data did not reveal an obvious conclusion, the team began investigating if a Machine Learning algorithm could be trained to distinguish carbon seal wear from other causes of variability in the OilPT Residual trend. This algorithm became known as NEOP (Non-seal Erratic Oil Pressure).

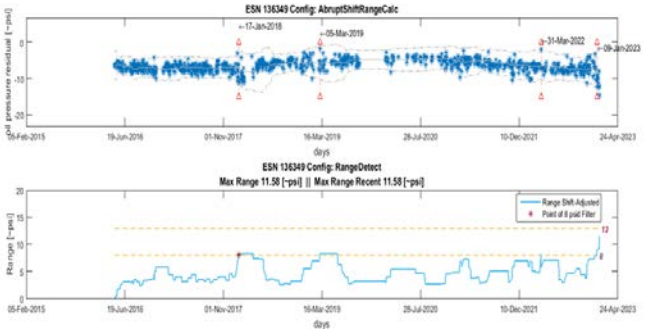

Figure 7. Cause of bimodality not obvious

4. ALGORITHM STRUCTURE

The NEOP algorithm is based on iterative development that progressed along with increased knowledge about collected oil system data and demand for further explanation of observed deviations from the model available at that time. The simplified diagram shown in Figure 8 involves the following steps:

• Data Filtering: this step applies known oil measuring system design limits to filter out invalid data, fuse data from multiple sources and in general assure that time series pressure and temperature data are of high quality.

• Oil Pressure Correction: applies known design factors that contribute to variability in measured Oil Pressure. These

corrections are not driven by data, they were engineered based on domain knowledge.

• Oil P/T Curve Residual: applies simple regression model that was trained from data across the fleet. The model captures the relation between oil pressure and temperature. This step eliminates the effect of oil viscosity on the flow of oil through the system and sensed oil pressure. Oil temperature is the data source that influences viscosity and can be smoothly correlated to oil pressure.

• Shift Adjustment Logic: applies detection of sudden shifts in Oil Pressure Residual to determine if there was a maintenance action to adjust oil pressure. This logic then eliminates the effect of the maintenance action to allow proper assessment of bimodality.

• Bimodality Detection Logic: OilPT Residual range proved to be good indicator of carbon seal wear.

• Calculate NEOP Features: extracts features for Non-seal Erratic Oil Pressure detection. Features are discussed in detail in section 7.

• Predict NEOP Class scores: Support Vector Machine classifier was trained and applied. One of its benefits over other classification techniques available in the legacy development environment in use (MATLAB 2015) is its ability to produce class scores, or confidence. These class scores are used to plot a continuous trend of the classification result, which is more informative than a binary output from decision trees, for example.

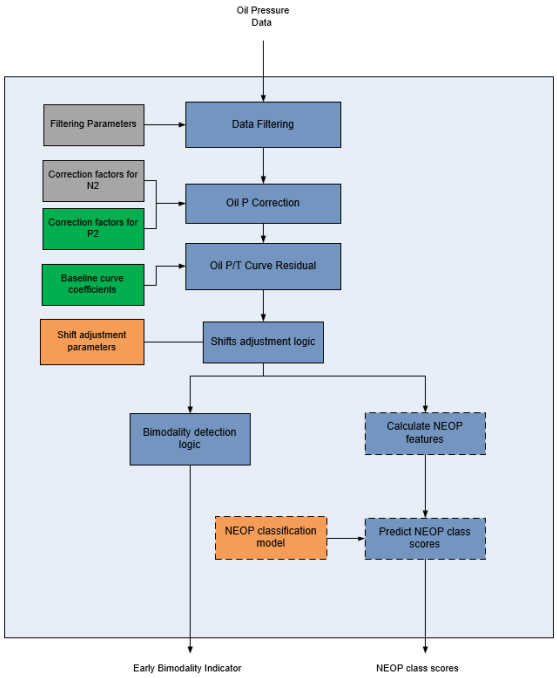

Figure 8. Structure of NEOP algorithm

5. TRAINING DATA

Aircraft engines are relatively low volume and high reliability assets. As a result, a very common problem when developing a diagnostic algorithm using a machine learning approach is shortage of training data for the fault cases. There is a huge imbalance between healthy and fault data. For the NEOP classifier training there were only a handful of engines exhibiting bimodality that, based on ground truth, could not be attributed to carbon seal wear. We'll denote these cases as "O" or Other Cause of bimodality. To describe the data, we used these groups:

• Healthy data: OilPT Residual with smooth trendline

• Severe carbon seal wear: OilPT Residual with very large bimodality in trendline

• "S" - Seal wear: OilPT Residual trend before the carbon seal replacement exhibiting the pattern of medium wear of the seal. See Figure 9.

• "O" - Other cause of bimodality (non-seal erratic oil pressure): OilPT Residual trend with known healthy seal but showing bimodal behavior that would be detected by Bimodality Detection logic and (incorrectly) marked as medium seal wear. See Figure 10.

Note that Figure 2 shows the characteristic progression through different data groups: from healthy data through "S" (Seal wear) to severe carbon seal wear.

The goal of this setup was to narrow down the classification problem to either class "S" or "O". This classification is only necessary during a portion of the fault progression. In early phases of wear, the bimodality range is low, and the original algorithm will correctly decide not to flag the engine for maintenance. For the advanced phases of wear, the fault signature changes, which would require the classification technique to learn a different pattern. Since the review team can visually classify advanced wear due to the signature over time, we decided to make a simplifying decision to focus the NEOP algorithm only on the middle phase of wear progression. As a result, severe carbon seal wear was excluded from the "S" group.

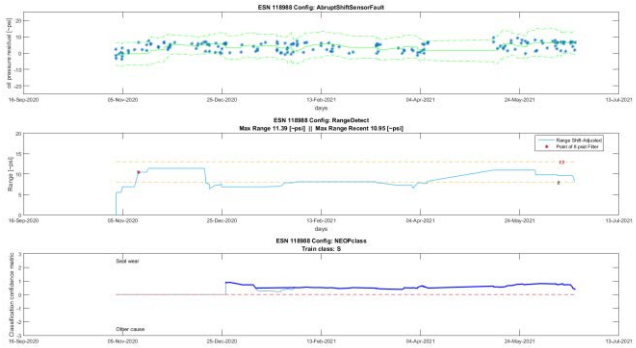

Figure 9. Training data example: "S" – Seal wear

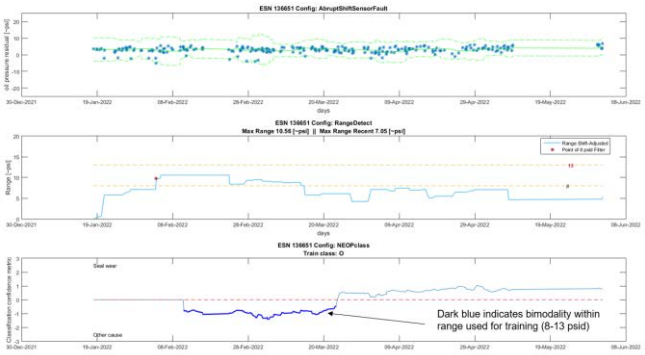

Figure 1010. Training data example: "O" - Other cause

Each engine that was included in the dataset provided one or more data series belonging to one of the groups. This led to variable lengths of OilPT Residual data series. To obtain a reasonable number of training samples we took several windows of 50 datapoints from each series. These windows were partially overlapping. The window size and overlapping step was chosen carefully to balance the need of having enough training samples and the need to have those samples be reasonably independent.

6. Configuration Management of Training Datasets

As discussed in the Society of Automotive Engineers Aerospace Information Report AIR6988, *Artificial Intelligence in Aeronautical Systems: Statement of Concerns*, one of the key considerations for developing and maturing a Machine Learning algorithm in an application like this is configuration management of training datasets. While configuration management and versioning of software modules is a well-understood activity in aerospace, configuration management and versioning of training and validation datasets used for machine learning is not as mature.

To ensure that the ML results were reproducible, and to enable iterative improvements as new cases became available for training, a repository was set up to store and version-control datasets. Standard naming conventions and processes were established so that multiple software developers could access the datasets and replicate each other's results.

7. Features

Features are calculated for the moving window, which moves along the timeline. The size of the window was set to be consistent with the bimodality detection logic: samples from 50 consecutive take-offs. This window is large enough to account for the fact that the bimodality signature in data was seen to temporarily cease for many consecutive datapoints.

The following features based on OilPT Residual were included in the final set:

• Range: this simple feature assures consistency with the previously implemented seal wear bimodality detector.

• Sigma (standard deviation): supplement to range feature.

• Gaussianity (fitness to gaussian distribution): this is the key measure that helps distinguish between noisy unimodal data and bimodal distribution.

• Skewness: it was observed that when bimodality starts occurring, the "S" class appears to have more evenly distributed datapoints between high and low OilPT Residual populations (skewness close to zero). While "O" class samples appear to have more occasional drops in OilPT Residual (negative skewness).

• Scatteredness: none of the measures listed above considers the order of datapoints inside the window. Although scatteredness is not a formally defined statistical measure, it is what we call what was implemented as RMS (Root Mean Square) of differences between consecutive points. This measure gives high values when OilPT Residual values are alternating between low and high values. This behavior is expected in medium seal wear. Domain knowledge of how the seal physically behaves in the engine (a worn seal randomly settles in one of two extreme positions where it's sampled during takeoff) enabled us to engineer this custom feature.

These features calculated on "S" and "O" training datasets were used to train the final Support Vector Machine classifier with Gaussian (or Radial Basis Function - RBF) kernel. Hyperparameter Kernel Scale was used to prevent overfitting to the training data. By tuning the kernel scale, we intentionally trained a medium-to-coarse model (in MATLAB Classification Learner terms) for the price of slightly decreased accuracy of the learned classifier. This setting was chosen to compensate for the fact that training samples were not perfectly independent, because they were taken from a limited set of engines. This fine-tuning is one example of using engineering experience and evaluation of individual plot results with analysts, rather than pure optimization of a goal metric, which is common in ML tasks with an abundant and balanced set of training data.

8. Example Cases

To illustrate how the NEOP output is interpreted, 4 real cases are discussed here. The first example, shown in Figure 11, is a straightforward case where the NEOP output (shown as 'classification confidence metric' in the third data series) is consistently above zero, indicating that the level of bimodality (shown as 'Range' in the second data series) can be attributed to real seal wear. This is useful to the review team because it increases confidence that an engine flagged for seal wear will not result in a False Positive disruption.

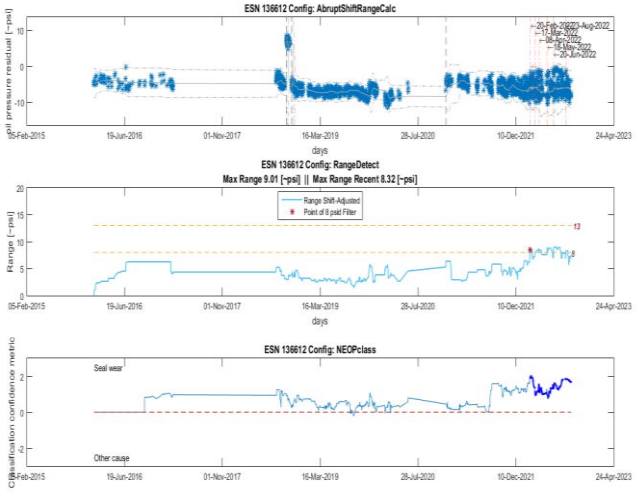

Figure 11. Consistently classified as seal wear

The second example, shown in Figure 12, illustrates how real-world limitations in data can affect the NEOP output. In this case there were large gaps in the data history. This caused the NEOP output to incorrectly interpret shifts as 'other cause', but the review team was able to use the NEOP output not affected by the data gaps to confirm that the carbon seal was worn. This is a good example where even when the ML algorithm encounters data outside of its training, an expert reviewer can still make sense of the data.

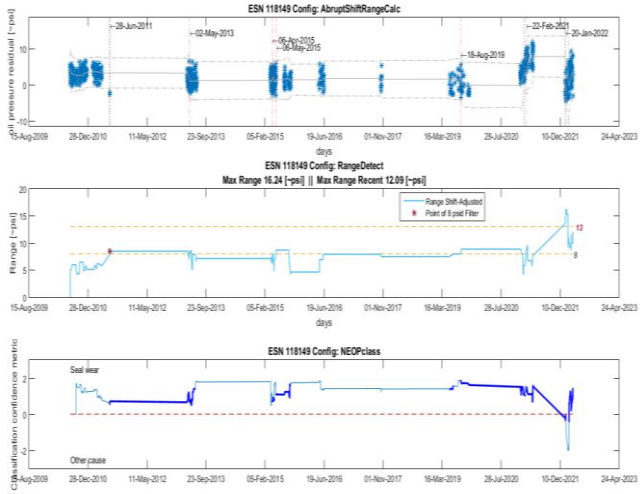

Figure 12. Large gaps in the data history

The third example, shown in Figure 13, is typical of the cases which motivated the creation of the NEOP algorithm. The bimodality range exceeds the threshold for seal wear, but the engine is known to have a healthy seal. The NEOP history in cases like this allows the review team to override the alert for carbon seal wear. Since there is no known operational impact associated with the 'other cause' classification, no supplemental maintenance is recommended.

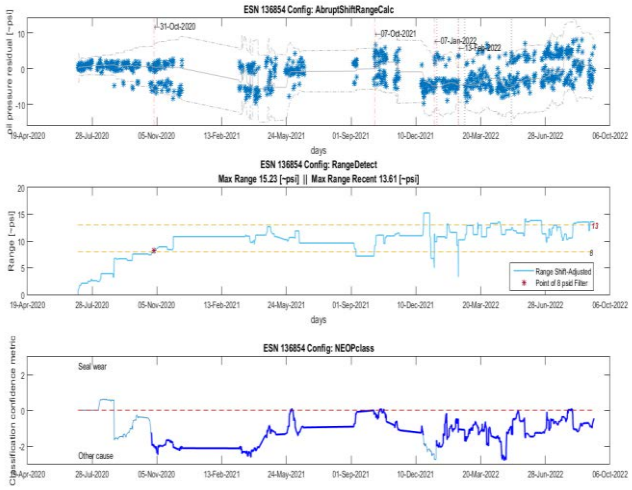

Figure 13. Healthy seal case with correct classification

The fourth example, shown in Figure 14Figure 13, is a case where the NEOP output moves back and forth between seal wear and 'other cause'. This is because the outliers which drive the bimodality range are intermittent, with periods of normal seal wear in between. By looking at the NEOP history, the review team can determine the true level of seal wear, and override the alert driven by the 'other cause' outliers.

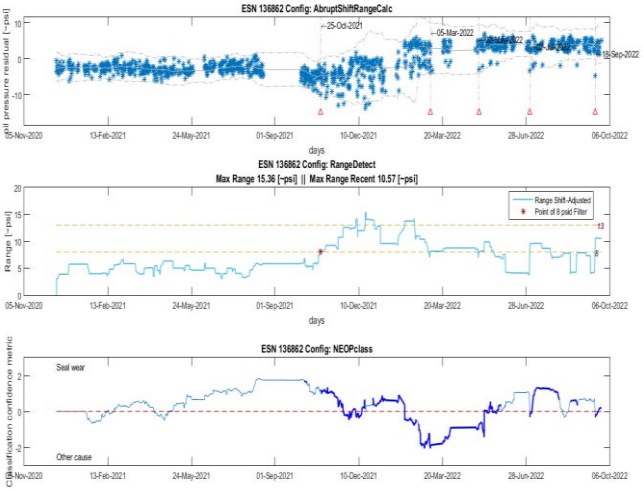

Figure 14. Intermittent outliers causing alternating classification

9. Combining Machine Learning with Domain Expertise

One of the fundamental lessons we've learned is that in applications like health monitoring of turbofan engines, synergy can be achieved when data scientists work closely with domain experts. Figure 1515 shows how these two groups of people make each other better. Data scientists are often able to use Machine Learning to identify relationships (correlations) between data. Domain experts can usually help the data scientist understand which correlations are meaningful (i.e., identify causation), and which correlations are trivial or meaningless. In doing this, the domain expert often learns more about their system, which in turn enables them to provide improved guidance for the next round of data science or machine learning.

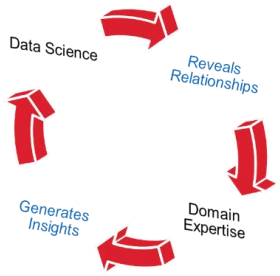

Figure 1515. Synergy between Data Science and Domain Expertise

In the case of the NEOP algorithm, several decisions were made by a domain expert to simplify the problem statement. For example, rather than requiring the algorithm to output a single answer, we recognized that showing the time-history and allowing a person to make a judgement is sufficient for the review team to decide on whether to flag an engine for seal wear. Another example is how the training data was limited to the time when OilPT Residual is between 8 and 13 psid. The data scientist learned that the algorithm did not train well across all OilPT Residual ranges. The domain expert recognized that there is a particular band of ranges where the interpretation is most critical, and the data scientist was able to refine the algorithm to focus on this area. The outputs from this refinement then helped the domain expert understand what is physically happening on the engine in these areas.

There are many examples where this synergy results in the data scientist making the domain expert more informed, and the domain expert contributing to making the data science more effective, which then provides additional information and feeds the cycle. The key is to have interactions early and often between the data scientist and the domain expert. This has proven to be much more effective than either a domain-independent data science approach or a purely expert-driven approach. For NEOP, this has resulted in the review team reviewing NEOP results 1-2 times per week, with the NEOP outputs being the key factor in the decision of whether to enter the engine in roughly 90% of those cases. Without this algorithm, many of those cases could result in unnecessary maintenance or failure of a carbon seal in flight.

10. Conclusion

As can be seen from the examples above, the NEOP output requires expert interpretation. Even though the algorithm does not provide a precise classification 100% of the time, it does provide valuable information which is of a practical benefit to the review teams. Often it is the simplifying assumptions/decisions like this which can move a potential machine learning approach from a great concept to a usable algorithm. With time, additional algorithm training could improve the ability of the NEOP algorithm to consistently classify the cause of wear, with less dependency on a domain expert; but even without improvement, the current algorithm has proven very valuable when the review team is faced with a signature that is difficult to explain.

ABSTRACT

Wind turbines (WTs) play an essential role in renewable energy generation, and ensuring their reliable operation is essential for sustainable energy production and reduction of levelized cost of energy. In this context, the field of prognostics and health management (PHM) is a powerful tool to predict and assess the health status of WT components, thereby enabling timely maintenance and reducing downtime. The study begins with an overview of WT components studied, including the blades, gearbox, generator, and bearings, and their common failure modes. For each component, various remaining useful life (RUL) estimation methods are explored, categorizing them into physics-based, data-driven, and hybrid methods. Despite the potential benefits, the application of PHM strategies in WTs is currently limited. Although PHM strategies have been present for years, their development in WTs remains a challenge. These key challenges are presented, including uncertainty management, integrating physical knowledge into models, variable operational conditions, data issues and system complexity.

1. INTRODUCTION

To meet the European Commission's target of achieving climate neutrality by 2050, reducing the levelized cost of energy (LCOE) is vital. According to the International Renewable Energy Agency (IREA, 2023), operation and maintenance (O&M) costs, which include fixed and variable components, typically constitute between 10% and 30% of the LCOE for most wind industry projects as of 2022. This underscores the importance of optimizing maintenance activities for wind turbines (WTs). It involves the transition from traditional corrective and preventive maintenance approaches to predictive maintenance strategies, where maintenance tasks are scheduled based on the real-time and projected condition of components. In this context, the field of prognostics and health management (PHM), which covers various techniques to monitor the evolution of component wear, plays a critical role. Through PHM, it becomes possible to forecast remaining useful life (RUL) of components using historical and current operational data (Ferreira & Gonçalves, 2022).

To effectively implement PHM strategies for WTs, it is essential to explore their target components and their failure modes. The main components of a WT's drivetrain include the rotor, gearbox, and generator, which are interconnected via the low-speed shaft (LSS) and high-speed shaft (HSS) (see Figure 1). The gearbox, generator, and rotor blades are identified as the most critical subsystems, both onshore and offshore, based on downtime analysis (Dao, Kazemtabrizi, & Crabtree, 2019). Moreover, failures associated with the gearbox, rotor blades, and generator represent a higher expenditure, in that specified order (Tazi, Châtelet, & Bouzidi, 2017).

The main failure modes that affect these components are the

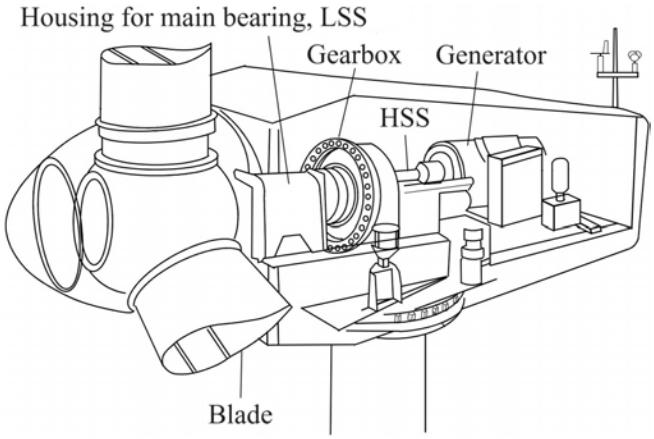

Figure 1. Schematic diagram of the components explored in this paper. Readapted from (Jiang et al., 2017).

following:

- **Blades**: fatigue, corrosion, and aerodynamic imbalance/ asymmetry (Catelani, Ciani, Galar, & Patrizi, 2020).
- **Gearbox**: abrasive wear, pitting, cracking, scuffing oil leakage, insufficient lubrication (Owolabi, Madushele, Adedeji, & Olatunji, 2023; Olabi et al., 2021).
- **Generator**: overspeed, overheat, wear, excessive vibration, rotor asymmetries, bar break, electrical problems (Olabi et al., 2021; Lydia & Edwin Prem Kumar, 2023).
- **Bearings**: axial cracking, spalling, pitting, brinelling (fretting) (Owolabi et al., 2023).

Based on the needs for PHM implentation in WT components, the scope of this review paper is to provide an in-depth analysis of the methodologies, algorithms, and techniques used to estimate the RUL of components within WT components. The aim of this review is to present works published from 2018 to March 25, 2024, thereby gathering recent advancements and trends in PHM specific to critical wind components, including blades, gearboxes, bearings, and generators. By addressing these challenges and providing a comprehensive review of the current state-of-the-art, this paper aims to contribute to a better understanding of the complexities and future research trends involved in developing RUL prognostics for wind turbines. The paper is structured as follows. Section 2 consolidates the research efforts made in the prediction of RUL classified by the component to which the techniques are applied; finally, Section 3 focuses on conclusions and key challenges.

2. Prognostics. RUL estimation

Prognostics refers to the examination of fault symptoms to forecast future conditions and RUL within designed parameters (ISO, 2012). This section aims to gather the works done for accurate prediction of RUL in WT components, classifying the methods into physics-based, data-driven and hybrid. The applications of components found coincide with the most critical components in terms of dowtime and repair costs mentioned above, classified in blades, gearbox, generator, other bearings (which include predictions of RUL of bearings whose location is not specified) and those that consider WT as a system. It is important to note that most of the works found focus on bearing prediction, many of them located on the HSS. These can be gearbox high-speed bearings, gearbox intermediate-speed bearings, and generator bearings (Z. Liu & Zhang, 2020). When the paper introduced specifies the location of these, they are included in the gearbox/generator subsection. If not, they are included in other bearings.

The distribution of eighty-one papers among years and components can be found in Figure 2. It can be seen that data-driven approaches are the most common ones to predict the RUL of WT components, and there is an increasing trend towards using hybrid models (Figure 2a). Furthermore, the components most studied have been the gearbox and the generator, respectively (Figure 2b). Figure 3 gathers all the methods found in the literature, classified by type and component.

2.1. Blades

WT blades are engineered for a minimum of 20-year lifespan, resulting in load cycles between 10 millions and one billion, making them very susceptible to fatigue (Moroney & Verma, 2023). Twelve studies have been found to estimate the RUL of WT blades.

2.1.1. Physics-based models

Physics-based models have been used for WT blades RUL estimation. Studies such as (Saathoff, Rosemeier, Kleinselbeck, & Rathmann, 2021) and (Moroney & Verma, 2023) employed aeroelastic load simulations, and durability and damage tolerance analysis (DADTA), respectively, to quantify the effects of factors like blade pitch misalignment, and material fatigue on RUL.

Furthermore, one of the most widely used physics-based techniques has been Kalman filtering. (Muto, Namura, Ukei, & Takeda, 2019) proposed a method that combines load monitoring with dynamic response estimation, enhancing the accuracy of RUL evaluation with Kalman filter (KF). (Boutrous, Puig, & Nejjari, 2022) introduced an innovative model-based prognostics procedure, leveraging zonotopic KFs to quantify uncertainties in degradation propagation. Moreover, (Vettori, Lorenzo, Peeters, Luczak, & Chatzi, 2023) presented an adaptive noise augmented KF approach, addressing challenges in noise calibration for joint input-state estimation. Their method demonstrated superior performance in virtual sensing (VS) applications in diverse structural scenarios.

(b) Percentage distribution of RUL prediction techniques found across WT components.

Figure 2. Classification of papers in this review: a) by year and type b) by component.

2.1.2. Data-driven models

Among data-driven methods that have been used to estimate the RUL of WT blades, particle filter (PF)-based approaches offer a dynamic and versatile solution. Studies conducted by (Valeti & Pakzad, 2018, 2019), (Jaramillo, Gutiérrez, Orchard, Guarini, & Astroza, 2022), and (Lee, Roh, & Park, 2022) demonstrated the efficacy of PF in accurately predicting RUL of blades under varying conditions, including fatigue damage and dynamic loading scenarios. Alternatively, various methodologies that employ data-driven strategies, particularly those using artificial intelligence (AI), presented different avenues. For instance, the work introduced by (Yue, Ping, & Lanxin, 2018), an end-to-end model based on convolutional neural network (CNN) combined with long short-term memory (LSTM) networks, exemplifies such approaches.

2.1.3. Hybrid models

Hybrid models offer promising results for an accurate prediction of the RUL of WT blades. (Rezamand et al., 2021a) introduced an integrated fuzzy-based failure prognosis method, leveraging recursive principal component analysis (PCA), a wavelet-based probability density function (PDF) estimation, a Takagi-Sugeno (T-S) fuzzy system, and a Bayesian algorithm. Their approach enabled real-time predictions by capturing blade failure dynamics, categorizing nonlinear degradation trends, and estimating RUL for each trend, culminating in an aggregated prediction for the entire system. Applied to supervisory control and data acquisition (SCADA) data from real wind farms, the methodology demonstrated robust performance, outperforming traditional Bayesian methods and effectively modeling nonlinear failure dynamics. In another study, (C. Peng, Chen, Zhou, Wang, & Tang, 2020) focused on improving the accuracy of icing failure prediction in WT blades through a novel balancing algorithm based on boundary division synthetic minority oversampling technology (BD-SMOTE) and a multi-step prediction process using multiple Elman neural networks (ENNs).

2.2. Gearbox

Gearboxes operate under harsh environmental conditions, including vibrations from turbine-side components and wind, as well as fluctuations from the load through the generator, while stepping up the speed from the LSS to meet the requirements of the HSS that drives the generator (Salameh, Cauet, Etien, Sakout, & Rambault, 2018). Their failures contribute to around 20% of WT downtime (Lydia & Edwin Prem Kumar, 2023); therefore, it is essential to accurately predict their RUL. Twenty-nine works have been identified.

2.2.1. Physics-based models

In the field of WT gearbox reliability estimation, only one work has been found in the literature. (Pagitsch, Jacobs, & Bosse, 2020) presented a pioneering approach for modeling WT gearboxes with minimal parameters, emphasizing its utility in estimating RUL and facilitating real-time condition monitoring (CM). The determination of forces and bending moments acting on the main components involves using information on non-torque loads from the rotor sub-model and rotor torque from the SCADA data record. These inputs are then employed to calculate inner loads on machine elements in the gearbox, using rigid beam models and analytical basic equations for a three-stage WT gearbox intermediate-speed shaft bearing forces. Finally, the modified life rating as defined in ISO 281:2007 is applied to predict RUL.

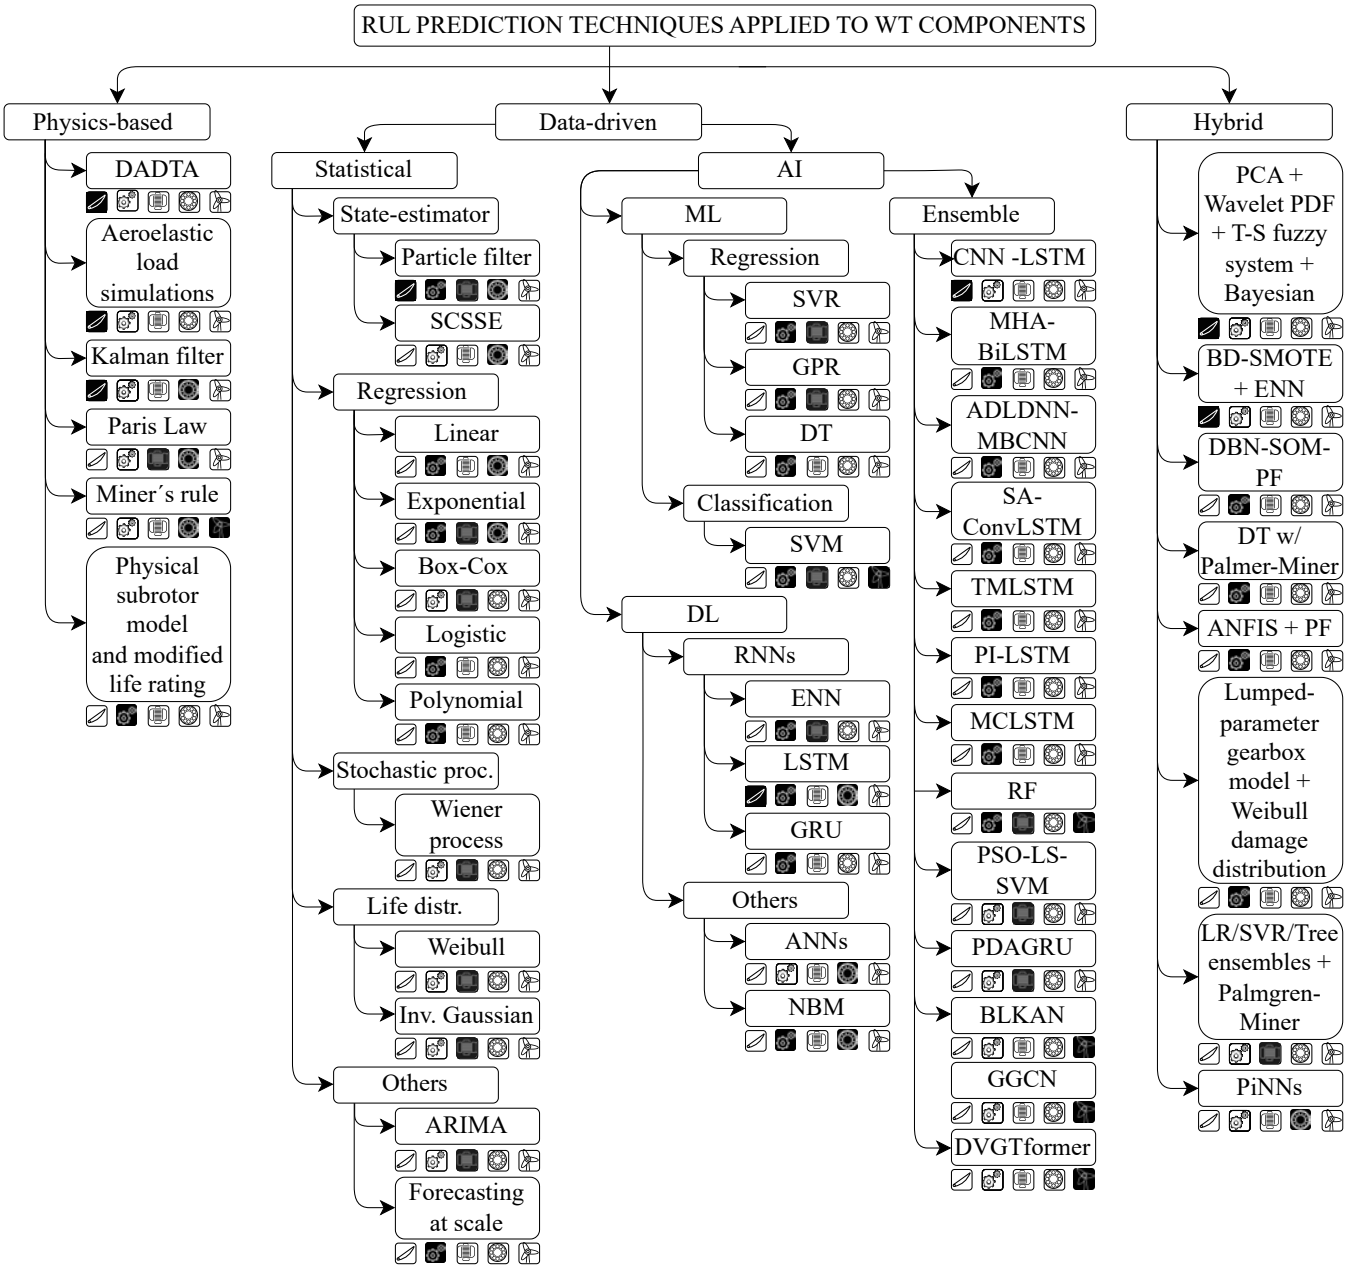

Figure 3. Techniques found in papers to predict RUL of WT components. The five categorical boxes correspond to, in order: blades, gearbox and its bearings, generator and its bearings, other bearings, and the WT as a system. The components highlighted with a black background represent those studied with the corresponding technique.

2.2.2. Data-driven models

Data-driven methodologies have gained attention to predict RUL of gearboxes. These approaches use advanced statistical methods, such as PF and regressions, and AI techniques such as advanced LSTM networks and artificial neural networks (ANNs).

Statistical PF methods have shown promising results. (J. Wang, Gao, Yuan, Fan, & Zhang, 2019) proposed an approach that integrates a PF with an expectation maximization algorithm, effectively predicting bearing defects from vibration signals in a 2MW WT gearbox. This method quantifies uncertainty in predictions, reduces false alarms, and highlights the importance of Bayesian inference for effective prognosis. (Cheng, Qu, Qiao, & Hao, 2019) introduced an enhanced particle filter (EPF) algorithm tailored for bearing RUL prediction in a 2.5 MW doubly fed induction generator (DFIG)-based WT gearbox. The EPF algorithm overcomes particle impoverishment

issues, demonstrating superior performance compared to traditional PF methods. Additionally, (J. Wang, Liang, Zheng, Gao, & Zhang, 2020) proposed a Bayesian framework integrating fault prognosis and PF-based RUL estimation, effectively predicting RUL while quantifying uncertainties.

The construction of a robust health indicator (HI) is crucial for effective RUL prediction. Methodologies often combine signal processing and statistical modeling to extract information from sensor data. Then, the trend of these indexes is estimated using different algorithms. For instance, (Praveen, Shah, Pandey, Vamsi, & Sabareesh, 2019) developed a HI from vibration signatures using wavelet transform and PCA, achieving high RUL prediction accuracy with an exponential degradation model. On the other hand, (Lázaro, Yürüen, & Melero, 2020) constructed a SCADA-based functional indicator (FI) methodology using Gaussian mixture copula model (GMCM) from SCADA signals.

Several studies have explored AI methods to predict RUL of gearboxes in WTs. Some of them have compared various techniques to determine the most effective approach. For instance, (Tayade, Patil, Phalle, Kazi, & Powar, 2019) explored regression models, such as support vector regression (SVR) and random forest (RF) regression, augmented with PCA for feature selection, demonstrating the superior accuracy of RF over SVR in early fault detection and performance degradation prediction. (Carroll et al., 2019) employed ANNs, support vector machines (SVMs), and logistic regression to predict failures, with ANNs outperforming other methods in accuracy, especially when using SCADA and vibration data. (Elasha, Shanbr, Li, & Mba, 2019) focused on gearbox bearing prognosis, demonstrating the superiority of exponential and polynomial regression models over multilayer ANNs, particularly in terms of root-mean-square error (RMSE) and R^2 coefficient. Lastly, (Elforjani, 2020) conducted a comprehensive comparison of machine learning (ML) techniques, revealing that Gaussian process (GP) exhibited the lowest error levels compared to decision trees, SVM and a feedforward ANN.

Traditional LSTM networks have widely been used for time series forecasting; nevertheless, they show some limitations in RUL prediction. Several recent works have aimed to address these issues, recognizing the challenges posed by their inability to effectively capture global trends over time and tap into backward and forward connections within time series data. (Shen, Tang, Li, Tan, & Wu, 2022) introduced the multi-head attention bidirectional-long-short-term-memory (MHA-BiLSTM), which incorporates a multi-head attention mechanism to dynamically weigh circulating data between cells, thereby enhancing the network's ability to focus on information crucial to the degradation process. In another study, (Xiang, Qin, Liu, & Gryllias, 2022) proposed the automatic multi-differential learning deep neural network (ADLDNN), leveraging a measurement level division unit and a multi-branch convolutional neural network (MBCNN) to address the varying input contributions over time, demonstrating superior performance over existing methods. (Xiang, Qin, Luo, & Pu, 2022) proposed the spatio-temporally multidifferential network (SMDN), which used temporally multidifferential LSTM (TMLSTM) and spatially multidifferential CNN (SMCNN) sub-networks to capture spatio-temporal information effectively, achieving superior performance in RUL prediction. Furthermore, (Xiang, Qin, Luo, Wu, & Gryllias, 2023) presented the concise self-adapting deep learning network (CSDLN), which integrates a multi-branch 1D involution neural network (MINN) and a multi-head graph recurrent unit (GRU) to dynamically extract hidden features and adaptively learn them, resulting in enhanced RUL prediction accuracy. In addition, (B. Li, Tang, Deng, & Zhao, 2021) introduced the self-attention ConvLSTM (SA-ConvLSTM), which combines ConvLSTM architecture with a self-attention mechanism to selectively focus on important information and improve training efficiency and prediction accuracy. Moreover, (Z. Wang, Gao, & Chu, 2022) presented the pre-interaction LSTM, designed to enhance the capture of sequential features in time-series limited samples, especially during periods of interrupted continuous feature. Lastly, (Xiang, Li, Luo, & Qin, 2024) introduced the multi-cellular long short-term memory (MCLSTM) to obtain distinct distributions of monitoring data and utilized domain adversarial and active screen mechanisms for transfer learning.

Efforts have been made to select suitable features and construct a HI to enhance RUL estimation with AI. Qin et al. introduced the shape-characteristic similarity autoencoder (SM-SAE) network to automatically extract HI curves with specific shape characteristics from raw sensing data, thereby improving degradation trajectory characterization (Qin, Yang, Zhou, Pu, & Mao, 2023). Similarly, He et al. present the self-calibration temporal convolutional network (SCTCN) model, leveraging multidomain feature extraction and a self calibration module for improved prediction accuracy, even with limited time series data (He, Su, Tian, Yu, & Luo, 2022).

One of the important data sources for predictive maintenance in WTs is SCADA data. (Verma, Zappalá, Sheng, & Watson, 2022) extensively explored the use of high-frequency SCADA data, employing advanced techniques to address imbalanced operational regimes and enhance detection capabilities in WT gearbox failure prediction, and using ANN-based normal behaviour model (NBM) and one-class SVM. In contrast, (Bermúdez, Ortiz-Holguin, Tutivén, Vidal, & Benalcázar-Parra, 2022) present an ensemble neural network model, combining a two-dimensional CNN for spatial information extraction and an LSTM network for spatio-temporal feature analysis. The model was trained only on data from SCADA (Bermúdez et al., 2022).

2.2.3. Hybrid models

Gearboxes have been the components to which most hybrid models found in this work have been applied. Desai et al. demonstrated the potential of integrating bearing-specific data from physics-based models with conventional SCADA data to enhance bearing failure prognostics (Desai, Guo, Sheng, Phillips, & Williams, 2020), highlighting significant improvements in F1 score and AUC. However, they suggested further refinement by developing individual models for each bearing type. Similarly, Mehlan et al. presented a VS method designed for online load monitoring and subsequent RUL assessment of WT gearbox bearings within a digital twin (DT) framework (Mehlan, Nejad, & Gao, 2022). The virtual sensor integrates data from readily available sensors in the condition monitoring system (CMS) and SCADA system with a physics-based gearbox model, employing multiple state estimation methods for load estimation and the Palmgren-Miner model for RUL assessment.

(Pan, Hong, Chen, & Wu, 2020) proposed a novel hybrid methodology which integrated deep belief network (DBN), self organizing feature maps (SOMs) and PF, DBN-SOM-PF. Their approach showcased superior performance in accurately predicting degradation tendencies and reducing RUL uncertainty. Moreover, (Cheng, Qu, & Qiao, 2018) introduced an adaptive neuro-fuzzy inference system (ANFIS)-based PF, demonstrating its superiority over traditional recurrent neural networks (RNNs). Their study addressed challenges in varying speed conditions through signal resampling, enhancing fault diagnosis effectiveness. (Qiao & Qu, 2018) also employed an ANFIS model in fault prognosis, showcasing accurate trend prediction validated by a gearbox run-to-failure test. Moreover, (Z. Li, Zhang, Kari, & Hu, 2021) proposed a comprehensive evaluation function combined with SOM network to construct a HI curve for gearbox-side high-speed shaft bearings (HSSB), then a Bayesian update model and expectation maximization algorithm were employed for RUL estimation. The model demonstrated superior accuracy in RUL prediction compared to SVR. Lastly, (Zheng et al., 2024) presented a multi-stage RUL prediction model tailored for WT planetary gearboxes, emphasizing interpretability and achieving promising results in real-world scenarios.

Finally, (Guo et al., 2020) integrated physics-domain models, SCADA data, and wind plant failure records to forecast the probability of failure for individual gearbox bearings. Focusing on bearing axial cracking, the study considers frictional energy accumulation and electrical power generation as prognostic metrics. The lumped-parameter gearbox model calculates gearbox bearing radial loads and displacements at any given torque, then Weibull distribution of the accumulated damage threshold of the accumulated energy is determined statistically.

2.3. Generator

Generators are labeled as critical components, as the O&M costs caused by the premature failure of the main components of WT generators can represent a significant portion –around 10-20%– of the overall energy expenses for a WT project (Cao et al., 2018). Twenty-six studies have been identified to predict the RUL of this component.

2.3.1. Physics-based models

Within physics-based models to predict the RUL of WT generators, Kalman smoother (KS) method has been uniquely identified. (Saidi, Ali, Benbouzid, & Bechhofer, 2018) introduced an integrated prognostics methodology for WT HSSB prognosis, focusing on bearing failure prognosis driven by excessive shaft vibration. Their approach used a usage model based on Paris' law and a KS to estimate RUL, addressing inherent phase delay cancelation from Kalman filtering for improved accuracy and smoother estimated with confidence bounds.

2.3.2. Data-driven models

In statistical methodologies, in both studies carried out by (P. Wang, Long, & Wang, 2020) and (Farhat, Chaari, Chiementin, Bolaers, & Haddar, 2022), the prediction of RUL for WT generator bearings is accomplished primarily through the implementation of exponential degradation models. Wang et al. used a fusion method based on PCA to construct a HI, which serves as a crucial metric reflecting the degradation level. This HI, alongside features extracted from vibration data and statistical analyzes such as monotonicity analysis and hierarchical clustering, contributes to accurate RUL estimation. Similarly, Farhat et al. also used an exponential degradation model for RUL prediction, initializing parameters based on healthy data and iteratively updating them as degradation progresses, obtaining a dynamic HI selection with good accuracy.

In their research, Rezamand et al. focused on reliability metrics for WT generators and real-time RUL prediction for critical bearings. In their study from 2019, (Rezamand, Carriveau, Ting, Davison, & Davis, 2019) explored reliability metrics using truncated WT generator data from a 100 MW wind farm, employing Weibull and accelerated life testing analysis to identify best-fitted distribution models and propose predictive PDF and hazard functions for the generator group. Subsequently, in their 2020 study, (Rezamand, Kordestani, Carriveau, Ting, & Saif, 2020) introduced a novel real-time Bayesian RUL prediction algorithm, incorporating comprehensive feature extraction, selection, and signal denoising techniques. It demonstrated superior performance over single-feature-driven Bayesian algorithms through experimental case studies, offering an improved approach to provide accurate RUL predictions by combining information

from various single features using an ordered weighted averaging (OWA) operator.

The use of the Wiener process to predict RUL is apparent in several studies focusing on WT bearing health prognosis. (Hu et al., 2018) proposed an RUL prediction model based on the Wiener process and inverse Gaussian distribution, specifically targeting rear bearings of a 1.5 MW WT generator. By establishing an inverse Gaussian distribution function and deriving drift and diffusion parameters, the model effectively predicts RUL based on temperature monitoring data, offering valuable insights for maintenance decision-making. In a similar approach, (M. Liu, Dong, & Shi, 2023) addressed challenges associated with traditional vibration data by introducing a nonlinear Wiener degradation model integrated with physical and data knowledge. Their approach, which incorporates multi-sensor temperature data fusion and Bayesian analysis, demonstrated superior accuracy and reliability compared to conventional models. Furthermore, (Song, Youliang, Kai, Cheng, & Tao, 2020) employed both linear and nonlinear Wiener processes to construct dynamic monitoring and performance degradation models, intricately linking bearing temperature parameters, wind speed, and time. Lastly, (Lan et al., 2023) developed a precise RUL prediction method for WT generator bearings using a nonlinear Wiener process. Their approach used the 3σ criterion for online monitoring, considering a two-stage evolution of bearing performance parameters.

Other statistical techniques have been used to improve RUL prediction and health state estimation in WT systems. (Y. Peng, Bi, & Wang, 2023) developed a model integrating an enhanced two-phase Box–Cox transformation into the switching state-space model, capturing nonlinear degradation with phase transition behavior. Their adaptive parameter learning method dynamically estimated transformation parameters, phase transition positions, and predicted uncertainty. In a different approach, (Peter, Zappalá, Schamboeck, & Watson, 2022) proposed a framework combining data preprocessing, anomaly detection, and time series forecasting using SCADA signals and one-class SVM. Time series is then forecasted using an autoregressive integrated moving average (ARIMA) mode. Additionally, (Kramti, Saidi, Ali, Sayadi, & Bechhoeferer, 2019) leveraged PF-based Bayesian inference with advanced signal processing methods like spectral kurtosis and high order statistics for health state estimation of the generator-side HSSBs, demonstrating promising results for RUL estimation.

On the use of AI, Cao et al. have contributed significantly to the field of WT generator bearing RUL prediction with a series of innovative approaches. In their 2018 work, (Cao et al., 2018) introduced the interval whitenization Gaussian process (IWGP) method, which integrates interval whitenization and Gaussian process algorithms to forecast RUL under non-stationary operating conditions. This method showcased notable improvements over SVR and ANN techniques. Building upon this foundation, their subsequent study proposed a more comprehensive methodology, incorporating empirical mode decomposition (EMD) for signal denoising and fault development featuress (FDFs) extraction, followed by SVR modeling (Cao, Qian, & Pei, 2019). Expanding further, their latest work introduced the parallel gated recurrent unit with dual-stage attention mechanism (PDAGRU) model coupled with a novel uncertainty quantification method, enhancing both prediction accuracy and uncertainty assessment (Cao, Zhang, Meng, & Wang, 2023). By integrating a dual-stage attention mechanism and employing kernel density estimation and Monte Carlo dropout, their approach achieved remarkable RUL prediction accuracy.

The use of neural networks (NNs) in prognostics of HSSB in WT generators has shown promising results in recent studies. (Kramti, Ben Ali, Saidi, Sayadi, & Bechhoefer, 2018) introduced an ENN architecture, employing statistical time-domain features extracted from vibration signals as inputs. Their model demonstrated reliable performance even in the presence of noisy measurements. Expanding on this work, (Kramti et al., 2021) proposed a novel feature selection method based on monotonicity, trendability, and prognosability metrics, enhancing the robustness of their ENN-based prognostic model. Similarly, (Merainani, Laddada, Bechhoefer, Chikh, & Benazzouz, 2022) developed an ENN-based approach, incorporating a novel HI derived from spectral shape factor entropy and the Teager energy operator. Furthermore, (Hayder & Saidi, 2021) proposed a deep learning (DL)-based approach using a multilayer NNs, emphasizing the significance of kurtosis as a HI.

Authors also have contributed ensembled AI models to improve the accuracy of predictions. (Pandit & Xie, 2023) introduced an innovative approach combining sparrow search algorithm (SSA) with SVM, RF regression, and Gaussian process regression (GPR). Their model, driven by vibration signal analysis and feature selection based on monotonicity, exhibited high performance. In contrast, (Du, Jia, Yu, Shi, & Gong, 2023) addressed the limitations of traditional CNN models in extracting critical features for RUL prediction of bearings. They proposed a CNN prediction model enriched with a global attention mechanism (GAM) to enhance prediction accuracy. By transforming one-dimensional vibration signals into two-dimensional image data suitable for CNN processing and incorporating a HI constructed based on time-domain degradation characteristics, their approach significantly improved RUL prediction performance.

(Dameshghi & Refan, 2021) presented an innovative framework for prognosis, focusing on the failure behavior of the DFIG due to rotor electrical asymmetries. Their approach integrates the CMS module with the prognosis module, em-

ploying agents like the degradation trend index to enhance RUL prediction accuracy. Using a particle swarm optimization (PSO)-least squares (LS)-SVM method, with parameter tuning for LS-SVM optimization and a radial basis function (RBF) kernel. In a related study, (Kamarzarrin, Refan, Amiri, & Dameshghi, 2022) introduced a novel method for fault prognosis related to DFIG rotor winding, leveraging feature level fusion and adaptive thresholding based on process parameters. Their approach used classical time and frequency domain features to represent degradation behavior, with fault prognosis conducted using PSO-LS-SVM. Experimental validation, including simulated breakdown scenarios and comparisons with SVM- and NN-based approaches, showcases superior performance.

In their collective effort, the research group lead by Rezamand and Kordestani presented a comprehensive approach to predicting the RUL of WT generator bearings, addressing the challenges posed by varying operating conditions and uncertainty in prediction horizons. (Rezamand et al., 2021b) introduced a prognostic method integrating real-time SCADA data and vibration signals to assess the influence of environmental conditions on bearing failure dynamics, coupled with an adaptive Bayesian algorithm for RUL forecasting . In parallel, (Kordestani et al., 2022) proposed a feature extraction approach from vibration signals, followed by Bayesian RUL determination and high-level fusion methods such as the Hurwicz operator and Choquet integral to integrate RUL values and mitigate uncertainty.

2.3.3. Hybrid models

Only one work has been found aiming to predict RUL for WT generators with hybrid models, carried out by (Mehlan, Keller, & Nejad, 2023). A DT framework is introduced for the virtual sensing of WT hub loads. The research focuses on the estimation of aerodynamic hub loads, monitoring accumulated fatigue damage, and predicting the RUL of high-speed shaft generator side bearings. Using various data-driven regression models (linear regression (LR), SVR and tree ensembles) and a low-fidelity physics-based model, the bearing fatigue damage and RUL is based on ISO 281, which defines the equivalent dynamic load for cylindrical roller bearings. Then, long-term damage is obtained with Palmgren-Miner.

2.4. Other bearings

Eight works identified address the prediction of RUL of WT bearings that have not been previously listed, others have not been specified. All of them are included in this section. For instance, (Moynihan, Liberatore, Moaveni, & Khan, 2021) presented a physics-based approach to estimate RUL of main shaft bearings, employing strain measurements collected from blades and validated using real WT data, and fatigue life analysis is conducted using Miner's rule.

Within data-driven methods, (Jellali, Maatallah, & Ouni, 2022) proposed a method using temperature, viscosity, dynamic load, and fatigue damage for RUL prediction of WT main bearing, achieving high accuracy rates with a LR. The work of (Teng et al., 2020) emphasized a model-based approach using an improved unscented PF to study bearings located in the gearbox high-speed shaft, generator driven end, and generator non-driven end. This was done through measurement-centric methods, enhancing applicability for on-site WT scenarios. Moreover, (X. Li et al., 2023) built upon this foundation by introducing a method integrating degraded feature fusion models, threshold determination techniques, and self-constraint state-space estimator (SCSSE) to further enhance RUL prediction accuracy. (Encalada-Dávila, Puruncajas, Tutivén, & Vidal, 2021) developed an advanced prognostic approach, also ANN-based NBM, that relies solely on SCADA data to predict main bearing failure, enabling strategic maintenance scheduling several months in advance. Lastly, (Le, Lee, Dinh, & Park, 2024) compared similarity based model, employing an LSTM model, and degradation model, using LR and a stochastic exponential random model. The degradation models showed better performance. Lastly, (Bousebsi, Medoued, & Saidi, 2023) addressed RUL prediction for HSSB using the KS method. By incorporating Paris' Law and the KS, their method achieved enhanced accuracy in tracking degradation trends across five states.

Finally, (Yucesan & Viana, 2022) introduced the physics informed neural network (PiNN), a hybrid model for bearing fatigue damage accumulation. This was embedded as a RNN cell, where reduced-order physics models used for bearing fatigue damage accumulation, standardized bearing life formula found in ISO 281, and NNs represented grease degradation mechanism that quantifies grease damage that ultimately accelerates bearing fatigue.

2.5. Wind turbine as a system

Other six works have considered the drivetrain of a WT as a system. (Benmoussa, Djeziri, & Sanchez, 2020) proposed an integrated fault diagnosis and prognosis approach for WTs, employing a physics-based model, multi-class SVM classification, and a similarity-based method for RUL estimation without prior knowledge of degradation profiles. This method demonstrates effectiveness in handling uncertainties and transient operating modes, validated through a laboratory case study on a 750 kW WT. Similarly, (Binsbergen, Soares, Pedersen, & Nejad, 2022) developed a comprehensive physics- and SCADA-based model for RUL estimation in the WT drivetrain. By employing techniques such as load duration distribution and Miner's rule, their approach offers a holistic evaluation of the drivetrain's health and expected RUL.(de Souza Pereira Gomes et al., 2024) employed a RF model prediction, which sequentially conducts binary classification stages to determine if input samples represent conditions leading to

a failure event within a specified time period.

In their series of works, (L. Wang, Cao, Xu, & Liu, 2022) proposed innovative methodologies aimed at improving RUL estimation within the drivetrain of WTs. First, they introduced the gated graph convolutional network (GGCN), focusing on multi-sensor signal fusion and precise RUL prediction. By leveraging spatial-temporal graphs constructed from multi-sensor signals, the GGCN effectively captured both temporal and spatial dependencies crucial for understanding degradation states. Furthermore, (L. Wang, Cao, Ye, & Xu, 2023) addressed the need for uncertainty quantification by incorporating a quantile regression layer, providing confidence interval estimated essential for maintenance planning. Building upon this foundation, their subsequent work introduced the Bayesian large-kernel attention network (BLKAN) to enhance RUL prediction and uncertainty quantification for bearings. The BLKAN balanced computational efficiency with long-range correlations and channel adaptability, employing Bayesian large-kernel convolutions and variational inference to infer probability distributions of model parameters. Finally, (L. Wang, Cao, Ye, Xu, & Yan, 2024) presented the dual-view graph Transformer (DVGTformer), which enhances RUL prediction accuracy by fusing information from multiple sensors to capture complex degradation patterns. By integrating temporal and spatial perspectives through cascading layers of a graph transformer, the DVGTformer achieved superior performance compared to existing state-of-the-art methods.

3. Conclusions and future directions

This review illustrates the dynamic field of RUL estimation for WT components, showcasing the evolution and diversity of methodologies and their respective challenges. The comprehensive analysis of eighty-one papers published since 2018 on RUL prediction models reveals a clear alignment with the identified critical subsystems and failure modes within WT systems in Section 1. The predominant focus on predicting the RUL of gearboxes (35.8%), generators (32.1%), blades (14.8%), and associated bearings aligns the findings from the downtime analysis and failure costs in the introduction, where these components emerged as the most critical.

Physics-based, data-driven, and hybrid models have been identified to achieve an effective prognosis, all gathered in Figure 3. When the underlying physics of the system is known, e.g., bearing fatigue analysis with Miner´s rule, physics-based methods offer interpretable results and accuracy without the need for large amounts of data. It is difficult, though, to obtain robust physics-based models of these complex systems. Data-driven methods, while requiring less physical knowledge, can effectively quantify prognosis uncertainty and process high dimensional data, though they may lack interpretability and generalize poorly with limited data, a common occurrence in many WT datasets, where data availability is often sparse or low quality. Hybrid methods combine the advantages of various approaches, but may face challenges in model selection and characterization of uncertainty. Figure 2a illustrates that data-driven methodologies are predominant in predicting the RUL of WT components, with a growing inclination towards hybrid models.

While the primary objective of these models is to improve the accuracy and robustness of their predecessors, significant barriers remain. The challenges outlined in our review of RUL estimation methods for wind turbine components were derived from an extensive analysis of existing literature and research findings. Through a systematic review process, recurring obstacles were identified and categorized into five distinct groups: inherent uncertainty management, integration of physical knowledge, consideration of variable operational conditions, data issues and complex system dynamics. This classification was based on the underlying nature of the challenges and their impact on prognostic accuracy and reliability. The distribution of papers that address these issues is shown in Figure 4 (one paper can address more than one challenge). These are discussed below.

1. **Uncertainty** from various sources, such as sensor noise and model variability, is a key obstacle. Thus, its quantification is essential to reduce the impact of uncertainties throughout maintenance optimization and decision-making. Techniques such as Bayesian belief networks (BBNs) and Monte Carlo methods aimed at minimizing it.
2. **Integration of physical knowledge**. The integration of underlying physics of the system is gaining attention to obtain higher accuracy and credibility of the prognosis, as shown in the hybrid methods subsections. However, there remains a need for further research and enhancement. Methods to integrate physical knowledge into NNs such as PiNNs offer promising avenues for accurate and interpretable prognostics (Chen, Ma, Zhao, Zhai, & Mao, 2022). In the industrial application facet, RUL prediction techniques have been applied to a number of important fields, including but not limited to aerospace systems, industrial robots, wind power systems, high-speed trains, etc. (H. Li, Zhang, Li, & Si, 2024), but there still remains a significant challenge in fully implementing these techniques within the components of WTs. However, there are some key limitations and challenges in model property aspects, which (Xu, Kohtz, Boakye, Gardoni, & Wang, 2023) summarized into five types: model selection, model structure, model parameter, model optimizer, and model prediction.
3. **Variable operational conditions**. WTs operate in dynamic environments characterized by fluctuating wind speeds, changing loads, and varying environmental con-

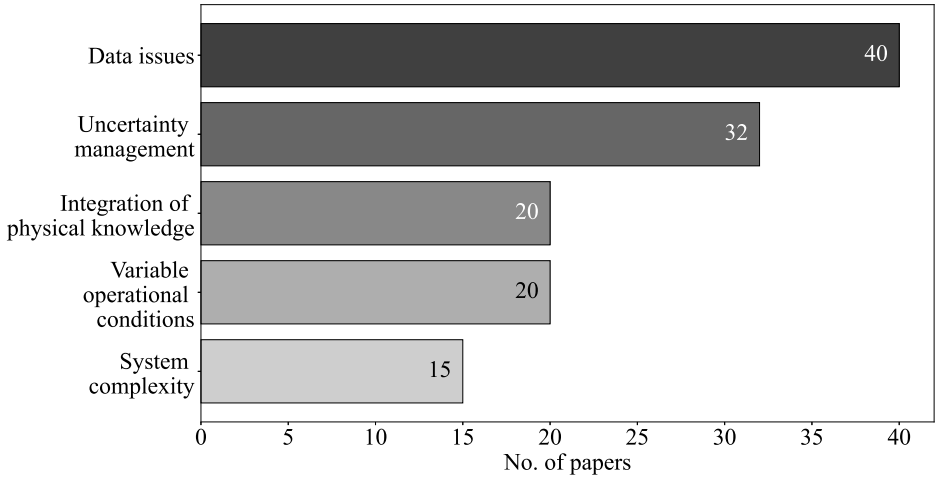

Figure 4. Amount of papers addressing challenges in WT component RUL prediction.

ditions. Such variability not only impacts the performance and wear of individual components, but also complicates the prediction of their future reliability and the accuracy of RUL models, often trained with similar operating conditions. The need for continuous online learning underscores the urgency for novel algorithms and hardware architectures (Elattar, El-Brawany, Elminir, Ibrahim, & Ramadan, 2023). In this context, transfer learning and domain adaptation present an opportunity to adapt models to varying operating conditions, although challenges remain to ensure prediction accuracy across different equipment (Ramezani et al., 2023). Therefore, the transferability assessment of different domains continues to pose a substantial challenge.

4. **Data issues**. Noisy measurements and a notorious lack of high-quality data are among these challenges. These difficulties are compounded by the scarcity of samples and monitoring data, which makes accurate predictive modeling even more challenging. Moreover, in many cases, only SCADA data are available, which presents a notable barrier, aggravated by the limited and low frequency samples, and the unbalanced nature of the condition data available for analysis. To overcome these obstacles, researchers must navigate the complexities of fusing multi-sensor signals to enrich the available data sources. Several papers within this study employ methodologies for multi-signal feature extraction and dimensionality reduction, such as PCA. However, it is beyond the scope of this review to delve into these techniques.
5. **System complexity**. WT are inherently complex systems, characterized by a multitude of interconnected components, as mentioned in the introduction. On one hand, multiple faults in a single component are a frequent occurrence, which are not considered in academic studies. On the other hand, the degradation process should take into account the way different components interact. To gain interpretability, more signal processing procedures could also be applied to the machine degradation process.

As research progresses, it is essential to address the identified challenges systematically, paying particular attention to the critical components within WT components. The implementation of PHM will facilitate the development of a robust predictive maintenance plan, which will contribute to the reduction of LCOE associated with O&M costs, thus aligning with the objectives of achieving green transition goals.

ACKNOWLEDGMENT

This study was partially funded by the Spanish Agencia Estatal de Investigación (AEI) — Ministerio de Ciencia e Innovación, the Fondo Europeo de Desarrollo Regional (FEDER) through the research projects PID2021-122132OB-C21, PID 2021-122132OB-C22, and TED2021-129512B-I00; and by the Generalitat de Catalunya through the research project 2021-SGR-01044.

BIOGRAPHIES

Jokin Cuesta holds a degree in physics by the University of the Basque Country - Euskal Herriko Unibertsitatea (EHU-UPV, 2020). He furthered his education with a

focus on data science master at Universitat Oberta de Catalunya (UOC, 2023) in Barcelona. He is currently engaged in the pursuit of an industrial PhD at the Artificial Intelligence and Data area in Ikerlan and the Control, Data, and Artificial Intelligence (CoDAlab) group in the Department of Mathematics at Universitat Politècnica de Catalunya. With a passion for the intersection of AI and CM, his research is dedicated to developing innovative methodologies for CM in the wind energy sector. His specific focus lies in identifying degradation patterns in WT components and estimating their RUL.

Urko Leturiondo is Industrial Engineer majored in Mechanics and Industrial Design by Tecnun - Engineering School of Universidad de Navarra (2012) and he received his PhD degree by Luleå University of Technology (2016). In 2012 he joined the Mechanical Engineering Department of Ikerlan as a PhD student, doing his research in collaboration with the Division of Operation and Maintenance Engineering of Luleå University of Technology. From 2016 to 2019 he worked as a researcher in the Control and Monitoring Area of Ikerlan. Since 2019 he has led different research teams in Ikerlan, being currently the DataOps team leader. His current research interests include condition monitoring, asset management, modelling of mechatronic systems, vibration and acoustic analysis, data analytics, artificial intelligence and DevOps.

Yolanda Vidal holds a degree in Mathematics (1999) and a PhD in Applied Mathematics (2005) from the Universitat Politècnica de Catalunya (UPC), Barcelona, Spain. As an Associate Professor at UPC and an IEEE Senior Member, she actively engages in multidisciplinary research. Her areas of expertise include condition monitoring, structural health monitoring, fault diagnosis and prognosis, predictive maintenance, machine/deep learning, mathematical modeling, and the application of these disciplines in WT technologies. She serves on the Editorial Board of several international journals, including Engineering Applications of AI (Elsevier), Wind Energy (Wiley), Wind Energy Science (Copernicus), Mathematics, Sensors, Energies, Frontiers in Built Environment, and Frontiers in Energy Research. Her prolific contributions are evidenced by more than 60 high-impact journal articles, 20 competitive R+D+I projects, 17 book chapters, 10 books, 3 supervised PhD theses, 1 invention patent, a collaboration contract with an industry partner, and over 110 conference papers.

Francesc Pozo obtained his degree in mathematics from the University of Barcelona in 2000, and his PhD in applied mathematics from the Universitat Politècnica de Catalunya (UPC) in 2005. Since 2000, he has been with the Department of Mathematics at UPC, where he is now a Full Professor and the coordinator of the Control, Data, and Artificial Intelligence research group. His expertise encompasses condition monitoring, control systems, data-driven modeling, identification, and structural health monitoring, with a special focus on WTs. He is an Editorial Board Member for several international journals, such as Structural Control and Health Monitoring, International Journal of Distributed Sensor Networks, Mathematical Problems in Engineering, Mathematics, Sensors, Algorithms, Journal of Vibration and Control, Frontiers in Built Environment, Frontiers in Energy Research, and Energies. His contributions to his field include over 70 high-impact journal articles, participation in 23 competitive R&D&I projects, authorship of 34 book chapters and 12 books, mentorship of 6 PhD candidates, the filing of 1 invention patent, a collaboration contract with an industry partner, and more than 130 conference papers.

A rolling bearing state evaluation method based on deep learning combined with Wiener process

ABSTRACT

As a key component of rotating parts, rolling bearings largely determine the operation safety of equipment. However, in practical applications, because the degradation trajectory of rolling bearings cannot be truly characterized, the existing model cannot accurately describe the degradation trajectory of rolling bearings, resulting in the running state of rolling bearings cannot be directly evaluated. Therefore, a method of rolling bearing state assessment based on deep learning combined with Wiener process is proposed in this paper. Firstly, a deep network model is constructed by deep learning to mine the degradation information of rolling bearings. Secondly, the mined degradation information is fused, and then the degradation indicator used to characterize the degraded trajectory of the rolling bearing is constructed. Then, based on Wiener process, the degradation model of rolling bearing is established to describe the degradation mode of rolling bearing. Finally, the constructed degradation indicator is input into the established degradation model to predict its RUL, and then the running state of the rolling bearing is evaluated.

1. INTRODUCTION

During the operation of mechanical equipment, due to the influence of many factors, mechanical equipment will inevitably degrade. This degradation process generally occurs first in components that produce relative motion, especially rolling bearings(Zhu et al. 2024). Therefore, in order to ensure that mechanical equipment always serves in a safe state, it is very necessary to evaluate the operating status of rolling bearings. The remaining useful life (RUL) prediction method has been recognized as a basic and effective method for state assessment of rolling bearings(Li et al. 2024). (If the RUL of the rolling bearing can be predicted, the current service status of the rolling bearing can be assessed) Currently, in the field of prediction of the RUL of rolling bearings, scholars have proposed a series of life prediction methods of rolling bearings, but generally they can be divided into methods based on expert knowledge base, data-driven, physical models and hybrid methods(Wang et al. 2023).

The method based on expert knowledge base achieves prediction by comparing the similarity between the observed data and the previously defined fault database through expert system or fuzzy system(Qin et al. 2023). For example, Qin et al. proposed a two-stage RUL prediction method based on similarity, constructing a degradation indicator (DI) of bearings through a multi-head self-attention mechanism, and comparing the constructed DI with other bearing degradation indexes in the expert knowledge base, thereby realizing the prediction of the RUL of the bearing(Qin et al. 2023). Xia et al. proposed a hybrid Gaussian-evidence hidden Markov model that integrates expert knowledge and condition monitoring information to predict the RUL of bearings under the framework of belief function theory(Xiahou, Zeng, and Liu 2021). These methods often require special knowledge about the fault data, however obtaining this knowledge is expensive in practice. The data-driven method uses the historical status data of the equipment to extract characteristic information related to the status changes of the monitored object. Through statistical analysis, pattern recognition, machine learning and other technologies, it attempts to simulate the fuzzy functional relationship between sensor data and equipment status, and then realize the status assessment and RUL prediction of the monitored object(Li et al. 2022). For example, Cheng et al. extracted nonlinear features from bearing vibration signals and inputted them into convolutional neural networks to evaluate the health status of bearings, and combined them with relevant vector machines to predict the RUL of bearings(Cheng et al. 2021). Yoo et al. used continuous wavelet transform to convert bearing vibration signals into image signals and input them into convolutional neural networks for predicting the RUL of bearings(Yoo and Baek 2018). Ren et al. used deep self-coding neural networks to compress the time-frequency wavelet features of rolling bearings and predict the RUL of

rolling bearings(Ren et al. 2018). However, these methods need to establish the state characterization function of the rolling bearing, and with the increase of the prediction time span, the characterization ability of the model decreases, and the prediction accuracy of the RUL decreases. The physical model method is based on the mathematical representation of the physical behavior during the degradation process to predict the degradation performance and RUL of the bearing. For example, Kogan et al. established a multi-body dynamics model of rolling bearings based on classical dynamics and kinematic equations to describe the health degradation process of rolling bearings under different faults and predict their RUL by fitting its degradation process(Kogan et al. 2015). Qian et al. improved the Paris-Erdogan model and constructed a multi-time scale degradation model to track the changes in the degradation rate of the bearing in different time periods to predict the RUL of the bearing(Qian, Yan, and Gao 2017). These methods can provide accurate prediction results, it still requires an in-depth understanding of the physical characteristics of the bearing and the prognosis of the bearing. The accuracy depends heavily on the accuracy of the physical model used. The hybrid prediction method is a RUL prediction method that combines the advantages of physical models and data drivers(Wang et al. 2020). Wang et al. constructed a new scalable two-stage linear/nonlinear composite model to describe various degradation behaviors of bearings through a hybrid data- and model-driven method, and predicted the RUL of bearings by using a long and short time memory network(Wang, Cui, and Wang 2022). Rezamand et al. defined the role of environmental conditions in the dynamics of bearing failure. They achieved the RUL prediction of faulty bearings through vibration signal recognition and fault dynamics analysis(Rezamand et al. 2021). The hybrid prediction method can effectively simulate the degradation process of rolling bearings. However, these methods complicate the algorithm and is limited by the physical behavior of the rolling bearing during the degradation process, which in turn leads to modeling difficulties.

Due to the limitations of different methods, the unclear exploration of the failure mechanism of rolling bearings, the lack of degradation data, and especially the neglect of historical operating data of rolling bearings in normal service, these methods cannot accurately evaluate the service status of rolling bearings. There are two reasons for this. First, the degradation characteristics used cannot accurately represent the degradation trajectory of rolling bearings; second, the degradation model used cannot map the failure mechanism of rolling bearings. Due to the powerful feature extraction ability of convolutional neural networks, by stacking multiple convolutional and pooling layers, more and more abstract and advanced features can be gradually extracted. This hierarchical feature extraction can better capture the degradation information of bearings, thereby improving the performance of the model. In addition, due to the excellent non monotonic characteristics of the Wiener process, it can effectively describe the local fluctuation characteristics on the degradation path of bearings. Therefore, in order to overcome the limitations of the above methods, this paper proposes a rolling bearing state assessment method based on deep learning combined with Wiener process, starting from the construction of degradation indicators of rolling bearings and the failure mechanism mapping of the model. This method first constructs a degradation indicator extractor for the full- life cycle of rolling bearings based on one-dimensional convolutional neural. Secondly, a mapping model between its degradation trajectory and RUL is established based on the Wiener process. Then, using DI to estimate the unknown parameters in the model, the RUL prediction of the rolling bearing at different monitoring points is completed. Finally, the status evaluation of the rolling bearing is realized through the prediction results at the current moment.

2. METHOD PROPOSED

2.1. DI construction method

Convolutional neural network is a type of deep neural network, which consists of multiple neural network layers. Each layer consists of multiple neurons that are connected to the neurons in the previous layer. Convolutional neural networks usually contain three types of layers: convolutional layers, pooling layers, and fully connected layers. Because the dimensional convolutional neural network has good information mining and weight sharing capabilities(She and Jia 2019). Therefore, this paper constructs the bearing degradation index of the rolling shaft based on the one-dimensional convolutional neural network. The specific construction method is as follows:

Let $\left[\boldsymbol{X}_1, \boldsymbol{X}_2 \cdots \boldsymbol{X}_{m-1}, \boldsymbol{X}_M\right]^T$ represent the full-life vibration signal of the M group of rolling bearings, and $\boldsymbol{X}_i = \left[\boldsymbol{x}_{i,1}, \boldsymbol{x}_{i,2} \cdots \boldsymbol{x}_{i,n-1}, \boldsymbol{x}_{i,N}\right]^T$ be the full-life cycle signal of the *i*-th group, where N is the number of sampling times of the bearing. Therefore, the whole life vibration signals of the group of rolling bearings can generate $\sum_{i=1}^{M} N_i$ group of samples. As shown in Figure 1, samples are input into the constructed one-dimensional convolutional neural network (1DCNN) in batches to perform convolution normalization and other operations. Finally, a neuron is connected to the output end to represent the current service status of the rolling bearing. In this way, the collected samples are sequentially input into the constructed one-dimensional convolutional neural network to obtain the degradation index that characterizes the degradation trajectory of the rolling bearing.

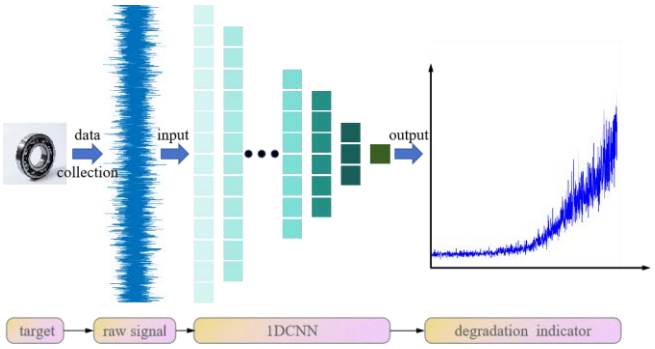

Figure1. DI construction process

2.2. State Assessment Method

The Wiener process has good statistical properties. Therefore, this paper establishes a degradation model of rolling bearings based on the Wiener process to describe its degradation state(Ta et al. 2023). The degradation process of the rolling bearing is described based on the Wiener process as shown in Equation (1), where $y(t)$ represents the degradation state of the rolling bearing at time t, and y_0 is the initial state of the rolling bearing. a is the drift coefficient, which represents the difference between similar rolling bearings and obeys the normal distribution $N(\mu_a,\sigma_a^2)$. t^b is the degradation trend term describing the severity of rolling bearing degradation, where b is a fixed coefficient. c is the diffusion coefficient, which represents the degree of fluctuation when the rolling bearing degrades, and $B(t)$ is the standard Brownian motion (BM), which represents the inherent variability of the random degradation process over time. The fluctuation term describes the uncertainty when the rolling bearing degrades and obeys the normal distribution $N(0,c^2t)$.

$$y(t)=y_0+at^b+cB(t) \tag{1}$$

In order to ensure that rolling bearings always operate safely. Therefore, as shown in equation (2), the RUL l_k of the rolling bearing at time k is defined based on the first hitting time(Cheng et al. 2023), where ω is the failure threshold.

$$l_k=\inf\left\{l:y\left(l+t_k\right)\geq\omega\middle|y\left(t_k\right)=y_k\right\} \tag{2}$$

According to the characteristics of BM and the definition of the RUL of the above formula, the probability density function (PDF) of the RUL of the rolling bearing at any time is shown in Equation (3)(Si et al. 2012).

$$\begin{aligned}f\left(l_k\right)\cong&\frac{1}{\sqrt{2\pi l_k^2\left(\sigma_a^2A\left(l_k\right)^2+\sigma^2l_k\right)}}\\&\times\left(w\left(t_k\right)-B\left(l_k\right)\frac{w\left(t_k\right)\sigma_a^2A\left(l_k\right)+\mu_a\sigma^2l_k}{\sigma_a^2A\left(l_k\right)^2+\sigma^2l_k}\right)\\&\times\exp\left[-\frac{\left(w\left(t_k\right)-\mu_aA\left(l_k\right)\right)^2}{2\left(\sigma_a^2A\left(l_k\right)^2+\sigma^2l_k\right)}\right]\end{aligned} \tag{3}$$

where $A\left(l_k\right)=\left(t_k+l_k\right)^b-t_k{}^b$, $B\left(l_k\right)=A\left(l_k\right)-l_kb\left(t_k+l_k\right)^{b-1}$ and $w\left(t_k\right)=w-y\left(t_k\right)$. After obtaining the PDF of the RUL. As shown in equation (4), the pseudo life is first integrated and averaged, and then the RUL of the rolling bearing at time is obtained(Hu et al. 2020). Then use equation (5) to evaluate the service status of the bearing at the current moment, T_{past} represents the length of time the bearing has been in service relative to the current moment, BC_k represents the service status of the bearing at the current moment, and the closer BC_k is to 100%, the healthier the bearing is.

$$L_k=\int_0^\infty l_kf\left(l_k\right)dl_k \tag{4}$$

$$BC_k=\frac{L_k}{T_{past}+L_k}*100\% \tag{5}$$

According to formula (3) and (4), if the RUL of the rolling bearing at the current time is obtained, the values of parameters μ_a,σ_a^2,b and c^2 need to be estimated. The parameters μ_a,b,c^2 can be obtained using the mapping model (1) as the fitting function. The parameter σ_a^2 can be obtained by the maximum likelihood estimation method. According to the nature of Wiener process, sample $\boldsymbol{y}_{1:N}=\{y_1,y_2,\cdots y_N\}$ follows multivariate normal distribution, let $\boldsymbol{\Lambda}=\left[t_1^b,t_2^b,\cdots t_N^b\right]^T$, then its mean and variance are shown in equation (6):

$$\begin{aligned}&\boldsymbol{y}\sim N\left(\mu_a\boldsymbol{\Lambda},\sigma_a^2\boldsymbol{\Lambda}\boldsymbol{\Lambda}^T+c^2\mathbf{Q}\right)\\&\mathbf{Q}=\left[\min\left\{t_i,t_j\right\}\right]_{1\leq i,j\leq N}\end{aligned} \tag{6}$$

Obtain the PDF of the multivariate normal distribution according to Equation (6) and take the logarithm of both sides to obtain the likelihood function containing unknown parameters. Then use the likelihood function to partially derive the parameter σ_a^2, and make the equation equal to 0.

The solution expression for parameter σ_a^2 is obtained as shown in Equation (7):

$$\sigma_a^2 = \frac{(y_{1:M} - \mu_a \mathbf{\Lambda})^T \mathbf{Q}^{-1} \mathbf{\Lambda} \mathbf{\Lambda}^T \mathbf{Q}^{-1} (y_{1:M} - \mu_a \mathbf{\Lambda}) - c^2 \mathbf{\Lambda}^T \mathbf{Q}^{-1} \mathbf{\Lambda}}{\left(\mathbf{\Lambda}^T \mathbf{Q}^{-1} \mathbf{\Lambda}\right)^2} \quad (7)$$

2.3. Method framework

The proposed method is shown in Figure 2. This method first divides the obtained full-life data into $\sum_{i=1}^{M} N_i$ samples according to the number of collections, and performs data processing on each sample to remove abnormal points and avoid interference with the DI construction model. Secondly, input the processed data into the constructed 1DCNN in batches to train the network until the network converges. Then, the trained network is used as the DI extractor of the rolling bearing, and the newly collected data is input into the DI extractor in sequence according to the number of sampling times, so as to obtain the DI describing the historical operating status of the rolling bearing. Then, use the historical DI data of the rolling bearing to estimate the unknown parameters in the mapping model, and bring them into equations (3) and (4) to obtain the RUL of the rolling bearing at the current moment. Finally, equation (5) is used to evaluate the current service status of the rolling bearing.

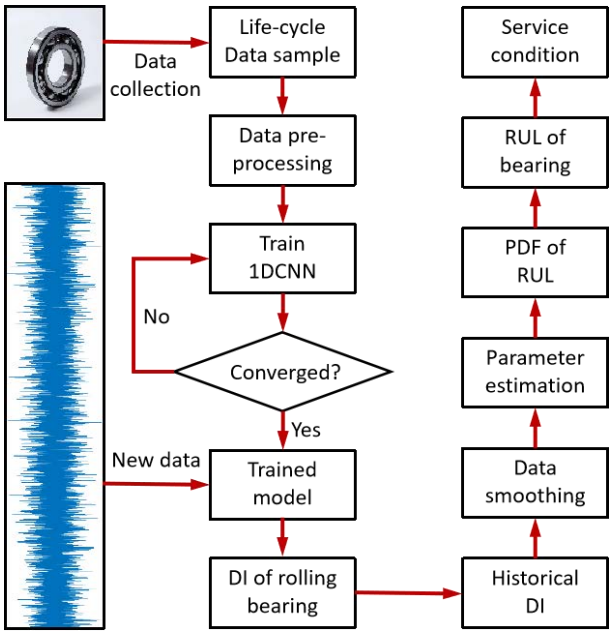

Figure2. Method framework

3. EXPERIMENT

In order to verify the effectiveness of the method, this paper uses two sets of public full-life rolling bearing data sets for verification. The constructed DI is quantitatively analyzed using robustness (Rob), monotonicity (Mon), trendability (Tre) and comprehensive evaluation methods (Com)(Ta et al. 2023). If these four evaluation indicators are larger, it means that the constructed DI can better characterize the degradation trajectory of the bearing. Similarly, in order to analyze the prediction results from a quantitative perspective, this paper uses root mean square error (RMSE), adaptability (R^2), mean absolute error (MAE) and cumulative relative accuracy (CAR) to analyze the prediction results. The smaller the RMSE and the MAE, the better the prediction effect; the larger R^2 means the model has stronger adaptability; the greater the CAR, the better the prediction effect.

3.1. Case 1

Case 1 uses the full-life bearing data provided by the IEEE PHM 2012 Challenge to verify the method. Experimental data comes from PRONOSTIA experimental bench. This data set contains a total of 17 sets of accelerated degradation experimental data of rolling bearings, which were completed under three working conditions, as shown in Table 1. The operating conditions of the 17 sets of rolling bearings are shown in Table 2.

Table1. Operating conditions table

Condition number	Conditions 1	Conditions 2	Conditions 3
Rotating speed	1800 rpm	1650 rpm	1500 rpm
Apply load	4000 N	4200 N	5000

Table2. IEEE PHM 2012 Dataset

Data set	Conditions 1	Conditions 2	Conditions 3
Training set	Bearing1_1	Bearing2_1	Bearing3_1
	Bearing1_2	Bearing2_2	Bearing3_2
Test set	Bearing1_3	Bearing2_3	Bearing3_3
	Bearing1_4	Bearing2_4	
	Bearing1_5	Bearing2_5	
	Bearing1_6	Bearing2_6	
	Bearing1_7	Bearing2_7	

In this experiment, each group of bearings used two vibration sensors to collect data. The sampling frequency was 25.6kHZ, the sampling interval was 10 seconds, and the duration of each sampling was 1 second. In this experiment, this paper uses Bearing1_3 as a test sample, and the others as training samples to train the network, and continuously adjust the network parameters until the network converges. Bearing1_3 data samples are input into the DI extractor successively, and the output DI are smoothed successively. The DI of Bearing1_3 is shown in Figure 3. The constructed DI is compared with the 7 commonly used DI of rolling bearings. The comparison results are shown in Table 3 (Proposed method (M1), Degenerate angle (M2), Maximum value (M3), Mean absolute value (M4), Root mean square (M5) Root

amplitude (M6), Standard deviation (M7) Variance (M8)). It can be seen from the table that the DI constructed using the proposed method has good Tre, Rob and Mon. Because the range of these three evaluation indicators is between [0,1]. Therefore, the three of them are added to form a Com. Judging from the comprehensive indicator column in the table, the DI constructed in this paper is the best.

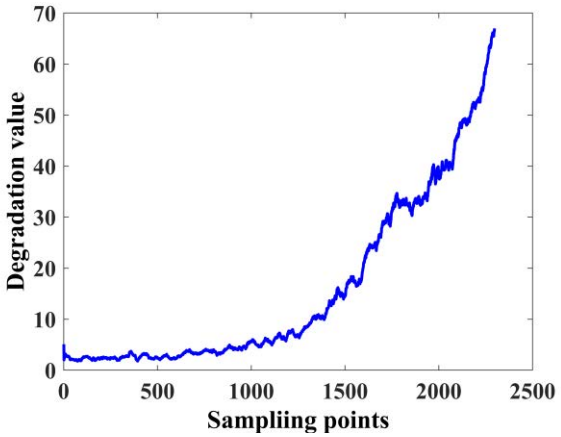

Figure3. Bearing1_3 DI

Table3. Performance comparison of 8 DIs

	Rob	Mon	Tre	Com
M1	0.9932	0.8484	0.8867	2.7283
M2	0.9932	0.1276	0.4102	1.531
M3	0.9797	0.4599	0.7402	2.1798
M4	0.9737	0.3571	0.7402	2.0710
M5	0.7311	0.4207	0.8216	1.9734
M6	0.5934	0.0113	0.2156	0.8203
M7	0.9931	0.4233	0.8145	2.2309
M8	0.9909	0.4382	0.7979	2.2270

Bearing1_3 conducted a total of 2375 samples in the experiment. In order to make the intervals between each condition monitoring (CM) point equal, this paper took the first 2300 samples as test samples, in which the monitoring interval was 100. Finally, Bearing1_3 was monitored 23 times according to the service process of the bearing. The *k*-th CM point represents the service status of the bearing at time *k*, and the previous *k*-th CM point represents the historical service status of the bearing at time *k*. The constructed DIs are input into the PDF of the RUL in batches and the corresponding unknown parameters are estimated. The obtained PDF of the RUL is shown in Figure 4. It can be seen from the figure that with more and more historical data, the PDF becomes more and more convergent, indicating that the credibility of the prediction is getting higher and higher.

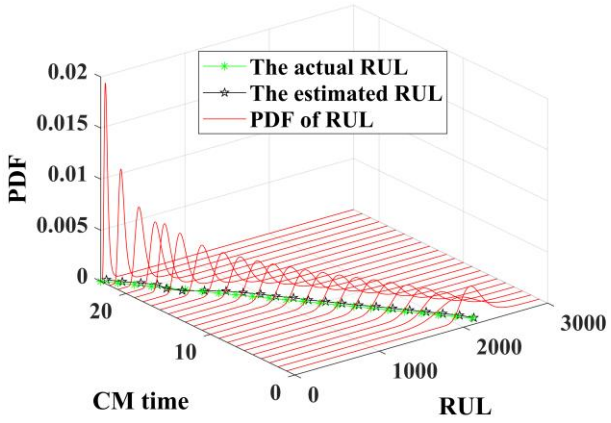

Figure4. PDF of RUL

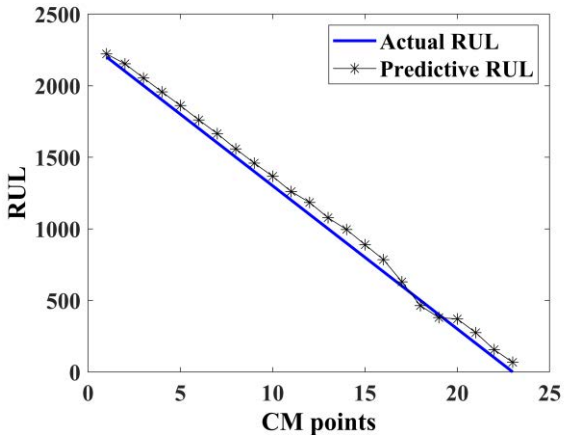

Figure5. Prediction results at different CM points

Table4. Quantitative analysis of prediction results

RMSE	R^2	MAE	CAR
63.5707 （2.76%）	0.9908	60.5620 （2.63%）	0.8610

As can be seen from Figure 5, the prediction results of different CM points are close to the actual RUL of the rolling bearing Bearing1_3. It can be seen from Table 4, the RMSE of the prediction result is only 2.76%, the MAE is 2.63%, R2 is close to 1, and the CAR is 86.10%. The above analysis results show that the method has good accuracy. In addition, Figure 6 shows the service status of the rolling bearing Bearing1_3 at different CM points. It can be seen from the figure that the service performance of the rolling bearing

Bearing1_3 gradually decreases as its service time becomes longer. It also illustrates the effectiveness of this method for evaluating the service status of rolling bearings.

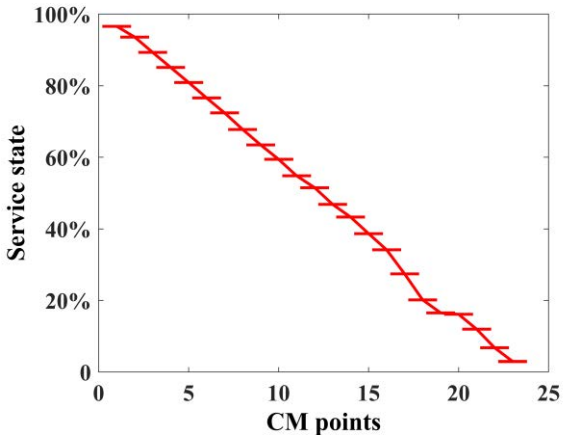

Figure6. Bearing1_3 service status

3.2. Case 2

Case 2 uses the public data set of XJTU-SY for verification. This data set contains a total of 15 sets of full-life bearing data. The sampling frequency is 25.6 kHz, the sampling interval is 1min, and each sampling is 1.28 seconds long. In the same verification method as Case 1, 14 sets of bearings are used as training samples and 1 set is used as test samples. The test sample is Bearing 3_1. The DI of Bearing 3_1 obtained after the final test is shown in Figure 7. It can be seen from the figure that although the DI produces large local volatility, the overall Tre and Rob show good performance. In addition, the performance comparison of different DIs in Table 5 also proves that the DI constructed by this method has good representation performance.

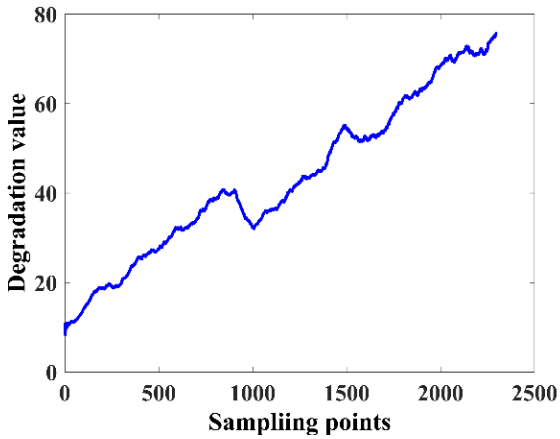

Figure7. Bearing1_3 DI

Table5. Performance comparison of 8 DIs

	Rob	Mon	Tre	Com
M1	0.9431	0.7887	0.9530	2.6848
M2	0.9968	0.0292	0.1321	1.1581
M3	0.9919	0.0252	0.3321	1.3492
M4	0.9919	0.0996	0.3423	1.4338
M5	0.6331	0.0548	0.0941	0.7820
M6	0.5731	0.0236	0.1641	0.7608
M7	0.9960	0.1204	0.3419	1.4583
M8	0.9961	0.1064	0.3427	1.4452

Bearing 3_1 took a total of 2538 samples. In order to keep the monitoring interval unchanged, the first 2500 sampling points were taken for verification, and a total of 25 times of monitoring were conducted. The RUL of PDF for each monitoring is shown in Figure 8. It can be seen from the figure that with more and more historical data, the PDF becomes more and more convergent, which shows that the credibility of the prediction is getting higher and higher. This leads to the same conclusion as Case 1.

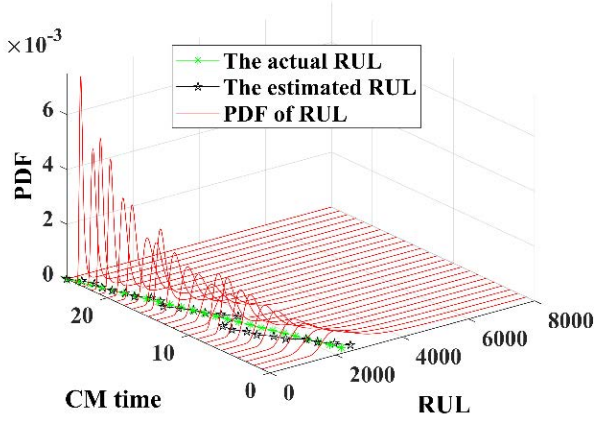

Figure8. PDF of RUL

Figure 9 shows the results of the actual life and predicted life of Bearing 3_1 at different monitoring points. It can be seen from the figure that the deviation at some CM points is larger, and the deviation at some CM points is smaller. This is because the constructed DI has greater volatility at this CM point, which in turn leads to a greater deviation between the prediction results and the actual results. However, from the overall prediction effect, the prediction results are gradually closer to the actual prediction results. As can be seen from

Table 6, the RMSE of the prediction result is 9.72%, MAE is 7.10%, R2 is 0.8865, and CAR is 77.01%. The above analysis results show that the method has good accuracy. Figure 10 is the result of mapping the predicted RUL to service performance, and then determines the service status of the bearing. It can be seen from the figure that as the service time of the bearing increases, the performance of the bearing gradually decreases. Although there was a "recovery" during the period, this can be considered as the self-healing behavior of the bearing during service. Therefore, this method can well evaluate the service status of bearings.

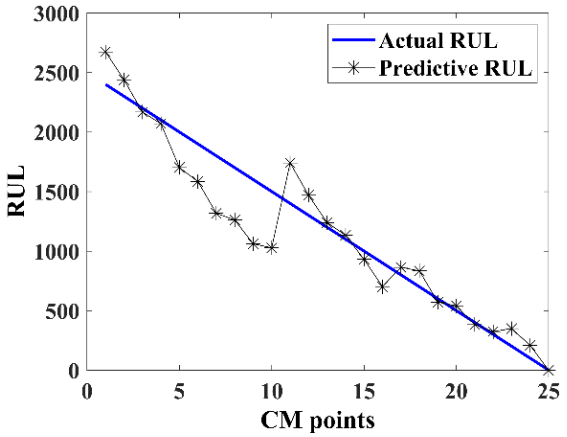

Figure9. Prediction results at different CM points

Table6. Quantitative analysis of prediction results

RMSE	R^2	MAE	CAR
242.9127 （9.72%）	0.8865	177.4692 （7.10%）	0.7701

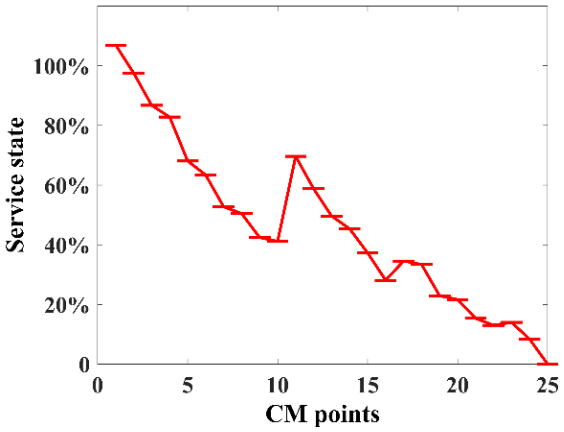

Figure10. Bearing1_3 service status

4. CONCLUSION

In order to evaluate the service status of rolling bearings, this paper proposes a rolling bearing status evaluation method based on deep learning combined with Wiener process. Since the existing DIs cannot characterize the degradation trajectory of rolling bearings. This paper uses a 1DCNN to extract the DIs of rolling bearings. Aiming at the problem of the RUL of rolling bearings, this paper constructs a degradation model of rolling bearings based on the Wiener process, and uses its PDF to estimate the RUL of rolling bearings. The RUL of the rolling bearing is mapped to its service status, thereby completing the service status assessment of the rolling bearing. This paper uses the IEEE PHM 2012 public data set to verify the method. The experimental results show that the extracted DI has good trend and monotonicity, and the service status assessment of the rolling bearing has good accuracy. However, the contribution of this paper is limited. From the verification results, the bearing prediction accuracy is largely determined by the constructed DI and the complexity of the model. Therefore, the follow-up work of this paper will start from mining the degradation information of bearings and establishing more complex prediction models to improve the prediction accuracy of bearings.

ABSTRACT

In practical bearing fault diagnosis, labeled fault data are difficult to obtain, and limited samples will lead to training overfitting. To address the above problems, a semi-supervised fault diagnosis method based on graph convolution is proposed. Firstly, the KNN graph construction method based on Euclidean distance (ED-KNN) is used to achieve label propagation. Then, a graph convolutional network framework based on dot product attention mechanism (GPGAT) was constructed to enhance the weights of high similarity nodes and diagnose bearing faults. The proposed method is validated on a public bearing dataset. The results show that the proposed method can make full use of very few labeled samples for fault diagnosis. Compared with other state-of-the-art methods, the proposed method achieves better diagnosis performance.

1. INTRODUCTION

Rotating machinery plays a crucial role in manufacturing, industrial robotics, transportation, and other fields. Bearings, as vital components of rotating machinery, may lead to significant economic losses if they fail. Bearings generate vast amounts of data during operation, and how to extract useful information from this data has become a hot topic in bearing fault diagnosis research in recent years n (Zhang et al., 2023). Intelligent fault diagnosis is an automated reasoning process based on data-driven approaches. In recent years, various deep learning models have been successfully applied to intelligent fault diagnosis (Jiao et al., 2020). However, their effective training relies on a large amount of labeled data, which is quite challenging in practical fault diagnosis (Yang et al., 2023). In engineering, labeling and screening data are time-consuming tasks, making it essential to study high-precision bearing fault diagnosis methods under extremely scarce labeled samples.

Semi-supervised learning can leverage a small number of labeled samples to learn the information contained in the vast majority of unlabeled samples. In recent years, it has been widely studied in intelligent fault diagnosis in mechanical systems. Ding et al. (2023) trained multiple GANs to eliminate abnormal cases, thereby enhancing the performance of small-sample fault diagnosis in a semi-supervised manner. Yu et al. (2020) investigated a data augmentation method based on consistency regularization, which achieved fault diagnosis of bearings in cases where labeled samples are limited. Zhang et al. (2019) proposed an Active Semi-Supervised Learning GAN (ASSL-GAN), which minimizes the loss function through alternate updates to achieve higher accuracy. These methods can to some extent address the challenge of insufficient labeled samples in fault diagnosis tasks.

In recent years, with the flourishing development of Graph Neural Networks (GNNs) (Scarselli, F. et al., 2019), graph-based semi-supervised algorithms have gradually become a research hotspot. A graph based semi supervised learning algorithm propagates labeled data labels to unlabeled data by constructing a graph. The following paper provides a similar method implementation. Xie et al. (2022) utilized multi-scale graph convolution to aggregate multi-scale information of labeled samples and introduced an attention mechanism to form a new adaptive feature fusion layer. They proposed the Semi-supervised Multi-Scale Attention Graph Convolutional Network (MSA-GCN) for fault diagnosis and achieved satisfactory results. Kavianpour et al. (2022) addressed the issues of insufficient labeling of fault diagnosis data, changing operating conditions, and data loss in practical applications by aligning subdomains of the same class. They proposed a semi-supervised method based

on Autoregressive Moving Average (ARMA) filter graph convolution, adversarial adaptation, and Multi-layer Multi-kernel Local Maximum Mean Discrepancy (MK-LMMD). The above literature demonstrates the unique advantages of Graph Neural Networks in semi-supervised learning. However, this research still faces challenges such as high labeling rates and model instability under extreme labeling conditions, and there are still some shortcomings in feature mining for low-labeled samples, limiting its practical application.

In response to the scenario of fault diagnosis with extremely few labeled data, this paper proposes a network that combines Euclidean distance-based KNN graph (ED-KNN) with dot product graph attention mechanism (DPGAT). By utilizing Euclidean distance to measure the distance between labeled and unlabeled samples, an accurate KNN graph is obtained. Then, the dot product attention mechanism is used to further increase the weights of neighboring nodes with high similarity, in order to learn the optimal representation of the graph. The proposed method is experimented on a publicly available bearing dataset. The results demonstrate that the proposed method achieves high-precision classification of unlabeled data with minimal training on extremely few samples, indicating its significant engineering application value.

2. RELATED THEORIES

2.1. Graph neural networks

Unlike convolutional neural networks (CNNs), graph neural networks (GNNs) are a class of learning models based on graph-structured data. They can define graph convolutions based on the connections between nodes in non-Euclidean space. The difference between CNNs and GNNs in terms of convolution can be intuitively illustrated as shown in Figure 1. The involved graph structure can be simplified as follows:

$$G = (H, A) \tag{1}$$

Here, $H = \{\boldsymbol{h}_1, \boldsymbol{h}_2, \cdots, \boldsymbol{h}_n\} \in R^{n \times d}$ represents the set of nodes; n is the number of nodes; d is the dimensionality of the input node features; $A \in R^{n \times n}$ represents the adjacency matrix representing the connections between nodes. The graph convolutional layer updates node features by aggregating neighboring node features. Typically, given the input graph G, the convolutional layer outputs a new set of node features $\boldsymbol{H}' = \{\boldsymbol{h}_1', \boldsymbol{h}_2', \cdots, \boldsymbol{h}_n'\} \in R^{n \times d'}$ with dimension d'. The graph convolutional layer can be represented as:

$$h_i^{'} = \Gamma(h_i, \mathrm{Y}(\{\boldsymbol{h}_j \mid j \in N_i\})) \tag{2}$$

Among them, N_i is the number of neighboring nodes of node hi; $\Gamma(\cdot)$ represents nonlinear layers; $\mathrm{Y}(\cdot)$ represents a certain node aggregation pattern.

2.2. Semi-supervised Learning with GNN

Graph-based semi-supervised learning typically involves establishing explicit relationships between labeled data and a large amount of unlabeled data using a graph structure, where data points are represented as vertices and the similarity between points is represented as edges. The constructed graph is then inputted into a graph neural network to obtain feature-level representations of the graph and its nodes. These graph-level or node-level features are then fed into a classifier for classification and fault diagnosis. This process leverages the graph structure to effectively utilize both labeled and unlabeled data for semi-supervised fault diagnosis.

3. PROPOSED METHOD

3.1. ED-KNN

Graphs can represent the similarity relationships between samples. Initially, the time-domain vibration signals collected from bearings are segmented via multiple sampling. Subsequently, these segments are transformed into frequency-domain signals using Fast Fourier Transform (FFT). The KNN graph is constructed by assessing the adjacency between labeled and unlabeled samples using Euclidean distance. The distance metric formula utilizing Euclidean distance is:

$$dis(x_i, y_i) = \left(\sum_{l=1}^{d} |x_i - y_i|^2 \right)^{\frac{1}{2}} \tag{3}$$

Where x_i represents the feature of the central node and y_i represents the neighboring node of x_i. For a certain central node $x' \in x_i$, the distance values between it and other neighboring nodes are arranged in ascending order:

$$D = \{dis_1(x', y_1), ..., dis_n(x', y_n)\}, (dis_1 < ... < dis_n) \tag{4}$$

The neighboring nodes of node x' are selected through k-nearest neighbors, denoted as:

$$\mathrm{Top-k} = \{x_1', x_2', ..., x_k'\} \tag{5}$$

Top-k represents the set of k-nearest neighbors of x_i, where k is the number of nearest neighbors. Through experiments, it has been found that when k is set to 5, the quality of the constructed graph is satisfactory. By constructing the ED-KNN graph, each time k unlabeled data points are assigned pseudo-labels. This step establishes an intrinsic graph structure connection between labeled and unlabeled observed data, which can be regarded as a form of label propagation process.

When applying KNN nearest neighbor search, the sample set consists of all the samples from the bearings in that sample set. The connecting nodes are selected based on the proximity

determined by distances, where the top K nearest neighbors are chosen.

ED-KNN graph construction utilizes the similarity of feature vectors among samples to establish connections between them. By exploiting the joint dependencies between labels, label information is propagated along these connections, enabling the assignment of pseudo-labels to unlabeled samples. This approach facilitates a more thorough exploration of limited label information, thereby augmenting the model's capacity to learn from label information. The intuitive workflow is depicted in Fig. 1. Among them, when constructing the training set, the ED-KNN graph is constructed with labeled data as the central node and unlabeled data as neighboring nodes. Due to the large number of unlabeled data, there will be unlabeled data that has not been assigned and will not participate in model training. Meanwhile, the same sample may also be repeatedly labeled and participate in the construction of graphs with different central nodes. It is worth noting that since we use the entire graph for training, Neighboring nodes output features through weighted output. Therefore, nodes that are repeatedly labeled will not affect training, as they will be assigned different node weights in different graphs. When constructing the test set, all unlabeled data points in the test set are sequentially used to calculate the Euclidean distance from all other samples, and the top K-nearest samples are selected as neighboring nodes. Therefore, the number of constructed graphs is the same as the number of samples in the test set. Labeled data is only provided during the training phase, while in the testing phase, there is no availability of labeled data. When performing convolution calculations after constructing a graph, it is necessary to ensure that the number of linked nodes is consistent, otherwise graph convolution calculations will be very difficult. Therefore, we construct a KNN graph based on the top 5 nearest neighboring nodes. In fact, calculating the distance between nodes, selecting nodes through counting, and selecting nodes through threshold are similar.

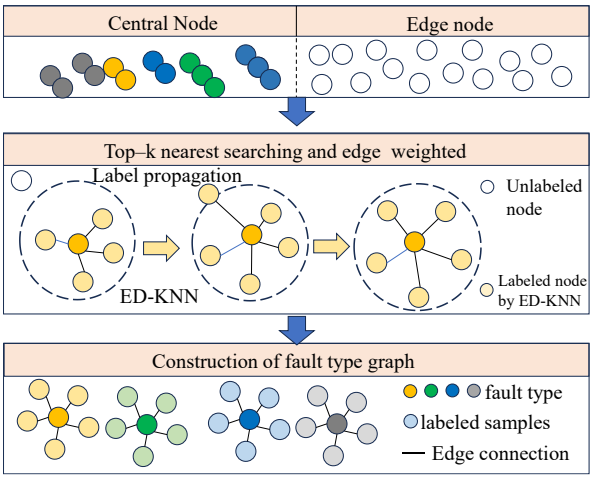

Figure 1. The process of ED-KNN.

3.2. DPGAT Diagnosis Framework

This paper proposes utilizing the dot-product attention mechanism to better learn graph representations by computing the weights of neighboring nodes' influence on the central node. Let $h=\{h_1,h_2,\ldots,h_N\}, h_i \in \mathbb{R}^F$ denote the input features of nodes, where N and F represent the number of nodes and the feature dimension, respectively. The output features of nodes are denoted as $h'=\{h_1',h_2',\ldots,h_N'\}, h_i' \in \mathbb{R}^{F'}$. $W \in \mathbb{R}^{F' \times F}$ represents the weight matrix of linear transformations applied at each node. Finally, softmax normalization is applied, followed by Leaky ReLU to introduce non-linearity. The output features of nodes are obtained using the following equation:

$$\mathbf{h}_i' = \sum_{j \in N_i} \alpha_{ij} \mathbf{W} \mathbf{h}_j \tag{6}$$

α_{ij} signifies the attention coefficient from neighboring node j to central node i, reflecting the significance of node j with respect to node i. α_{ij} is derived through SoftMax normalization of the attention parameter e_{ij} for each edge. The expression for the attention coefficient of node pair (i,j) is given by:

$$\alpha_{ij} = \mathrm{softmax}(e_{ij}) = \frac{\exp(e_{ij})}{\sum_{k \in N_i} \exp(e_{ik})} \tag{7}$$

The attention parameter e_{ij} is obtained through the outer product attention mechanism, which originates from node representation learning (Kim, D., & Oh, A. , 2022). The outer product of a node with its transpose can be regarded as its attention score. The mathematical expression for the outer product attention mechanism is:

$$e_{ij} = (\mathbf{W}h_i)^{\mathrm{T}} \cdot \mathbf{W}h_j \tag{8}$$

Plugging it into Eq. (7) enables us to obtain the attention coefficients for each pair of nodes.

$$\alpha_{ij} = \mathrm{softmax}(e_{ij}) \tag{9}$$

The features outputted by DPGAT are inputted into a fully connected (FC) layer to obtain the predicted label set. The prediction process can be represented as:

$$z_i = FC(\mathbf{h}_i') \tag{10}$$

The loss function of the DPGAT is:

$$loss_{Class} = -\frac{1}{I} \sum_i^I \sum_t^T y_i^{(t)} \ln(z_i^{(t)}) \tag{11}$$

Here, I denotes the label index; T stands for the number of classes; $y_i^{(t)}$ represents the t-dimensional value of the true labels; and $z_i^{(t)}$ signifies the t-dimensional value of the predicted label z_i.

3.3. The Overall Procedure

The overall framework of the proposed method is shown in Fig. 2, with specific explanations as follows.

1) Signal Acquisition: Collect vibration signals from bearings using sensors on the experimental platform.

2) Graph Construction: Divide the collected vibration signals into multiple independent samples and split them into training and testing sets. The training set comprises a small amount of labeled data and real collected data, while the testing set consists only of unlabeled data. Utilize the ED-KNN method to obtain the KNN graph.

3) Model Training: Construct a feature extraction network based on DPGAT. Obtain output features through Eq. (6). Input the training set sequentially into two DP-GAT layers and two FC layers, and obtain the predicted label set through Eq. (10). Then compute the loss using Eq. (11).

4) Model Testing: Feed the unlabeled testing set into the trained model to obtain diagnostic results and compare them with other semi-supervised fault diagnosis methods based on common GNNs.

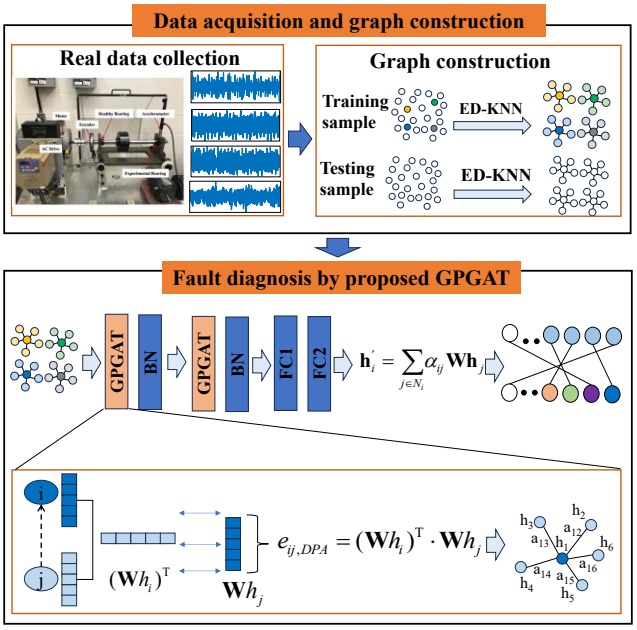

Figure 2. The framework of proposed method.

4. Validation Of Performance

The effectiveness of the proposed method was validated through two semi-supervised fault diagnosis instances. In Case 1, the dataset from Case Western Reserve University (Smith et al., 2015) was utilized, while in Case 2, the dataset from the University of Ottawa (UofO) (Huang & Baddour, 2018) was employed. To demonstrate the superiority of the proposed approach, it was compared with seven widely researched graph neural networks, including Basic GAT (Veličković et al., 2018), DGAT, Graph Transformer (Shi et al., 2021), GraphConv (Morris et al., 2019), ChebConv (Defferrard et al., 2016), GraphSage (Hamilton et al., 2017), and GEN (Li et al., 2016). The above methods are only for graph convolutional models and do not involve a semi supervised learning process. We put it into the semi supervision framework proposed in this paper (using ED-KNN construction diagram) to verify the progressiveness of the proposed GPGAT.

4.1. Case 1: CWRU Dataset

The CWRU dataset was tested using SKF 6205 drive-end bearings. The sampling frequency of the accelerometer was 48 kHz. The bearing loads were categorized as 0HP, 1HP, 2HP, and 3HP, with corresponding speeds of 1797rpm, 1772rpm, 1750rpm, and 1730rpm, respectively. The health conditions of the bearings included four forms: Inner Race Fault (IF), Rolling Element Fault (ReF), Outer Race Fault (OF), and Normal Condition (NC). For each health condition's vibration signal, a sampling length of 1024 and the same sampling interval are used to ensure that there is no repetition between the data, resulting in 400 samples. These 400 samples were then randomly divided into training and testing samples at a ratio of 1:1. Verify the effectiveness of the proposed method through accuracy validation on the test set

Table 1. Description of the CWRU dataset.

Fault type	Speed(rpm)	Labeled samples and labeled rate	Train	Test
OF IF ReF NC	1730	4×1(0.25%)	4× 200	4× 200

4.2. Case 2: UofO Dataset

The dataset originates from the SpectraQuest Mechanical Fault Simulator at the University of Ottawa. Two ER16K ball bearings were installed to support the rotating shaft, which could be replaced with bearings in different health states. Accelerometers (ICP accelerometer, model 623C01) were placed on the experimental bearing housing for vibration data collection, while an incremental encoder (model EPC-775) measured the shaft speed. The signal sampling frequency was 200 kHz, and each experiment lasted for 10 seconds, including both acceleration and deceleration processes. For Case 2, vibration signals from bearings in four different states, including three types of faults and normal condition, were selected. The length of each sample was 4096 sampling points.

Table 2. Description of the UofO dataset.

Fault type	Speed(rpm)	Labeled samples and labeled rate	Train	Test
OF IF ReF NC	846~1428	4×20(5%)	4×200	4×200

4.3. Experimental Results

To validate the superiority of the proposed construction method, the GPGAT was compared with seven others advanced GNN methods, and the average diagnostic accuracy is shown in Tables 3. In Case 1, the proposed GPGAT achieved a classification accuracy of 98.67%, which is 2.5% higher than the other best-performing method DGAT. In Case 2, the proposed GPGAT achieved a classification accuracy of 97.38%, which is 2.71% higher than the other best-performing methods GAT and ChebConv. The GPGAT proposed in this paper achieved better diagnostic accuracy compared to other graph convolution methods on both datasets, validating the effectiveness of the proposed approach.

Table 3. The test accuracy on the Case 1 and Case 2.

Method	Case1	Case2
GPGAT(Proposed)	**98.67%**	**97.38%**
GAT	95.57%	94.87%
DGAT	96.17%	90.38%
Graph Transformer	90.58%	85.00%
GraphConv	94.17%	93.63%
ChebConv	95.14%	94.87%
SAGE	95.83%	87.17%
GEN	91.75%	91.37%

To further demonstrate the diagnostic performance of the proposed method, we visualize the confusion matrix for Case 2, as shown in Fig. 3. Each health state has 200 test samples. The horizontal axis represents the predicted labels, while the vertical axis represents the true labels, where 0-3 denote the four health states OF, IF, ReF, and NC listed in Table 2. It can be observed that for the multi-class classification task, the proposed method GPGAT exhibits the best diagnostic performance.

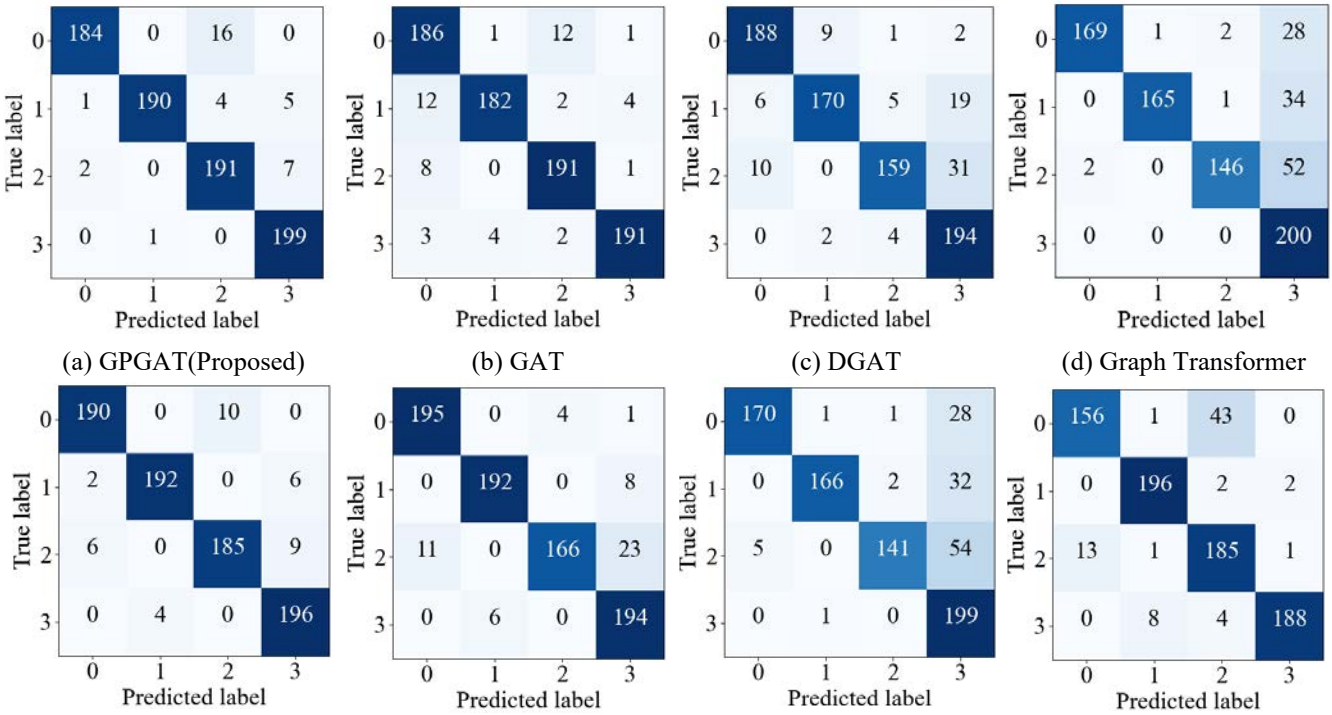

Figure 3. Classification confusion matrix for Case 2.

To better illustrate the feature extraction performance of the proposed method, the output feature vectors are reduced to two dimensions using T-SNE for Case 2, as shown in Fig. 4. From (a), it can be seen that the four types of features

represented by the four colors have a good degree of aggregation, and the distance between each type is relatively far, indicating that the proposed GPGAT has a good feature extraction ability. The features extracted by GPGAT exhibit higher aggregation and greater distances from each other compared to other methods. The proposed method demonstrates better discriminative ability for all health states, and GPGAT maintains good diagnostic performance even at extremely low label rates.

(e) ChebConv (f) GraphConv (g) SAGE (h) GEN

Figure 4. 2D visualization of the output features for all the methods on Case 2.

4.4. Discussion on Labeled Rate and K-value

To validate the effectiveness of the proposed method under small sample conditions, Case 2 dataset was trained and tested with labeled samples of 4, 8, 12, 16, and 20. The experiments were repeated ten times to obtain diagnostic accuracy. As shown in Fig. 5, it can be observed that as the label rate increases from 1% to 5%, the testing accuracy continues to improve. Even with a label rate of 1%, a fault diagnosis rate of 93.75% can be achieved, while a label rate of 5% yields a fault diagnosis accuracy of 97.38%.

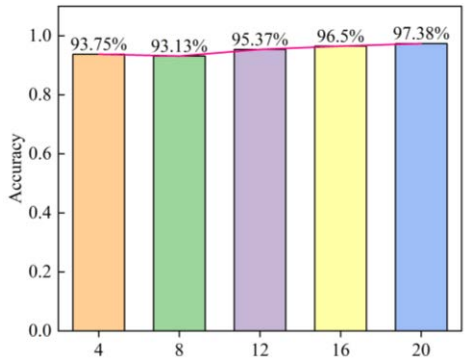

Figure 5. Accuracy of the proposed method with different low labeling rates.

Next, we discuss the influence of the *k* value used to construct the ED-KNN. The *k* value represents the number of neighboring nodes connected to each central node when creating the KNN graph. Using the proposed method, experiments were conducted on the two datasets at a label rate of 1%. Fig. 6 shows the effect of different *k* values on the diagnostic accuracy of the proposed model. It can be observed that on both the CWRU and UofO datasets, the diagnostic accuracy reaches its highest value when *k*=5, with accuracies of 100% and 93.75%, respectively. On the CWRU dataset, the change in accuracy with increasing K values is not particularly significant. This is mainly because the CWRU dataset is collected under steady-state conditions with artificially injected bearing faults, resulting in clean data with very distinct fault characteristics. Therefore, even with smaller K values, a good label propagation efficiency can be maintained. In contrast, the UofO dataset is collected under time-varying conditions, with faults occurring naturally, making fault characteristics less pronounced. Hence, an appropriate K value is required for ED-KNN. A suitable K value ensures that as much unlabeled data as possible is incorporated into the graph while minimizing graph construction errors.

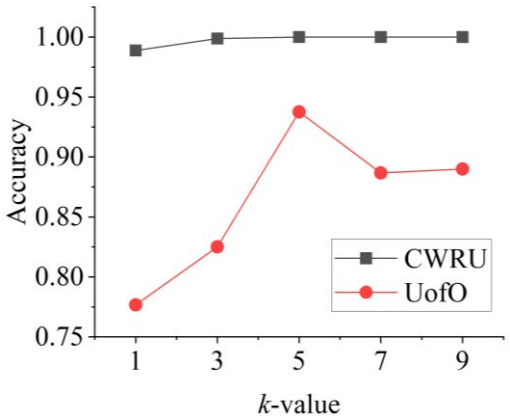

Figure 6. Diagnostic accuracy with different k values.

5. Conclusion

In response to the challenges faced by fault diagnosis under conditions of few samples, this paper proposes a new semi-supervised fault diagnosis method. The proposed ED-KNN calculates the Euclidean distance and sorts the distances in order to obtain the nearest neighboring nodes. It achieves label propagation from labeled data to unlabeled data. The designed GPGAT assigns different importance information to neighboring nodes through the dot product attention mechanism, further enhancing the reliability of the graph. Experimental validation was conducted on the CWRU and UofO dataset. Comparative results indicate that: (1) ED-KNN can effectively construct an undirected graph of labeled and unlabeled data, achieving label propagation. (2) The constructed GPGAT can assign different importance to neighboring nodes, thereby more accurately extracting node features and classification information from the KNN graph. (3) Compared with other state-of-the-art methods, the proposed approach can more accurately diagnose unlabeled samples under conditions of few or even extremely few samples.

ABSTRACT

This research presents an integrated PHM system for 2,000 rotating equipment units across press, car body, paint, and assembly lines in Hyundai/Kia factories. The system addresses limitations of individual monitoring systems by consolidating vibration, current, robot AI diagnostics, PLC backup status, and operational data. Vibration monitoring utilizes wired/wireless sensors, server storage, and automated analysis for trend detection and fault diagnosis. PLC data monitoring retrieves motor drive information (current, temperature, frequency, etc.) to predict equipment anomalies. Robot monitoring integrates with various manufacturers and tracks operational status, motor load, and alarms for maintenance and lifespan management. The PLC backup solution ensures proper backup functionality. The integrated PHM architecture manages data collection, analysis, diagnostics, reporting, and visualization, enabling comprehensive equipment health monitoring and proactive maintenance.

1. INTRODUCTION

The optimal approach to equipment maintenance in the factory involves a maintenance strategy divided into reactive, preventive, and predictive methods. Among these, predictive maintenance stands out as an effective way to anticipate failures through equipment condition monitoring [Paulina Gackowiec]. It provides timely insights into breakdown causes, which is increasingly vital due to the industrial internet of things. The shift from reactive to predictive maintenance represents an innovative process improvement. In the reactive maintenance method, urgent repairs must be carried out post-failure, degrading maintenance quality and endangering workers. Conversely, predictive maintenance enables preemptive action, preventing factory shutdowns. By monitoring conditions and analyzing root causes in advance, maintenance can be performed proactively, and equipment condition can be evaluated thereafter. Sudhanshu Goel's paper highlights the significant potential of condition monitoring in enhancing operational reliability, machine uptime, damage reduction, and operational efficiency at a lower cost [Sudhanshu Goel]. Equipment incipient faults often exhibit variations in temperature, vibro-acoustic signature, etc. Different condition monitoring techniques utilize dedicated sensing and data analysis tools to analyze specific operational characteristic variations [Figure 1].

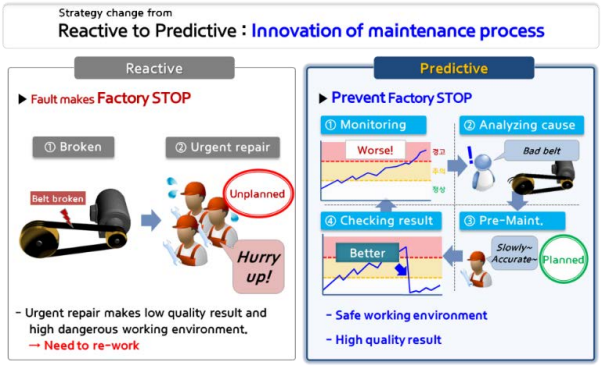

Figure 1. Strategy changes from reactive to predictive

Various sensing techniques such as temperature, pressure, flow, ultrasonic waves, vibration, and acoustic emission can be used to monitor the equipment condition. Among them, vibration monitoring can cover most of mechanical failures such as imbalance, mismatch, bearing defects, gears, looseness, noise, cracks, resonance, etc. [ISO 18436-2:2014] [Figure 2]

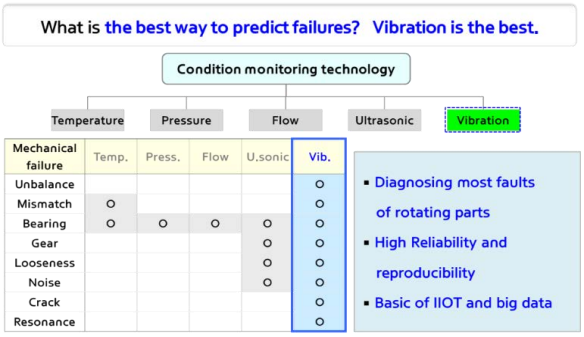

Figure 2. Comparison of Condition monitoring technology

For predictive maintenance, not all equipment is monitored. Instead, sensors, signal processing modules, and servers capable of collecting equipment status data are installed selectively, focusing on those that can lead to extended downtime failures. The primary target equipment includes conveyors, drop-lifters, air conditioner fans, robots, controllers, and communication systems. VMS, or Vibration Monitoring System, monitors vibration data at the equipment's drive in real-time and can predict failures in advance. This system comprises a sensor unit for real-time vibration measurement, a signal processing module, a server for data collection and storage, and a monitoring device for status display. It is implemented on main equipment causing extended downtime failures (downtime exceeding 60 minutes). Over 5,000 sensors are installed in more than 2,000 machines across Hyundai/Kia factories worldwide. All system servers are connected to the company network, allowing authorized executives and employees to access data conveniently from anywhere, enabling real-time monitoring of equipment installed worldwide [Figure 3].

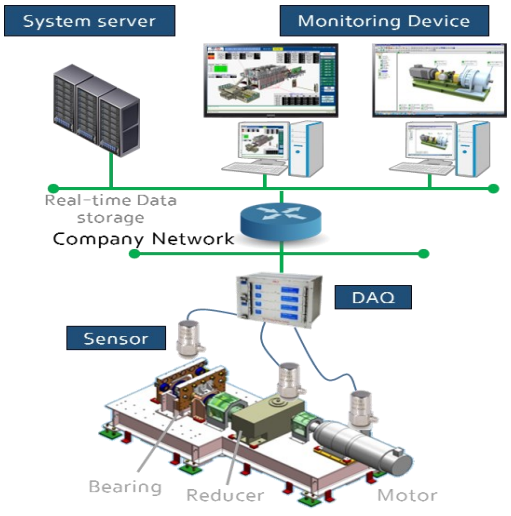

Figure 3. Vibration Monitoring System configuration

Similar to vibration monitoring, an approach to determine the number of shorted turns based on the difference between the phase current of the healthy and faulty machine is proposed [Nandi, S., Toliyat]. Condition monitoring of rotating machinery is crucial for ensuring operational reliability and preventing catastrophic failures. While vibration monitoring has long been the primary method for detecting mechanical faults, current monitoring offers a complementary approach with distinct advantages. Current monitoring is comparatively inexpensive to implement and is well-suited for diagnosing electrical faults in motors and inverters. This system also includes development and application of current-based condition monitoring technology to prevent electrical faults in rotating machinery. Technology for monitoring the current of the equipment's driving unit has been developed and implemented. However, challenges such as slow sampling of current data, the requirement for a large-capacity server, and a lack of diagnostic technology persist. To address this issue, a diagnostic function block capable of current analysis has been developed and deployed. Integrated within the PLC controller's code programs, this diagnostic function block receives various parameters including current, frequency, and control setting values of the equipment's driving unit as input. The output comprises diagnostic results, which are transmitted to the cloud server for analysis. The figure depicting the diagnostic function block is shown below [Figure 4].

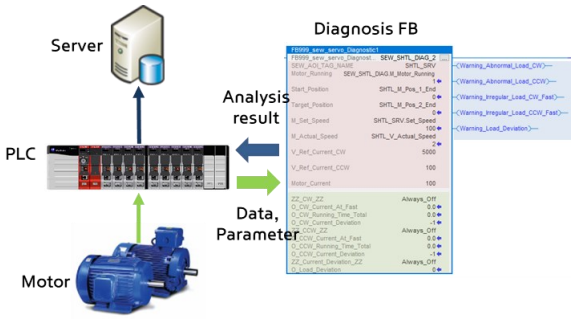

Figure 4. diagnostic function block for current monitoring

The increasing complexity and autonomy of robotic systems necessitate advanced condition monitoring techniques to ensure their reliable operation and prevent costly downtime. Traditional condition monitoring approaches often rely on centralized cloud-based data processing, which can lead to latency issues and communication bottlenecks. Edge computing offers a promising alternative by enabling real-time data analysis and decision-making at the edge of the network, closer to the data source [Niklas Tritschler].

This system involves installing vibration sensors on the motor and reducer of each axis of the robot and applying an autoencoder algorithm to assess anomaly scores. An edge

device was developed and utilized as a CMS (DAQ) to gather vibration data from the robot. Figure 5 illustrates the structure of robot vibration diagnosis system based edgeCMS system.

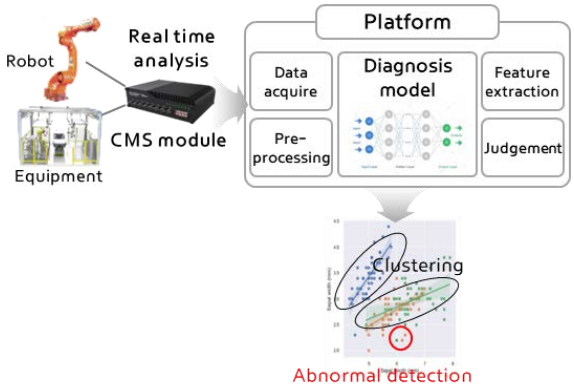

Figure 5. Robot vibration diagnosis system with edgeCMS

To monitor the condition of industrial robots, each manufacturer develops and provides a robot monitoring system. Hyundai(HRMS-Hyundai Robot Monitoring System), Yaskawa(Y-FAI) , Kawasaki(KRDS-Kawasaki Robot Diagnostic System), and Fanuc(ZDT-Zero Down Time system) robots are representative examples. The manufacturer's monitoring system typically displays basic operation information such as model and operation status graphs, along with notification history. It also provides alarm information and component replacement time when the reference value deviates from statistical norms. However, this system lacks failure prediction functionality. To address this, a Robot Predictive Maintenance System (RPMS) was developed. This system utilizes autoencoder models to learn normal states from manufacturer-provided robot monitoring data and identifies deviations from normal states [Figure 6].

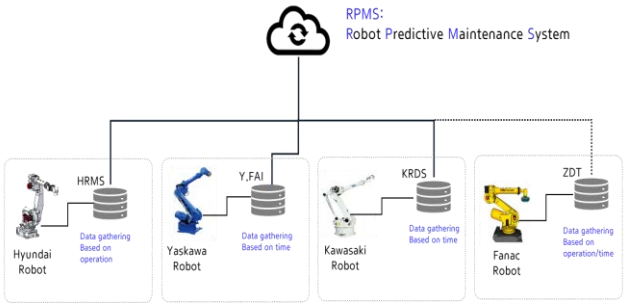

Figure 6. Robot monitoring system

The PLC(Programmable Logic Controller) program backup system is being implemented. It mainly consists of an agent PC managing program change points and a database storing the results. Hyundai/Kia factories employ PLCs from various manufacturers including Siemens, Rockwell, Mitsubishi, Fuji, and LS, and all systems managing program change points of these PLCs are in use. However, to address issues related to ineffective program backup when the agent PC is improperly managed, a cloud-based technology integrating agents and databases has been developed. This technology manages fluctuation points effectively. Figure 7 illustrates the structure of the PLC program backup system based on the cloud.

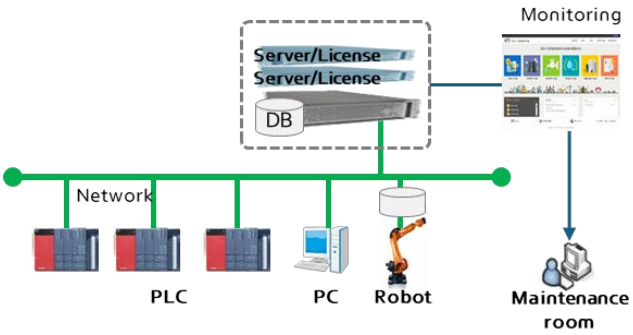

Figure 7. PLC program backup system based on cloud

2. INTEGRATED PHM SYSTEM

As the equipment monitoring system is currently implemented as separate systems, managing equipment becomes cumbersome. This involves checking multiple individual systems separately to diagnose a single piece of equipment, and there is no comprehensive system for analyzing equipment data. To address these challenges, a next-generation integrated Prognostics and Health Management (PHM) system is being developed. This integrated PHM system, based on existing accumulated monitoring technology and diagnostic expertise, is being deployed in new factories within the Hyundai/Kia company.

2.1. Configuration of Integrated PHM system

The aim of the integrated PHM system is to consolidate equipment failure data monitoring and enhance failure diagnosis and analysis capabilities. The system comprises sections for equipment monitoring, diagnostic report management, fault diagnosis algorithms, and data transmission/reception interfaces.

Equipment monitoring encompasses vibration, drive current, electrical equipment status, PLC program backup status, robot operation status, robot vibration status monitoring, alarm lists, and maintenance history inquiries. Additionally, it enables monitoring of equipment status trends and system resources through trend graphs.

Diagnostic report management is linked with equipment abnormality alarm event management, facilitates automatic report generation and email dispatch of diagnostic reports, and integrates with the prevention task instruction module in ERP(SAP).

The analysis algorithms promote advanced analysis techniques, including time series trend analysis, frequency/pattern analysis, harmonic/rotational speed analysis, automatic vibration state analysis, and automatic failure type determination algorithms that detect sudden state changes.

Utilizing the IoT(Internet of Things) platform and Hyundai/Kia's standard collection module, the system collects equipment state data and offers basic functions for efficient and reliable data management. These include alarm management, equipment registration, device control, data collection, and algorithm management.

Currently, the integrated PHM system monitors equipment/robot vibration status, status of current, control panel status, network switch status, robot status, and PLC backup status. However, it can accommodate new monitoring solutions for equipment condition diagnosis. Figure 8 illustrates the configuration of the integrated PHM system.

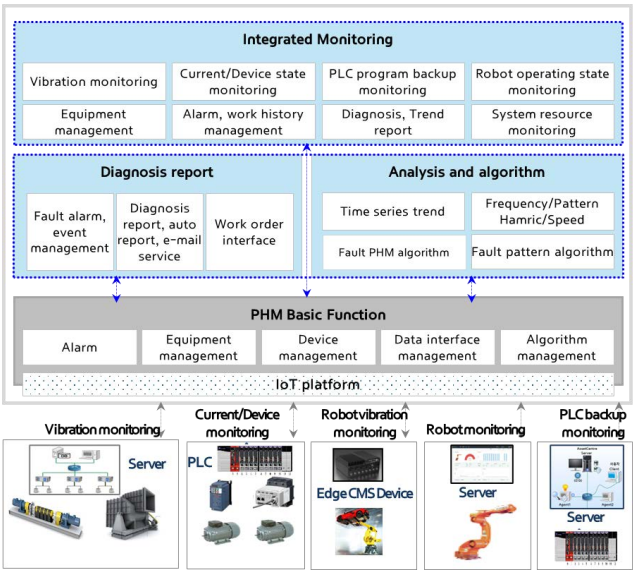

Figure 8. Configuration of integrated PHM system

Several data transactions and signal processing tasks are necessary for the integrated PHM system, including real-time data collection and analysis, CMS(Condition Monitoring System) device control, AI(Artificial Intelligence) algorithm execution, and accounting for network load and security considerations. Consequently, physical servers need to be configured for each factory.

The integrated PHM server comprises a web/app server, a DB(Database) server, and an Factory Talk Linx Gateway server(Rockwell) for interfacing with current and electronic component data. Figure 9 illustrates the configuration of the integrated PHM server.

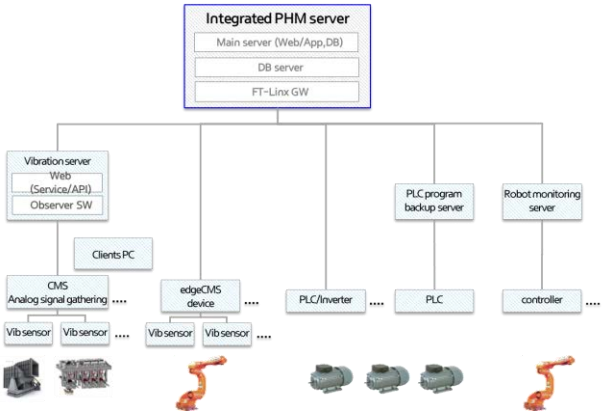

Figure 9. Configuration of integrated PHM server

2.2. Architecture of Integrated PHM system

The architecture of the integrated PHM system is designed to collect, analyze, and present equipment source data. Vibration monitoring, robot monitoring, and PLC backup utilize dedicated servers, with data stored on these servers interfacing with the integrated PHM server via a DB-to-DB interface method.

For collecting current/control panel state monitoring data, PLCs in the control panel gather and analyze necessary data using function blocks. This data is then collected by a dedicated collection server such as FTLinx GW and stored in the integrated PHM's InfluxDB using the OPC-UA protocol. FTLinx GW serves as a collecting tool for Rockwell systems, whereas different servers are required for PLCs from other manufacturers such as Siemens, LS, and Mitsubishi.

Robot vibration data is collected from the edge CMS device, and the analysis result is transmitted to the integrated PHM server through a file collection batch process. As the results from edgeCMS are stored as files, the system must possess the capability to collect and manage files.

The collected equipment status data undergoes backend analysis, including vibration and current abnormality diagnosis, diagnosis notification/report management, equipment status management, external system connection, data collection management, device/alarm management, and visualization data management.

At the front end, functions such as factory map-based equipment management, equipment status management/alarm management, and equipment-based information data visualization are implemented. Further details are provided in Figure 10 below.

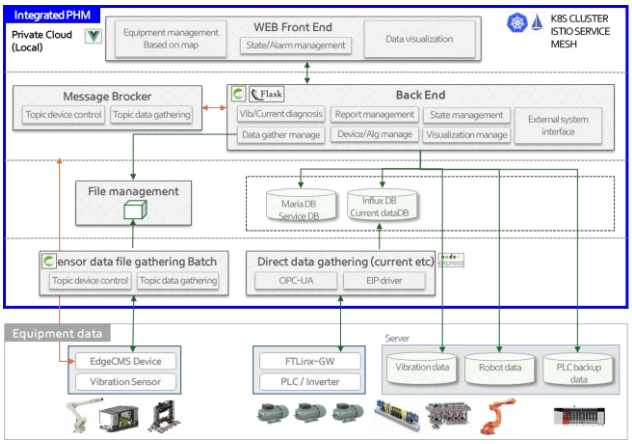

Figure 10. Architecture of Integrated PHM system

2.3. Monitoring contents and user interface

2.3.1. Main integral monitoring

The integrated system encompasses various monitoring purposes and incorporates a user-friendly UI/UX application, incorporating different factors based on a map interface. This enhances efficiency for maintenance engineers. Additionally, AI PHM algorithms are integrated into the system, enabling automatic vibration detection and spectrum analysis, serving as powerful tools. Automatic email notifications of abnormalities further enhance maintenance efficiency.

The main page of the integrated PHM system shows the equipment list, equipment status statistics (normal, caution, warning), daily alarm trends, shop-specific diagnostic result statistics, itemized diagnostic result statistics, and equipment status displayed on a map. Moreover, the system automatically presents analysis results on the main page to improve user intuition. Alarm history, diagnosis reports, action details, and maintenance work management content are also accessible on the main page. Specific and detailed results can be viewed by clicking on each menu. Figure 11 provides an example of the integrated main page.

Figure 11. Main page of Integrated PHM system

2.3.2. Vibration monitoring

The vibration monitoring analysis page configuration presents the average vibration level for each sensor along with the automatically calculated vibration variation. Sensors exhibiting significant changes are highlighted in red. Additionally, the page displays the equipment's vibration trend over time and automatically analyzed results of frequency spectrum analysis. For detailed spectrum analysis, 3D plots and heat maps are provided. Furthermore, the system features automatic generation and emailing of diagnostic reports [Figure 12].

Figure 12. Vibration monitoring page

2.3.3. Current and control panel state monitoring

For equipment current state monitoring, the system displays comprehensive analysis results of parameters such as current data and frequency data from the inverter driving the motor. These values indicate diagnostic results such as load current performance and fluctuations during machine operation. Additionally, the system enables monitoring of elements crucial for the inverter's lifespan, including IGBT, capacitor, and temperature. Sensor data for each location of the drop-lifter equipment, responsible for moving the car up and down, is also presented for monitoring sensor status. Furthermore, the system organizes a page to monitor power, temperature, and lifespan of the main elements in the control panel [Figure 13].

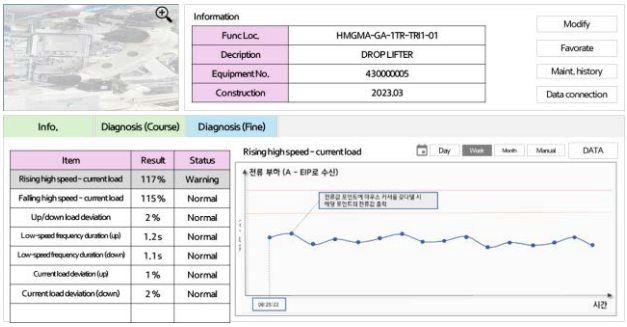

Figure 13. Current/Control panel monitoring page

2.3.4. Robot vibration monitoring

The method for diagnosing the vibration state of robots differs from that of general equipment described earlier. Unlike conventional equipment, robots lack distinct movement patterns and have short constant speed sections, making diagnosis challenging with traditional vibration analysis methods. To address this, a vibration sensor is attached to each axis of the robot, and an AI algorithm, specifically the auto-encoder method, is employed to predict signal outliers. By utilizing an auto-encoder, the difference between normal and abnormal data can be transformed into a health index score, facilitating equipment state trend prediction. The figure below illustrates the monitoring of the robot's vibration status [Figure 14].

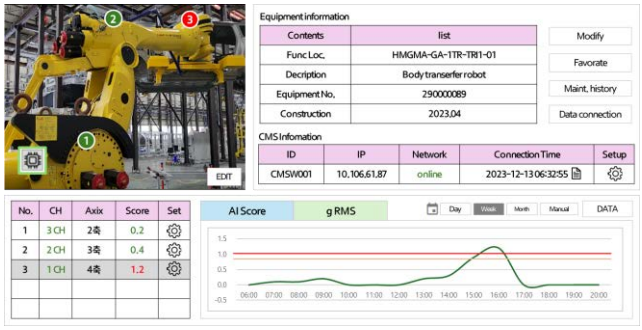

Figure 14. Robot vibration monitoring page

2.3.5. Robot operation monitoring

In the automotive manufacturing factory, there are 600 industrial robots in the vehicle welding factory, 200 in the painting factory, and 100 in the assembly factory. A robot monitoring system is developed and installed in each factory to monitor the operation information and condition of the robots. Since monitoring the operation status, alarm history, and error information of hundreds of robots in individual systems is challenging, the system is configured to initially display key results in coordination with the integrated PHM system, allowing users to review detailed information in individual robot monitoring systems as needed [Figure 15].

Figure 15. Robot operation monitoring page

2.3.6. PLC program backup monitoring

The equipment controller utilizes PLC, primarily employing ladder programs. When equipment operation is altered, monitoring the normality of program backups is managed through the PLC backup status inquiry page. This page displays the location, equipment name, and final backup date, and indicates any communication issues or conditions if backups are not performed. The image below depicts the PLC backup status inquiry page [Figure 16].

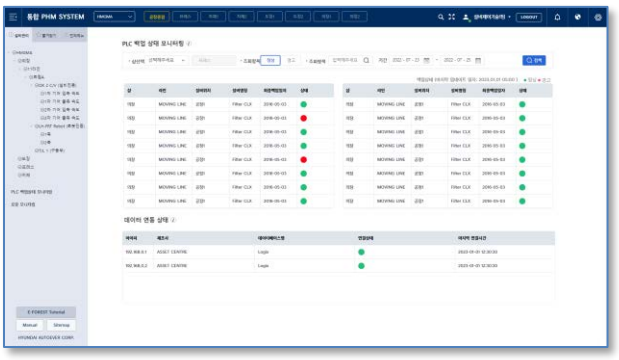

Figure 16. PLC backup monitoring page

3. Practical Application

Various PHM technologies for monitoring and predicting equipment conditions are being implemented in production plants. Initially, an integrated PHM system, integrating these technologies, is being deployed in new factories within Hyundai/Kia. These include the HMGMA Plant under construction in Savannah, Georgia, as well as the Gwangmyeong EVO Plant, Ulsan EV Plant, and Hwaseong EVO Plant in Korea. Subsequently, monitoring will extend to enhance equipment uptime across mass production plants. Equipment monitoring and technical support are facilitated by the Equipment Monitoring Center at Hyundai Motor's Ulsan plant [Figure 17].

Figure 17. Equipment Monitoring Center in Hyundai motor.

4. Conclusion

Vibration and current monitoring are underway for 2,000 rotating equipment units throughout Hyundai/Kia factories.

An integrated PHM system is being developed to streamline equipment management and analysis. It integrates data from various monitoring systems, including vibration, PLC, and robot diagnostics, facilitating trend detection and fault diagnosis. The system architecture encompasses components for data management, diagnostic reporting, and external system integration. We plan to continue activities using the integrated PHM system to efficiently monitor equipment status and dramatically improve downtime.

ABSTRACT

Condition monitoring of gears in gearboxes is crucial to ensure performance and minimizing downtime in many industrial applications including wind turbines and automotive. Monitoring techniques using indirect measurements (i.e. accelerometers, microphones, acoustic emission sensors and encoders, etc.) face challenges, including the defect interpretation and characterization. Vision-based gear condition monitoring, as a direct method to observe gear defects, has the capability to give a precise indication of the starting point of a potential surface failure, but suffers from the image annotations (to train a reliable vision model for automatic defect detection of gears). In this paper, we propose an active learning framework for vision-based condition monitoring, to reduce the human annotation effort by only labelling the most informative examples. In particular, we first train a deep learning model on limited training dataset (annotated randomly) to detect pitting defects. To select which samples have the highest priority to be annotated, we compute the model's uncertainty on all remaining unlabeled examples. Bayesian active learning by disagreement is exploited to estimate the uncertainty of the unlabeled samples. We select the samples with the highest values of uncertainty to be annotated first. Experimental results from defect detection of gears in gearboxes show that with less than 6 times image annotations, we can achieve similar performances.

1. INTRODUCTION

Detecting defects on gear surfaces is essential for maintaining the safety, performance, and longevity of machinery, while also ensuring quality control and minimizing downtime and costs, especially for gearboxes in high-power-density machines (e.g., wind turbines). Many approaches exploit indirect measurements acquired from accelerometers, microphones, acoustic emission sensors and encoders to monitor the damage evolution in gears (Surucu, Gadsden, & Yawney, 2023; Feng, Ji, Ni, & Beer, 2023). However, this indirect way of gear condition monitoring (e.g., vibration analysis) suffers from relative indicators and setting good thresholds to accurately track the gear damage (Surucu et al., 2023). Moreover, the indirect measurements cannot well characterize the defects (e.g., size, location, type) of the gears (Van Maele et al., 2023). Vision monitoring, which is a direct method to observe defects has the capability to give a precise indication of the starting point of a potential surface failure. Gear damage is often validated using visual inspection with borescopes or fibre scopes. However, such a system is used in some domains (mainly in wind turbines) as a periodic maintenance procedure but expensive equipment and permanent machine stop is needed (Coronado & Fischer, 2015). Recent advances in computer vision and machine learning have revolutionized industrial maintenance practices, allowing for the development of automated systems capable of visually inspecting and analyzing gear surfaces. Vision-based approaches utilize cameras and sensors to capture images or videos of gears during operation, enabling the extraction of meaningful visual features for condition assessment (Allam, Moussa, Tarry, & Veres, 2021; Qin, Xi, & Chen, 2023; Miltenović, Rakonjac, Oarcea, Perić, & Rangelov, 2022). This shift towards visual inspection not only facilitates continuous monitoring but also provides a more comprehensive understanding of gear health by capturing subtle surface details and anomalies. Massive image data can be acquired by high-speed cameras for visual condition monitoring of gears. Deep learning, particularly convolutional neural networks (Allam et al.,

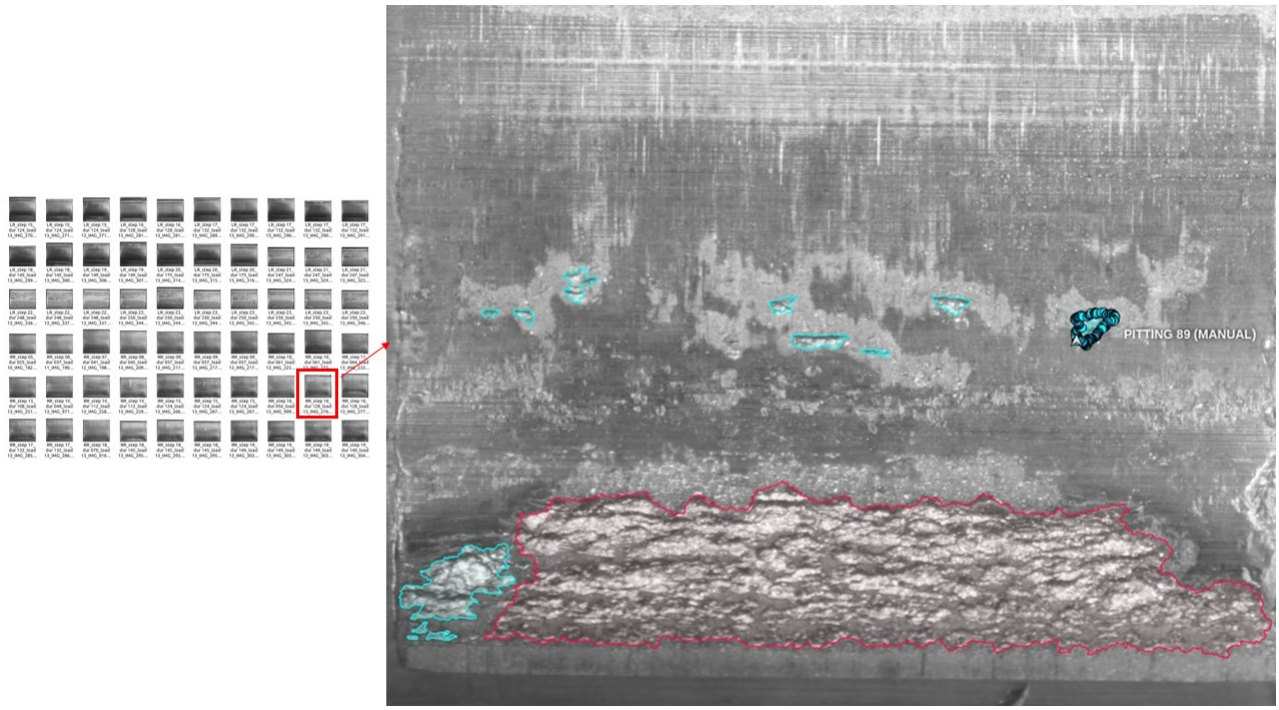

Figure 1. More than 20 minutes were taken by our experts to annotate defect of pitting in a single frame of image. Two types of defects were annotated for all images: micropitting (red), and pitting (cyan).

2021), has shown remarkable success in image-based tasks, making it well-suited for gear surface defect detection. However, to train a reliable vision deep learning model for automatic defect detection of gearboxes, a huge amount of image data typically needs to be annotated, which is expensive and time-consuming (Alzubaidi, Bai, Al-Sabaawi, & et al., 2023). For example, it takes more than 20 minutes to annotate all pitting defects in a single frame of image, as shown in Figure 1. Moreover, image datasets acquired during full lifetime degradation tests datasets contain many similar examples that bring no additional information to the diagnostic model. To overcome these problems, the active learning method was exploited to select the most informative indirect signals (e.g., vibration, supervisory control and data acquisition) for gearbox fault diagnosis (Chen et al., 2019) or wind turbine condition monitoring (Bao, Zhang, Hu, Feng, & Liu, 2023). Recent work on vision-based defect segmentation also showed that active learning framework can reduce data storage and labeling costs for imbalanced industrial datasets (Li et al., 2023).

To reduce the cost on manual annotation, this paper proposes an active learning framework to address the challenge of acquiring labeled data by iteratively selecting the most informative images for annotation. To the best of our knowledge, this paper is the first study to apply deep active learning for vision-based gear defect segmentation/detection in gearboxes. Specifically, a few images (i.e. around 20) were initially annotated to train a deep learning model for defect detection. To choose which gear images will be the first priority to be annotated, we then compute the model's uncertainty on all remaining unlabeled examples, where Bayesian active learning (Atighehchian et al., 2022) by disagreement is exploited to estimate the uncertainty of the unlabeled samples. The samples with the highest values of uncertainty will be chosen to be annotated first. We repeat the image annotations iteratively (e.g., top 10 images ranking according to the uncertainty will be annotated in each iteration) until we achieve a satisfactory performance.

The structure of this paper is as follows. Section 2 introduces the active learning framework. Section 3 details the experimental data collection and processing. The experimental results of defect detection on gear flanks are presented and discussed in Section 4. Finally, the conclusions of this paper are drawn in Section 5.

2. METHODOLOGY

2.1. Deep segmentation model

To monitor the damage evolution in gears, our solution first segments the damaged regions (defect) in the acquired images, then characterizes these damaged regions (change of size, shape, depth, etc.). A Python library with Neural Networks for Image Segmentation based on PyTorch (SMP) (Iakubovskii, 2019) is exploited for defect segmentation task

in this paper, as it is an open-source library built on top of PyTorch, specifically tailored for semantic segmentation tasks in computer vision. Semantic segmentation involves assigning a class label to each pixel in an image, thus dividing the image into distinct regions corresponding to different object classes. Semantic segmentation is additionally assigning each detected object a category and discriminates between objects of the same category. SMP includes an efficient and flexible implementation of Feature Pyramid Network (FPN) (Lin et al., 2017) for semantic segmentation tasks, combining low- and high-resolution features via a top-down pathway to enrich semantic features at all levels (multi-scale features). By leveraging multi-scale features and transfer learning, SMP-FPN enables accurate and robust segmentation of objects in images across various scales and contexts, fitting perfectly with the defect detection in the gears (defect area sizes changing).

The initial training dataset is very limited, since image annotation of these defect in the gears are challenging and time consuming. Therefore, we leverage pre-trained weights from models trained on large-scale image datasets such as ImageNet. The pre-trained weight of ResNet-18 (He, Zhang, Ren, & Sun, 2016), with a convolutional neural network that is 18 layers deep[1], is exploited in our segmentation model. The pre-trained model has been previously trained on more than a million images from the ImageNet database and contains the weights and biases that represent the features of whichever dataset it was trained on. These low-level learned features are often transferable to different data, including gears. For example, a model trained on a large dataset of natural objects (e.g., bird, fish images) will contain learned features like edges or textures that would be transferable defects in gears, which helps improve the performance of the segmentation model (especially with very small training sample size).

2.2. Active learning for image annotation

Even with a pre-trained model, the segmentation performances are still poor, especially for images mixed with two classes of "micropitting" and "pitting", as shown Figure 2, regions of micropitting were misclassified into pitting (poor performances in confusion matrix), while pitting defects were misclassified into background. An easy and simple solution to improve the performances is to add more annotated images into the training dataset. With a high-speed camera, we can acquire more than 60 image per second, around 30,000 images for 8 hours. However, image annotation is time consuming for our experts (an image shown in Figure 1 may take 20 minutes to annotate), even with advanced annotation tool CVAT [2]. Since it is infeasible for an expert to annotate all the acquired images, two challenges need to be solved: (1) which images should be first annotated? (2) how many images should be annotated for a reliable prediction?

Active learning aims to minimize the annotation effort required by selecting the most informative samples for annotation, i.e., the samples that would most increase the model accuracy. Active learning is a machine learning paradigm where a model iteratively queries the user or a human annotator for the labels of the most informative samples. This can lead to significant savings in time and resources compared to traditional approaches that rely on labeling large amounts of data upfront or passive learning from a fixed dataset.

Many active learning approaches have been proposed (Beluch, Genewein, Nürnberger, & Köhler, 2018; Kirsch, Amersfoort, & Gal, 2019; Wan et al., 2023), but some of these methods are either not scalable to large datasets or too slow to be used in a more realistic environment (e.g., in a production setup) (Atighehchian, Branchaud-Charron, & Lacoste, 2020). We exploit Bayesian Active Learning by Disagreement (BALD) (Atighehchian et al., 2020) in this paper to select the most informative samples for annotation. BALD leverages Bayesian modeling to estimate the uncertainty of a predictive model and selects samples where the model's predictions are most uncertain. In particular, BALD involves calculating the mutual information between the model's predictions and the model's parameters, given the observed data. Let D denote the labeled dataset, where $D = (\boldsymbol{x}_i, y_i)_{i=1}^{N}$ with inputs $\boldsymbol{x}_i$ and corresponding labels y_i. Let θ represent the model parameters, and $f_\theta(\boldsymbol{x})$ denote the predictive distribution of the model. The BALD acquisition function is defined as the mutual information between model parameters and potential labels of unlabeled data $\boldsymbol{x}$:

$$\begin{aligned} BALD(x) &= \boldsymbol{I}[y, f_\theta(\boldsymbol{x})] \\ &= \boldsymbol{H}[y] - \boldsymbol{E}_{p(f_\theta(\boldsymbol{x})|D)}[\boldsymbol{H}[y|f_\theta(\boldsymbol{x})]] \end{aligned} \tag{1}$$

Where:

- $\boldsymbol{I}[y, f_\theta(\boldsymbol{x})]$ is the mutual information between the label y and the model's prediction $f_\theta(\boldsymbol{x})$ for an unlabeled data point $\boldsymbol{x}$.
- $\boldsymbol{H}(y)$ is the entropy of the label distribution, measuring uncertainty in the label predictions.
- $\boldsymbol{E}_{p(f_\theta(\boldsymbol{x})|D)}$ is the expectation over the posterior distribution of the model given the current dataset D
- $\boldsymbol{H}[y, f_\theta(\boldsymbol{x})]$ is the conditional entropy of the label distribution given the model's prediction.

Intuitively, samples with higher BALD scores are those for which the model's predictions are most uncertain and thus are most informative for learning. By querying such uncertain samples, the model can learn more effectively with limited annotated data, leading to efficient data annotation for model training. In a normal image annotation task, our expert

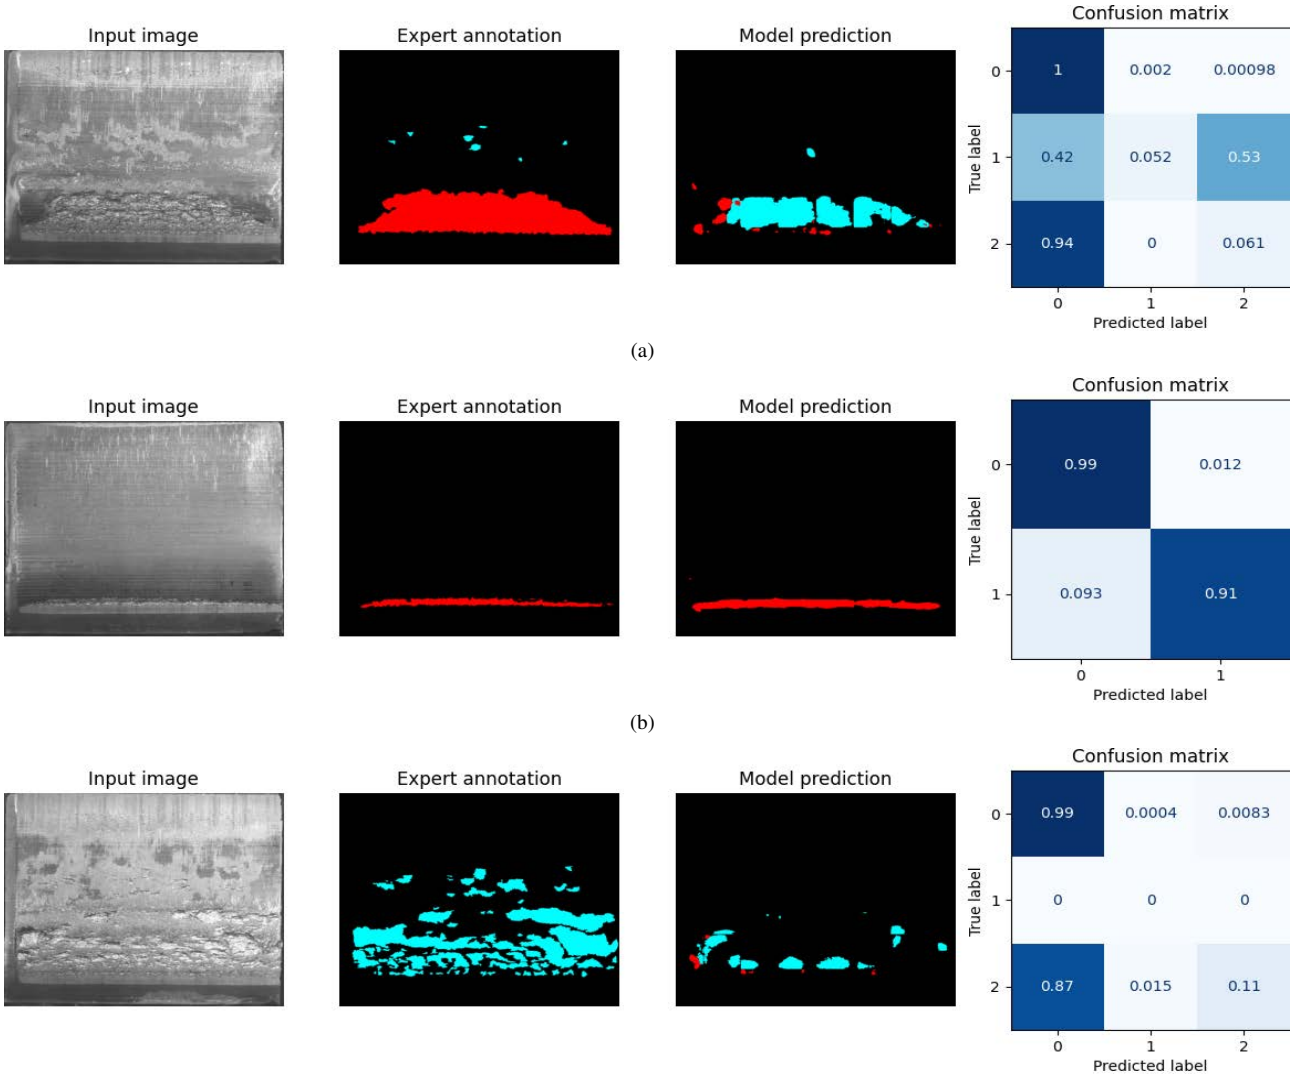

Figure 2. Performances on segmentation model trained on a small training dataset. The confusion matrices in the right column show the performances for three test images, 3 classes were defined by our experts in the images, with class label (color) 0: background (dark), 1: micropitting (red), 2: pitting (cyan).

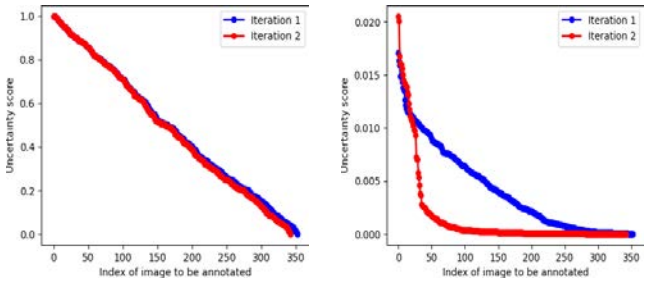
annotators will start annotate images according to their order uploaded into a annotation tools (CVAT) or the project coordinator will assign a certain number of images randomly to each annotator. Compared to the active learning with random selection of samples for annotation, the uncertainty score of active learning with BALD tends to zero when reaching to 300 images in the first iteration, as shown in Figure 3. The active learning process using BALD is iterative. After annotating the selected samples and incorporating them into the training set, the model is retrained, and the process repeats. Over multiple iterations, the model becomes increasingly accurate, and the uncertainty decreases, leading to more confident predictions. The annotation loops will stop until the end-users satisfy with the performances, which can be evaluated by either through a matrix on validation dataset, or by manually interpretation on randomly selected images (if not enough validation reference images). Figure 3(b) shows that the uncertainty score of active learning with BALD tends to zero after 180 images in the second iteration, while active learning with random sample selection still needs to annotate all images to achieve this. By focusing on samples where the model's predictions are most uncertain, BALD enables efficient learning with limited annotated data.

Table 1. Acquired images and manual annotations.

No. Teeth	No. Annotated teeth	No. Images	No. Annotated Images	No. Annotated Polygons
54	18	1370	438	1036

Table 2. Data split (within 18 annotated teeth, 438 annotated images) for active learning.

Initial training dataset	Tooth 1 (23 images)
Validation dataset	Tooth 15 (31 images)
Test dataset	Tooth 5 (31 images)
Pool dataset	The other 15 teeth (353 images)



(a) (b)

Figure 3. Uncertainties scores by active learning with: (a) random selecting samples for annotation, (b) BALD. Iteration 1 means 10 annotated images are added into the initial training dataset and retrain the model of active learning; iteration 2 means 20 images are iteratively annotated and added into the initial training dataset.

3. Experiments Data Collection and Processing

3.1. Data Collection

A dataset containing images of gears subjected to accelerated lifetime tests was provided by ZF Wind Power. While a brief description of the dataset acquisition is present here, the reader is referred to the work of (Boemher, 2019) for further details. The dataset consists of two accelerated lifetime tests, and was generated on a standard FZG[3] gear test rig at ZF Wind Power. At selected moments of the test, the equipment was stopped and images of both meshing gears were manually captured using a Canon EOS 500D camera. Figure 4 illustrates the gear degradation of a gear flank throughout the test. Two pairs of standard FZG C14 spur gears with 16 teeth (pinion) and 22 teeth (wheel) were tested on each accelerated lifetime test. In the first test, with total duration of $152h$, the test was stopped 31 times for acquiring the image of the gear flanks. Meanwhile, on the second test with total duration of $250h$, image acquisition was performed 23 times. A prior qualitative assessment determined that the wheel of the first test did not developed damage. Hence, the assessed dataset is composed of 54 teeth: pinion (16) of first test, plus pinion (16) and wheel (22) of the second test.

[3]Forschungsstelle für Zahnräder und Getriebebau, which denotes the Gear Research Center at the Technical University of Munich

3.2. Experimental Setup

The accelerated lifetime testing procedure was designed to generate micropitting and pitting wear on the visually monitored gear surfaces. As shown in Table 1, 54 teeth were used in experiments and a large amount of images was acquired by our camera. After filtering the unclear images (i.e., blurry, noisy, etc.) and pre-processing, we obtain 1370 images, of which 438 images were annotated by our experts, as shown in Table 2. The annotation effort varied according to the amount of defects in each image, taking approximately 60 hours to fully annotate the dataset (438 images), and in some cases up to 30 minutes were required to annotate a single frame.

Two sets of experiments are compared:

- **Fixed_SMP**: train the SMP-FPN models using Initial training dataset + Pool dataset, totally 16 teeth, 376 annotated images;
- **Active_SMP**: train the SMP-FPN model initially on Initial training dataset (Tooth 1, with 23 annotated images in total)

Then a number of annotated samples (i.e. 10 in each iteration) selected by active learning from the Pool dataset are iteratively added into the training dataset, and the model is retrained. Within active learning segmentation, we will compare different methods to select samples for first priority to be annotated, such as:

- **Active_SMP_Random**: select 10 images randomly in each iteration;
- **Active_SMP_BALD**: select 10 images by using BALD method in each iteration.

We set some parameters for model training as: batch size: 8, epochs: 100, learning rate: 0.0001. To reduce inherent randomness in the training of deep networks, each experiment runs five times for active learning.

For performance evaluations, we exploit the confusion matrix (Powers, 2011) to report the performance of a segmentation model on a single image. This confusion matrix helps in understanding where the segmentation model is making errors, whether it is under-segmenting or over-segmenting certain classes, or if there are misclassifications between classes. It is an essential tool for evaluating the effectiveness of segmentation algorithms. To evaluate the segmentation models on the whole test dataset, we exploit mean intersection over

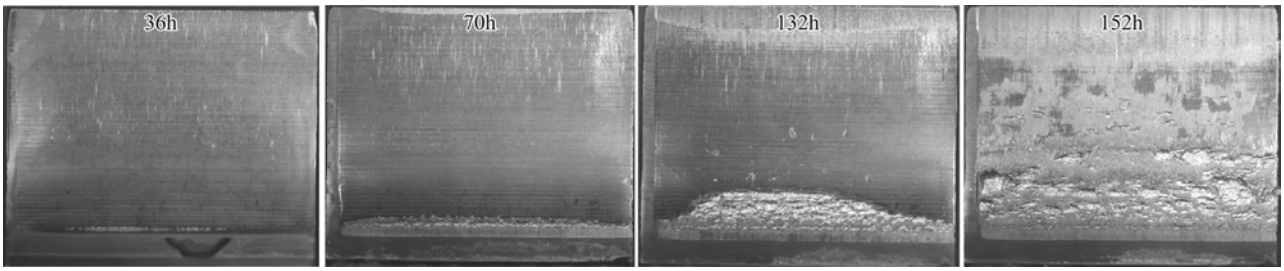


Figure 4. Example of images collected at selected moments of the test, showing the evolution on the gear degradation with the test duration.

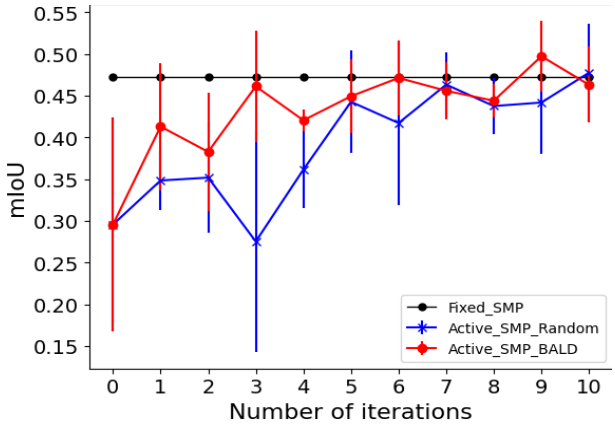

Figure 5. Mean and standard deviation mIoU of different segmentation methods. Note: the Fixed_SMP method is trained by using fixed number of 376 annotated images; iteration 0 means the model of active learning is trained on Initial training dataset (Tooth 1 with 23 images); 10 images will be selected in each iteration for annotation and then added into the training dataset, the model with active learning will be retrained (for example iteration 3 means 30 images are iteratively annotated and added into the Initial training dataset). We repeated the active learning segmentation experiments 5 times.

union (mIoU), which measures the overlap between the predicted segmentation and the ground truth segmentation for each class or object in the image (with Python implementation[4]). The value of the metric ranges from 0 to 1, higher value indicates better performance on segmentation.

4. Results and Discussions

Figure 5 compares the performances of segmentation models trained by Fixed_SMP and Active_SMP. The changes of the predicted segmentation maps by adding more annotated images into the training dataset can be found in Figure 6. We take several test images as examples and show the segmentation results and their confusion matrices by using Fixed_SMP and active SMP_BALD in Figure 7.

Based on Figure 5, we can find that with 53 annotated images (i.e. 3 iterations), active learning with BALD can achieve similar performances as Fixed_SMP (where more than 360 annotated images are used for training), which requires 6 times less annotated images for training, reducing more than 6 times the manual annotation effort. Moreover, Active_SMP_BALD performs better than Active_SMP_Random, especially for the first 5 iterations, when a small number of images are selected for annotations. This means that BALD can select the most informative images (out of a large dataset) for annotation when limited manpower is available for annotation. The model can learn more effectively with fewer BALD selected images, leading to efficient data annotation for model training. As more annotated images (more than 70 annotated images) are added into the training dataset, Active_SMP_Random converges to similar performances as the method of Fixed_SMP, indicating the redundancy in the image annotations. This is because images acquired during full lifetime degradation for multiple teeth contain many similar defects that bring no additional information for model training.

The segmentation models with active learning becomes more stable, as more annotated images added into the training dataset, as indicated by the changes of standard deviation in Figure 5. However, there are scenarios where increasing the training sample size (by adding more annotated images) might seemingly degrade segmentation performance, defects of “micropitting” appear in Figure 6-7 (Fixed_SMP for the third image) as more annotated images added. This may be due to overfitting, the model should generalize better with more training samples (that have similar distributions as the test images). One solution is to add more images that are representative of different classes into the pool dataset for active learning.

Compared to the human expert annotations, the segmentation results predicted by deep learning models (even for Fixed_SMP) need to be improved, regions of “micropitting” and “pitting” are misclassified into background, whereas some background regions are also misclassified into “micropitting”, as indicated by the confusion matrices in Figure 7. Challenges remain in predicting very tiny ”pitting” defects, as well as images mixed with big “micropitting” defects and

Each row has one test image, column 1 shows highlighted annotated images by experts, column 2 and 3 show predicted segmentation maps and confusion matrices by Fixed_SMP, column 4 and 5 are predicted segmentation maps and confusion matrices by Active_SMP_BALD with three iterations (53 training images).

tiny ”pitting” defects.

5. Conclusions

This paper focus on training a reliable deep learning segmentation model for defect detection in gears using less image annotations. In particular, Bayesian Active Learning by Disagreement (BALD) was exploited to select the most informative images for annotation iteratively until the satisfied performances were achieved. Experimental results show that with less than 6 times image annotations, we can achieve similar performances, leading to significant savings in time and resources compared to traditional approaches that rely on labeling large amounts of data upfront. However, gear surfaces exhibit a variety of defect types and patterns, and the successful identification of these defects requires a model capable of learning intricate features and subtle variations. The initial results in this paper can be extended by considering: (1) uncertainties from human annotations (annotations may be different by different human annotators in Figure 8), (2) imbalance in class distribution (some classes have more annotations than the other classes), (3) data augmentation to increase diversity in the training image dataset, (4) validation of the active learning methods on wider applications using some public datasets (e.g., ball screw drive surface defect dataset (Schlagenhauf & Landwehr, 2021)) for more comprehensive comparisons.

Acknowledgment

ABSTRACT

In automotive Powered Door Systems (PDS), the emergence of grinding and clicking noise over time is a common failure mode. This issue typically arises from design or assembly inconsistencies and intensifies due to wear or increased clearance at its component, becoming noticeable to passengers, and causing discomfort. Numerous automotive manufacturers conduct comprehensive durability tests to tackle such issues during the development. Conventional durability tests, however, rely on the manual effort such as visual and auditory inspection at regular intervals, hence, is subjective and inefficient. This study introduces a novel method by the prognostics and health management (PHM) approach to detect anomaly and assess its severity of the noise during the durability test of the PDS, which may improve the reliability of noise detection and reduces the test time by early termination using prognosis capability. The results demonstrate the potential, paving the way for its broader application across various domains to advance testing processes and reliability.

1. INTRODUCTION

In recent developments in the automotive industry, many components are electrified to enhance the user convenience. Prominent examples include power window, automatic tailgates, and power door systems. These systems, however, often have various forms of wear and joint failures, significantly impacting user satisfaction and perceived vehicle quality.

Most issues with these components stem from design flaws or problems during the assembly process. To address these challenges and improve vehicle durability and reliability, automotive manufacturers conduct durability tests. Conventionally, these tests have relied on manual visual and auditory inspections performed at regular intervals, which are both subjective and inefficient.

Prognostics and Health Management (PHM) technology has gained considerable attention across various industries, including aerospace, smart manufacturing, power plants, and transportation, for its potential to prevent failures, reduce operational costs, and facilitate predictive maintenance.(Choi, 2014; Zio, 2022) The potential of PHM to enhance durability testing is substantial. In this paper, we discuss the application of PHM techniques and frameworks to durability testing, focusing on developing more accurate and automated diagnostic models.

1.1. Power Door System (PDS)

The case study presented in this paper focuses on the Power Door System (PDS), a feature designed to enhance user convenience in high-end vehicles. Figure 1 illustrates a vehicle equipped with the PDS on its rear door, showcasing the application of the PDS. This system automatically closes the door after a passenger enters.

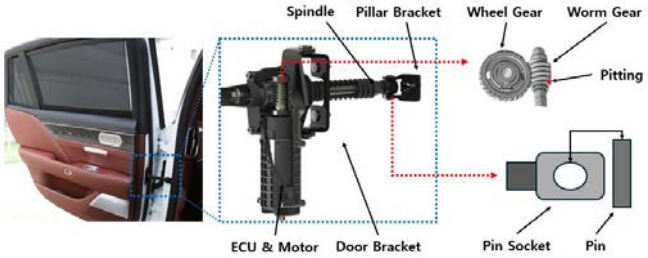

Figure 1. Power door system installed on a vehicle

The PDS is mounted on each door, and as shown in Figure 1, the ends of the spindles are connected into the pillar of vehicle. When the motor rotates, it drives the worm gear to turn the wheel gear. The relative motion then pulls the spindle, closing the door with a mechanism that takes about 3 seconds for the closure operation.

In case of the poor design or manufacturing, the PDS can encounter issues such as a grinding or clicking noises during the door closing, which usually occurs after cycles of door closing. The grinding noise is a continuous rough sound heard throughout the closure. This noise is often caused by small pitting on the drive worm gear, as depicted in upper right corner of Figure 1. On the other hand, the clicking noise is a sharp sound heard at a certain moment during the door closing. It occurs due to clearance, wear or assembly damage between the pin and pin socket connecting to the body's pillar. These noises are characterized as periodic and impulsive, respectively.

In order to determine the occurrence of these noises in the PDS, a durability test is conducted, incorporating both visual and auditory inspections at regular intervals. The method, however, is not reliable nor efficient due to the manual procedure. To overcome this, a diagnostic model is developed, thereby enhancing the reliability and functionality of the PDS.

1.2. Sensor Selection

To choose a sensor that can reveal useful features for the diagnosis, four sensors are considered for the potential candidates: motor current, motor rotation (hall sensor), and accelerometer attached to the PDS and to the body side. The current and hall sensor data are collected at a rate of 4 kHz, while the accelerometer data at 25.6 kHz.

Figure 2 illustrates the signals captured by these sensors during the operation of PDS. Each graph within the figure represents the data from different sensors, plotted over time to show the dynamic changes in sensor readings as the door progresses through 3 repetitions of open and close motions.

Upon comparison of these signals in terms of efficacy of diagnostic, consistency, strength and the convenience of installation, the accelerometer signals perpendicular to the body side is found appropriate for the study. Consequently, all the signals discussed in this paper are measured from this sensor.

The rest of the paper is outlined as follows: Section 2 introduces the PHM framework, Section 3 and 4 detail the process of developing diagnostic models for grinding noise and clicking noise, respectively. Lastly, conclusions are presented in Section 5.

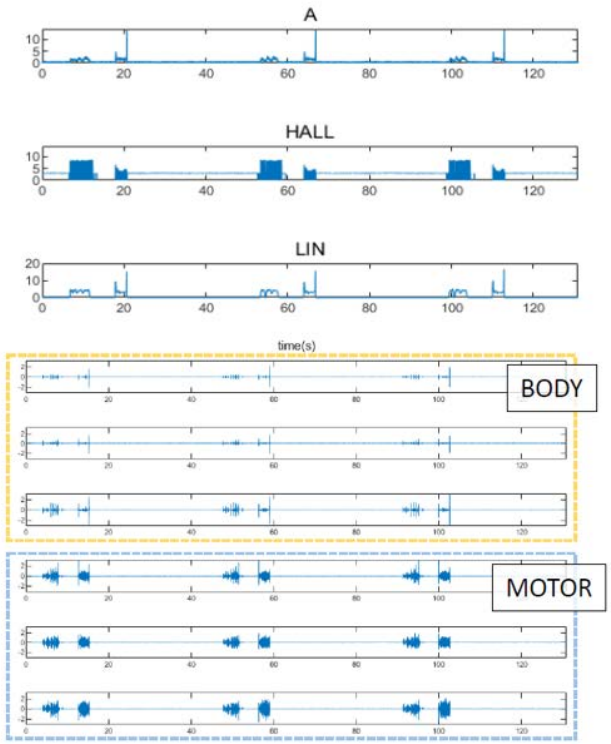

Figure 2. Various sensor signals of the PDS motion

2. PHM FRAMEWORK

In this section, the development procedure of diagnostic model and its application to test data are addressed. Figure 3 illustrates the overall flowchart of the PHM process. It has two major phases: construction of the diagnostic model and its application.

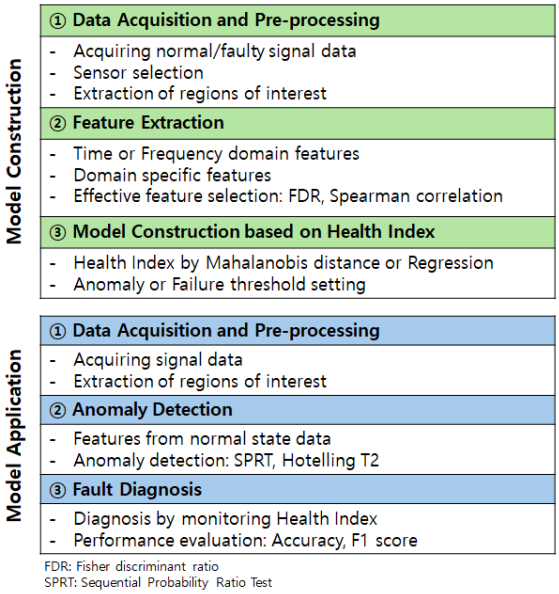

Figure 3. Flowchart of PHM framework

In the construction phase, the first step is the collection of sensor signals and pre-processing. Two types of signal data are collected in the test: first is the discrete data for normal and faulty conditions. second is the continuous data from the normal to the failure. In a single set of signal data, not the whole period is exploited but only a segment is taken for a better feature extraction. This varies depending on the considered noise, which accounts for the symptoms and causes of failures as well as the operational mechanisms of the system.

Next is the feature extraction and selection. Various features are extracted, including time domain, frequency domain, and domain-specific features.(Sim et al., 2020) Effective feature selection involves choosing the features with higher value of Fisher Discriminant Ratio (FDR) that can better distinguish the normal and faulty conditions in case of discrete data and the features with a higher Spearman correlation in case of the continuous data.

Based on the selected features, a health index (HI) is constructed in the next step. While there are several approaches for this, Mahalanobis distance is employed in this study, which is useful when there are the normal features only. Thresholds for anomaly and failure are established for the HI, respectively, to effectively distinguish between the normal, warning and failure states.

In the application phase, data from the test subjects are collected. Following the procedures defined in the diagnostic model, the HI is calculated and monitored to perform anomaly or fault detection. This systematic approach allows for precise and proactive management of system health.

3. Diagnosis Model for Grinding Noise

To develop the diagnostic model for grinding noise, normal and faulty data sets are collected from three specific cases. Among these, case A involves less severe noise occurrence, while the cases B and C involve relatively severe noise occurrences.

Table 1. grinding noise datasets

Vehicle / Placement	Class	Features	Case
Vehicle1 / Front	Normal	-	A
	Faulty	Small grinding noise	
Vehicle1 / Rear	Normal	-	B
	Faulty	Loud grinding noise	
Vehicle2 / Rear	Normal	-	C
	Faulty	Loud grinding noise	

As described in Section 2, for the development of the diagnostic model, accelerometer which attached to the vehicle's body is utilized. Figure 4 presents simultaneous recordings of the motor's relative rotational speed and vibration signals. It can be observed that the motor operates in three phases of acceleration, constant speed, and deceleration.

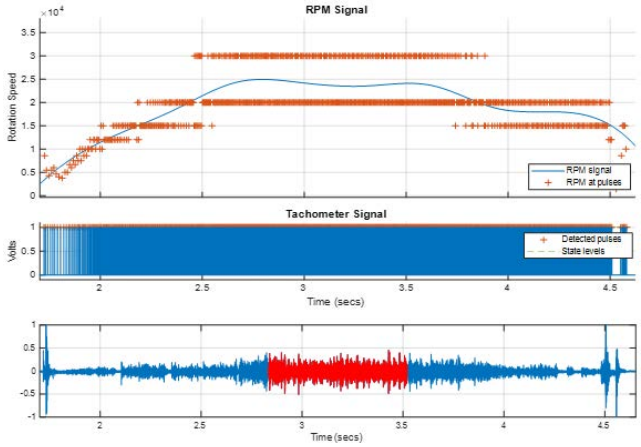

Figure 4. Motor speed and accelerometer signal while closing

Since the grinding noise occurs continuously during the closing operation, the signal over the whole period can be responsible for the noise. However, only a part with constant speed is chosen for the efficacy of feature extraction.

Using the signal in constant speed, numerous candidate features are extracted as shown in Figure 5, in which the blue o and red x denote the normal and fault respectively. Note that all the features are normalized by Gaussian distribution. Among these, more significant features are selected that can distinguish the two classes more clearly. For this purpose,

Fisher discriminant ratio (FDR) is calculated, defined as follows.

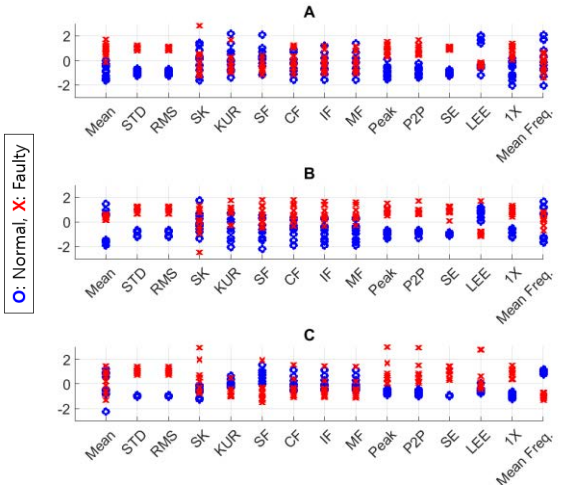

Figure 5. Features from each signal of four datasets

$$FDR = \frac{(\mu_1 - \mu_2)^2}{\sigma_1^2 + \sigma_2^2} \quad (1)$$

where μ_i is mean value of feature, and σ_i is standard deviation of feature for i-th class. As a result, the root mean square (RMS) and Shannon entropy (SE) are recognized as the most important features.

Using these selected features, an HI based on the Mahalanobis distance is constructed from the normal data as defined in the following equation.

$$HI = (\mathbf{x} - \mu_n)' \mathbf{S}_n^{-1} (\mathbf{x} - \mu_n) \quad (2)$$

where $\mathbf{x}$ is feature vector of input data, μ_n is mean of feature vector for normal data and $\mathbf{S}_n$ is covariance matrix of feature for normal data. The results as shown in Figure 6, demonstrate a clear distinction between the normal and faulty data across all cases. Based on the HI values of the collected normal and faulty data, thresholds for anomaly and failure are established as the dotted blue and magenta lines, which are the normal HI at upper 95% confidence and fault HI at lower 95% confidence levels, respectively. This diagnostic model can be utilized in the future tests to determine whether the product yields the grinding noise during the cycles of operation.

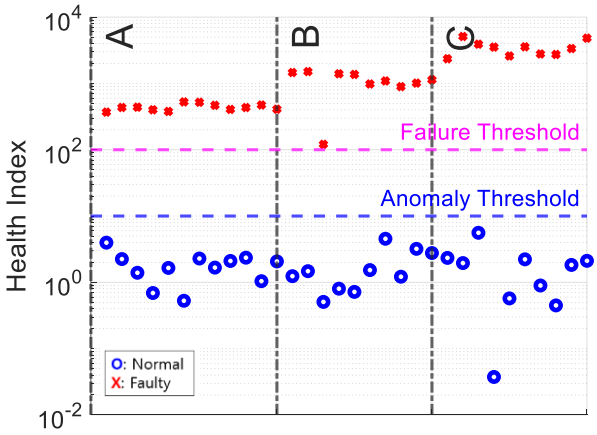

Figure 6. Health index for three cases

4. DIAGNOSIS MODEL FOR CLICKING NOISE

To develop the diagnostic model for clicking noise, datasets are collected from both the front and rear doors of vehicles. The collected datasets are given in Table 2. Front door datasets include four discrete states: two normals and two faults, each collected from different PDS installed on two vehicles. In the table, Normal 1 and Normal 2 indicate no clicking noise. However, Normal 2 is with a subtle grinding noise. And Fault 1 indicates a small clicking noise, while Fault 2 indicates a significantly loud clicking noise. For the rear door, run-to-failure data are collected for up to 38,000 cycles, from which the normal and fault are defined by those less than 10,000 and over 23,000 cycles based on the experts' opinion.

Table 2. Clicking noise datasets

Vehicle / Placement	Class	Feature	Case
Vehicle1 / Front	Normal1	-	Front
Vehicle1 / Front	Normal2	Small grinding noise from motor	
Vehicle2 / Front	Faulty1	Small clicking noise	
Vehicle1 / Front	Faulty2	Loud clicking noise	
Vehicle2 / Rear	Normal	- (Cycle 0 ~ 10000)	Rear
	Warning	Tiny clicking noise (Cycle 10000 ~ 23000)	

	Faulty	Small clicking noise (Cycle 23000 ~ 38000)	

As opposed to the grinding noise, clicking noise, characterized as an impulsive signal, typically occurs only at a certain moment during the door closing. To isolate these impulsive events, kurtosis in a short interval with 0.1 second is computed over a sliding time window, which is a widely used feature in vibration analysis for its ability to detect spikes in signals.(Cerrato-Jay et al., 2001; Honarvar & Martin, 1997)

Figure 7 illustrates both the original and its kurtosis for the sound and vibration signal, respectively. In the analysis, signals at the beginning (0-0.3 seconds) and after 2.5 seconds are disregarded as they are those at the start and end of closing, respectively. In the upper two figures, it is observed that the moments when the noise is heard and when its kurtosis shows local peak are the same, as marked by the red explosion symbols. Based on this finding, the vibration signal is processed in the similar manner, which are given in the lower two figures. Interestingly, the moments when the kurtosis shows local peak are the same in the sound and vibration signals. Therefore, the kurtosis is used as the means to identify the moment of clicking noise, and the signal over a small time period of 0.1 second is taken for further processing towards the feature extraction.

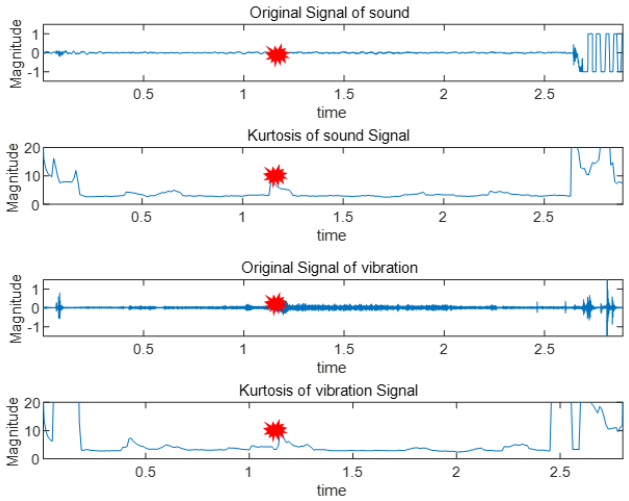

Figure 7. Raw signal and frame kurtosis for sound and vibration signal

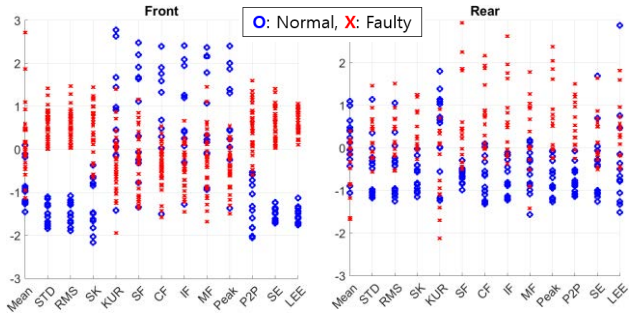
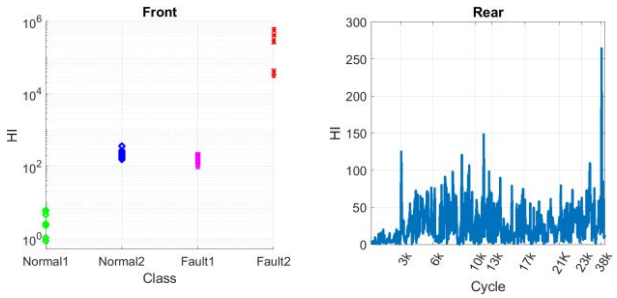
As in the previous section, several candidate features are extracted, from which the most significant ones are sought for. The results are in Figure 8, in which (a) are those for the front (normal 1 and fault 1 only), and (b) are for the rear (normal less than 3,000 cycles and fault over 33,000 cycles) are taken among the run-to-failure data). The blue o and red x denote the normal and fault respectively. In comparison with the grinding noise, the separation between the normal and fault both in the front and rear are less clear.



(a) (b)

Figure 8. Features from each dataset

Nevertheless, the same procedure is taken to select the most important features, which are RMS (root mean square), P2P (peak-to-peak), and SE (Shannon entropy). The diagnostic performance by the HI made of these features are shown in Figure 9. In Figure 9(a), which is the result of front door, considerable overlap is found between the HI for normal 2 (blue o) and fault 1 (magenta x). Furthermore, in the case of rear door as shown in Figure 9(b), clear increasing trend are not present towards the fault conditions. All these suggest that the selected features are not so effective to use to construct HI.



(a) (b)

Figure 9. Health Index from each dataset

To discover more effective features, another attempt is made, which is the time-frequency analysis. Figure 10 displays a spectrogram of continuous wavelet transformation (CWT), obtained for the instant of 0.1 second centered at the clicking noise. The result reveals that the clicking noise occurs in a very short 10 ms time window at a certain frequency range. In order to quantify this into the feature and use it as the HI, total energy of the impulsive moments within specific time and frequency windows is used. The results are illustrated in Figure 11, in which the Figure 11(a) for the front door shows a better distinction between the normal and fault, and Figure 11(b) for the rear door with run-to-failure presents a better increasing trend in HI, demonstrating the superiority of the CWT based approach over the time-based ones.

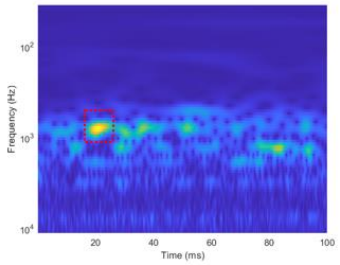


Figure 10. Spectrogram for click noise

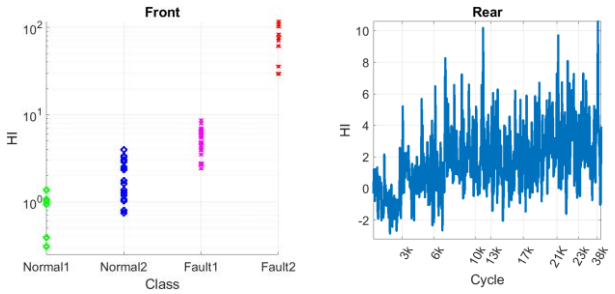
Despite these advancements, there remains considerable dispersion in the HI, which makes it still challenging to apply in the field. This variability could stem from various external factors that influence the occurrence of clicking noises. Further signal processing efforts to mitigate these influences or the identification of more effective features will be essential to enhance diagnostic accuracy.



(a) (b)

Figure 11. Health Index from new feature

5. CONCLUSIONS

In this study, prognostics and health management (PHM) approach such as the signal processing, feature extraction and selection, and construction of HI, was applied to develop diagnostic models for two representative faults occurring in the power door systems (PDS): grinding and clicking noises. These faults are characterized by a continuous rough sound and a sharp, transient sound during door closure, respectively.

The method has facilitated the development of diagnostic models capable of detecting both types of noises, demonstrating the potential in the real-world applications.

However, much more data are necessary to refine the model and validate its performance, which requires a lot of efforts in time and money. Particularly for the clicking noise model, the HI contains significant uncertainty, highlighting the necessity for exploring diverse approaches and possibly new features to enhance diagnostic accuracy.

By integrating the PHM into the durability tests, we have showcased the potential for automation and quantitative fault assessment. If we can obtain comprehensive run-to-failure (RTF) data, it might also enable us to predict the remaining useful life of components, which could significantly reduce testing time by preemptively forecasting the occurrence of noise issues.

ABSTRACT

Most manufacturing facilities driven by motors generate vibration and noise representing critical symptoms against facility malfunctioning conditions in the manufacturing industry. Due to the difficulty of obtaining abnormal data from facilities in manufacturing sites, many prior researchers who have studied predicting facility faults have adopted unsupervised learning-based anomaly detection approaches. Although these approaches have a strength requiring only data on from facility normal behaviors, it is not clear that the anomalies detected by an anomaly detection model are due to the real component faults. Also, the model performance is likely to change according to the diverse abnormal conditions of the given facility. In this paper, we took an experiment with a fault vibration simulator to measure the anomaly detection performance of a one-dimensional convolutional autoencoder model with different fault conditions. In the experiment, we used four different abnormal conditions: imbalance, misalignment, looseness, and bearing faults, which are the most frequently occurring facility component failures from the rotating machineries. Data were gathered from the simulator with the IEPE(Integrated Electronics Piezo-Electric) type sensor. We proposed the N-Segmentation algorithm that performs anomaly detection in segmented frequency region according to corresponding component faults for better anomaly detection performance. In conclusion, the proposed algorithm showed about 15 times better anomaly detection rate than not applying it.

1. INTRODUCTION

Artificial Intelligence (AI) technologies are adopted in various field domains to replace human beings or improve legacy systems. The manufacturing sector has also gradually tackled AI-based anomaly detection (AD) approaches for facility monitoring and fault detection. (Kumar, Khalid, & Kim, 2022; Zhang, Lin, Liu, Zhang, Yan, & Wei, 2019). AI-enabled facility monitoring systems are necessary to improve productivity, reduce costs, and ensure worker safety in manufacturing sites. Facility anomaly is an abnormal condition where defects or failures occur, and it can be determined and predicted by analyzing physical data measured during the facility operation from physical sensors such as those of vibration, current, and temperature. Since motors drive most manufacturing facilities, they generate various vibration signals during operation. These vibration signals represent a valuable basis for predicting whether the facility is in normal operations or defective status. When the vibration increases or becomes excessive, certain mechanical trouble has usually occurred. Since the vibration does not increase or become excessive for no reason, it is considered an indicator of machinery malfunction (Shreve, 1994). However, since the types of facility defects or failures are so diverse, obtaining sufficient data on facility defects and failures in manufacturing sites is impractical (Hiruta, Maki, Kato, & Umeda, 2021; Li, Li, & Ma, 2020). As a result, unsupervised learning approaches that use only data acquired when the facility is in a normal condition are very practical.

As the fault situations are diverse and unsupervised AD models require reconstruction of input signals, there are two important considerations, namely, types of faults (Thi, Do, Jung, Jo, & Kim, 2020) and the reconstruction range (Amarbayasgalan, Pham, Theera-Umpon, & Ryu, 2020). Considering these points, we conducted a vibration AD test using a fault vibration simulator and an Integrated Electronics Piezo-Electric (IEPE) type vibration sensor. We collected the vibration data of the simulator's normal signals and abnormal signals generated under normal operation and conditions of imbalance, misalignment, looseness, and bearing faults. Then, we trained the normal signals with a one-dimensional convolutional autoencoder (1-D CAE) and measured the AD performance by normal signals and fault signals. We introduce the N-segmentation algorithm for the better AD

performance, which performs it by segmenting the frequency range into N different regions. The proposed algorithm can detect fault vibration signals with improved performance.

2. BACKGROUND

AI models are classified as supervised or unsupervised learning, depending on whether labels are used during the learning process. Applying supervised learning to AD requires data for all types of anomalies. Since gathering anomaly data for enough training is practically impossible, unsupervised learning using only the normal-condition data of the facility is more suitable, and the Autoencoder (AE) is representative of unsupervised learning (Lee, Lee, & Kim, 2024; Wei, Jang-Jaccard, Xu, Sabrina, Camtepe, & Boulic, 2023). AE is an AI model that learns how to produce output data as close as possible to the input data without data labels. Using a difference between the input data of the AE and the reconstructed data generated by the output data of the AE detects anomalies. In this case, the reconstruction error, the difference between the input data and the output data of the AE, is calculated by error functions such as mean absolute error (MAE), mean squared error (MSE), and root mean squared error (RMSE).

Various research has been performed regarding AD using fault vibration signals. Wisal and Oh (2023) developed a new deep learning algorithm that utilized ResNet and convolutional neural networks to detect the unbalance of a rotating shaft for both binary and multiclass identification. Kamat et al. (2021) used random forest, artificial neural network, and AE to detect the bearing fault. Their experiment showed the AE provides the highest accuracy of 91% over the others. Ahmad et al. (2020) has taken experiment with AD for rotating machines by comparing a long short-term memory-based AE (LSTM-AE) and an isolation forest model. The experimental results on real-world datasets showed that the LSTM-AE achieved an average f1-score of 99.6%. Most previous works focused on developing the model achieving high accuracy for AD, but they are suggested within the limited fault environment or dataset.

In vibration accuracy for condition monitoring, an IEPE-type sensor is usually capable of more precise vibration measurement than a Micro-Elector-Mechanical System (MEMS) type sensor. (Hassan, Panduru, & Walsh, 2024). In the previous research regarding AD by frequency segmentation, Park & Lee (2022) successfully performed AD by synthesizing the frequency domain data of the IEPE-type vibration sensor collected from the printing facility and the virtual frequency signals. However, for the objective performance evaluation of the approach, it is necessary to utilize data collected in a simulator environment like actual facilities, not a virtual signal.

3. PROPOSED ALGORITHM

We propose the N-Segmentation algorithm that detects abnormal vibration signals by segmenting the frequency domain measured by a vibration sensor into N frequency ranges. The algorithm uses N reconstruction errors and N thresholds to determine anomalies in the target vibration signal. The algorithm predicts whether the frequency section corresponding to each segment is a normal or an anomaly using the threshold that is the maximum reconstruction error value of the segment. Therefore, the algorithm can perform not only AD of the target signal but also AD of the segments. In other words, it can present additional information on which segment of the entire frequency range has an anomaly occurred. Here, N, the number of segmented frequency ranges, is a kind of hyperparameter designated by analysts, so applying various N values is necessary to measure the performance of a model like 1-D CAE through the proposed algorithm. Figure 1 shows a schematic diagram of the proposed algorithm when N is 4.

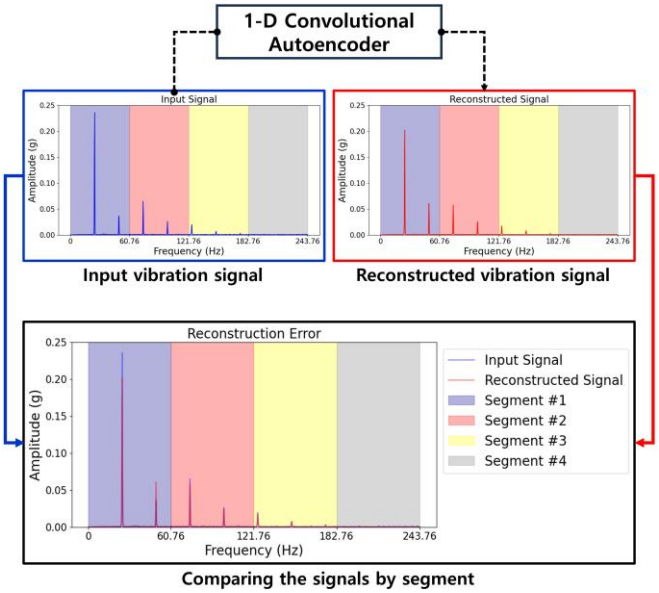

Figure 1. N-Segmentation Algorithm (N=4)

3.1. 1-Dimensional Convolutional Autoencoder

1-D CAE is an AE composed of encoders and decoders using one-dimensional convolutional layers (Zhang, Wang, Yi, Wang, Liu, & Chen, 2021). Convolutional layers can learn the data with high accuracy when the data size is constant, such as image data with two-dimensional data shape of width and height in pixels. Compared with two-dimensional images, as one-dimensional input vectors like vibration signals contain intuitive data characteristics, it is a great opportunity to use deep learning-based methodology for AD (Chen, Yu, & Wang, 2020). In the case of the frequency domain data used in this study, a 1-D CAE model is applied to capture the

status of the simulator with the vibration signal having one-dimensional 1024 numerical data. We developed the 1-D CAE model that consists of two 1-D convolution layers as encoder and two 1-D transposed layers as decoder using Python 3.10.9 and TensorFlow 1.12.0. Table 1 shows the structure of the model and hyperparameters.

Table 1. Structure of the model and hyperparameters

Layer	# of Filters	Kernel Size	Activation Function
1-D Conv.	64	8	RELU
1-D Conv.	32	8	RELU
1-D Trans. Conv.	64	8	RELU
1-D Trans. Conv.	1	8	-

Since MSE and RMSE can lead to higher weights given to higher errors, the model tends to be more sensitive to noise that might cause false positives (Kang, Kim, Kang, & Gwak, 2021). In the reconstruction loss function for AE-based AD models, MAE is more appropriate than the other two functions (Xu, Jang-Jaccard, Singh, Wei, & Sabrina, 2021). Therefore, the loss function used in the training process using the model is MAE in Eq. (1). Here, n denotes the number of numeric values contained in one vibration signal. X' denotes the reconstructed signal from the model, and X denotes the input signal to the model.

$$MAE = \frac{1}{n}\sum_{i=1}^{n}|X'_i - X_i| \quad (1)$$

3.2. Thresholds

Unsupervised learning-based AD requires a threshold to determine whether the vibration signal represents an anomaly. In the existing AD using AE, the maximum reconstruction error value (Kang, Kim, Kang, & Gwak, 2021; Wei, Jang-Jaccard, Xu, Sabrina, Camtepe, & Boulic, 2023) or the 3-sigma value (Lee, Lee & Kim, 2024; Panza, Pota, & Esposito, 2023) among the reconstruction errors of the training data has been set as a threshold. In this case, the threshold has to be only one. However, in the proposed method, thresholds are generated as many as the number of segments N. Figure 2 shows the reconstruction error distributions as a histogram for each segment of the training data when N is 4. The red vertical line in each histogram in Figure 2 represents the maximum reconstruction error used as a threshold to determine the anomaly in the segment.

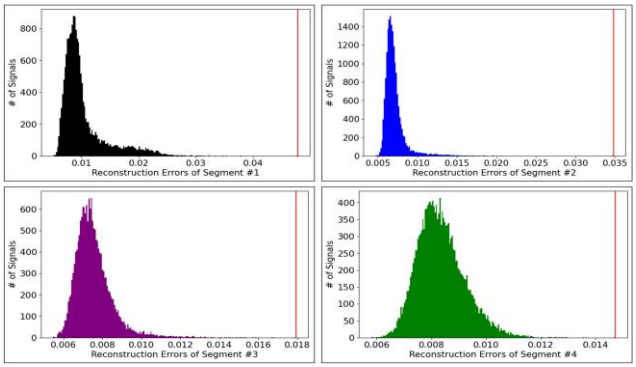

Figure 2. Reconstruction error distributions and thresholds (N=4)

3.3. Anomaly Detection

The proposed algorithm uses all N thresholds to detect the fault vibration signals among the test signals. If all the N reconstruction errors in the N segments of a target signal are lower than the corresponding thresholds, the signal is considered normal. Otherwise, it is a fault vibration signal. Figure 3 shows an example of the AD process of the proposed algorithm when N=2.

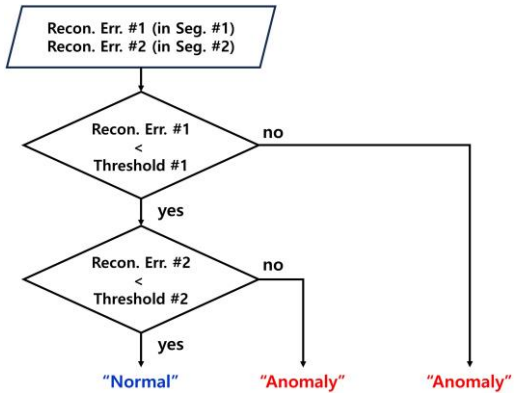

Figure 3. Process of anomaly detection (N=2)

The true-positive rate (TPR) in Eq. (2) was set to measure the performance of AD. Here, TP is the number of correctly predicted vibration signals, and FN is the number of incorrectly predicted ones.

$$TPR = \frac{TP}{TP + FN} \quad (2)$$

4. EXPERIMENT

4.1. Setup

The vibration signals were gathered with a fault vibration simulator and an IEPE-type sensor for about two months. The simulator is the AST-VFS product of AST company of the Republic of Korea, and the sensor is the Model 131.02

product of VibraSens company of France. The vibration signals were collected every two minutes and obtained by Vib-AiR, the wireless health monitoring solution of RESHENIE company of the Republic of Korea, through open platform communication-unified architecture (OPC-UA) protocol (Schleipen, Gilani, Bischoff, & Pfrommer, 2016). Figure 4 shows the experimental environment. In Figure 4, R and L in parentheses mean Right and Left, respectively. The sensor (red square in Figure 4) was set on the top of the right-bearing housing of the simulator (blue square in Figure 4). The sensor can collect vibration signals in three-axis directions. In the experiment, only the Y-axis signals, which is the direction of rotation of the motor (the orange arrow in Figure 2), were used.

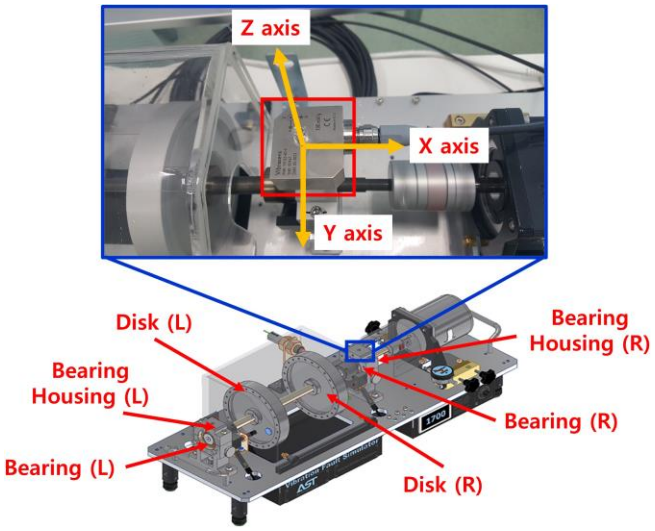

Figure 4. The fault vibration simulator and the IEPE sensor

4.2. Data Description

The dataset includes normal vibration signals at the motor rotation speed of 1,500 RPM and four fault vibration signals: imbalance, misalignment, looseness, and bearing faults. Table 2 summarizes the 16 simulator settings for generating fault signals. In Table 2, settings #1 to #6 are the conditions for the imbalance. Setting #7 is for the misalignment. Settings #8 to #10 are for the looseness. Finally, settings #11 to #16 are for the bearing faults.

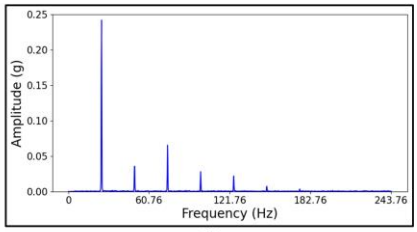
Table 2. Simulator settings for the faults

No	Setting
#1	Attaching 1.7g mass to the right disk
#2	Attaching 1.7g mass to the left disk
#3	Attaching 1.7g mass to each disk
#4	Attaching 6.25g mass to the right disk
#5	Attaching 6.25g mass to the left disk
#6	Attaching 6.25g mass to each disk
#7	Set to 1.2mm
#8	Loosening the left bearing housing
#9	Loosening the right bearing housing
#10	Loosening both bearing housing
#11	Applying outer wheel defect bearing to the left
#12	Applying outer wheel defect bearing to the right
#13	Applying inner wheel defect bearing to the left
#14	Applying inner wheel defect bearing to the right
#15	Applying ball defect bearing to the left
#16	Applying ball defect bearing to the right

One vibration data has 1,024 features that are numerical values representing amplitudes of each frequency from 0 to 243.76Hz. Figure 5 (a) is an example of the normal vibration data, and Figure 5 (b) is the result of visualizing it.

Frequency	Amplitude
0	0.000009
0.24	0.000015
0.71	0.000020
:	:
243.29	0.000458
243.52	0.000239
243.76	0.000327

(a)



(b)

Figure 5. An example of the normal data

Figure 6 shows the sample fault signals collected from the simulator using the sensor. Figure 6 (a), Figure 6 (b), Figure 6 (c), and Figure (d) are the results of the visualization of the signals collected under the imbalance of setting #1, the misalignment of setting #7, the looseness of setting #8, and the bearing fault of setting #11, respectively. These fault signals in Figure 6 showed different patterns in the number of peaks and amplitude values of peaks compared to the normal vibration signal in Figure 5(b). However, most frequencies in all signals showed very low amplitudes close to zero, except for a few frequencies. These frequency data characteristics affect the reconstruction results of the model and can consequently influence the AD performances.

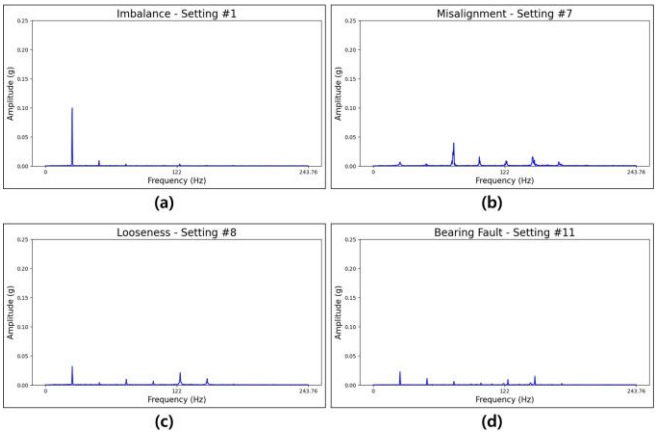


Figure 6. Example of the fault signals

A total of 21,365 vibration signals were collected from the simulator, of which 17,624 (82.5%) vibration signals were used as training data and 3,741 (17.5%) vibration signals as test data. Table 3 shows a detailed description of the dataset. Normal vibration signals of 17,624 training data and 481 test #1 data in Table 3 were generated when the motor in the simulator rotated at 1,500 RPM without applying fault condition settings described in Table 2. Test data used in tests #2 to #17 in Table 3 were generated from the operating conditions of the simulator with settings #1 to #16 in Table 2, respectively. In summary, the AD performances were measured with TPR for a total of 17 test cases (tests #1 to #17 in Table 3) in the experiment. The experiment was conducted in two cases: with and without the proposed algorithm.

Table 3. Description of the dataset

Purpose		Type	# of Data
Training		Normal	17,624
Test	#1	Normal	481
	#2	Imbalance (setting #1)	154
	#3	Imbalance (setting #2)	279
	#4	Imbalance (setting #3)	120
	#5	Imbalance (setting #4)	213
	#6	Imbalance (setting #5)	230
	#7	Imbalance (setting #6)	184
	#8	Misalignment (setting #7)	241
	#9	Looseness (setting #8)	319
	#10	Looseness (setting #9)	118
	#11	Looseness (setting #10)	265
	#12	Bearing Fault (setting #11)	138
	#13	Bearing Fault (setting #12)	251
	#14	Bearing Fault (setting #13)	127
	#15	Bearing Fault (setting #14)	269
	#16	Bearing Fault (setting #15)	196
	#17	Bearing Fault (setting #16)	156

5. Experimental Results

5.1. Anomaly Detection without N-Segmentation

Figure 7 shows the results of AD for the test data (Test #1 to #17 in Table 3) when the N-Segmentation algorithm is not applied. The blue dots and the red horizontal line in Figure 7 represent the MAE values for the test data and the threshold, respectively. Therefore, the dots above the threshold line mean predicted anomalies. The normal vibration signals (Test #1 in Figure 6) were exactly predicted as normal vibration signals. On the other hand, the performance of AD for the fault vibration signals (Test #2 to Test #17 in Figure 7) was too low. A few data were detected as anomaly signals in misalignment (Test #8 in Figure 7) and looseness (Test #10 and Test #11 in Figure 7), where TPRs were measured as 0.21, 0.19, and 0.05, respectively. Except for these cases, no detection was made for the rest of the anomalies. Overall, AD performances with the traditional approach using the model were too poor.

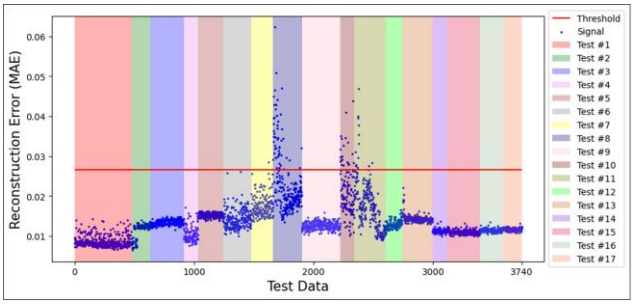

Figure 7. Result of anomaly detection without N-Segmentation

5.2. Anomaly Detection with N-Segmentation

As mentioned in Section 3.3, the proposed algorithm finally determines an anomaly signal by OR operation of AD results in segmented frequency ranges. Since the IEPE sensor collected a frequency signal of 0-243.76Hz, the segments are made by dividing the frequency range evenly. Figure 8 shows AD results in the segmented frequency ranges when N is 4: 0~60.76Hz (Figure 8 (a)), 61~121.76Hz (Figure 8 (b)), 122~182.76Hz (Figure 8 (c)), and 183.76Hz (Figure 8 (d)). In the example, as shown in Figure 8 (c) and Figure 8 (d), the proposed algorithm can detect most anomalies belonging to misalignment (Test #8 in Figure 8 (c)) and imbalance (Test #5 and Test #7 in Figure 8 (d)) compared to Figure 7. AD performance with the proposed algorithm has improved dramatically in these faults compared to the results of Figure 7.

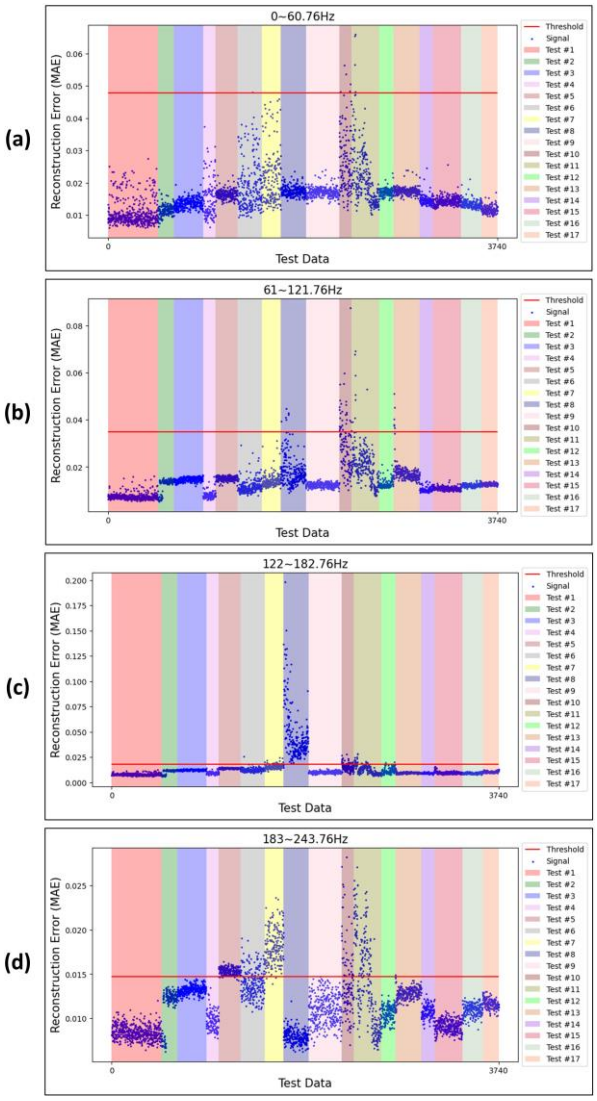

Figure 8. Result of anomaly detection with N-Segmentation (N=4)

As mentioned before, because N is a kind of hyperparameter, the proposed algorithm needs to be confirmed by changing N. Figure 9 shows the AD performance of the algorithm according to the change in the N value. When N is zero in Figure 9, the TPRs indicate AD results of not applying the proposed algorithm. The AD performance with N-Segmentation shows higher TPR scores than without it in all fault cases: imbalance (Figure 9 (a)), misalignment (Figure 9 (b)), Looseness (Figure 9 (c)), and Bearing Faults (Figure 9 (d)). Especially when N was 8, the TPRs for imbalance (Test #7) and misalignment (Test #8) improved dramatically from 0.01 to 0.99 and 0.21 to 1, respectively. In this case, the TPR for all fault signals was 0.40, and the proposed algorithm detected 1,301 anomalies among a total of 3,260 anomalies. On the other side, the traditional approach without the proposed algorithm just detected 87 anomalies.

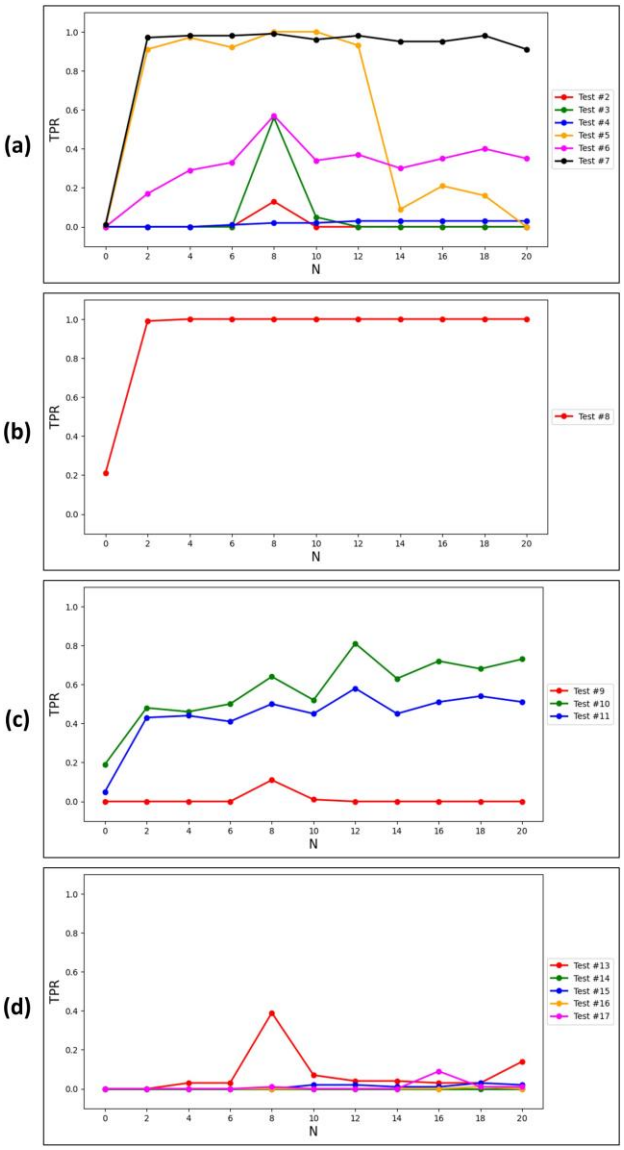

Figure 9. Performance of anomaly detection by N

6. Discussion

The results of the experiment can be summarized as follows. First, the N, the number of segmentations, did not affect the AD performance for the normal vibration signals in the test data. Regardless of N, the TPRs for the normal vibration signals were always measured as 1. Second, even if anomaly signals were the same fault type, the TPRs for the same fault signals showed differences according to the specific settings. Overall, anomaly signals measured in higher physical changes near the sensor were relatively better detected (see Table 2, Table 3, and Figure 9). Therefore, when detecting facility faults using a vibration sensor, the position of the sensor must be carefully determined. Third, the proposed algorithm can improve the performance of the unsupervised-based AD. In our experiment, the proposed algorithm

detected about 15 times fault vibration signals in the best case (N=8) than N=0. Even in the worst case (N=14), it could detect fault vibration signals more than 8 times. Fourth, the proposed algorithm not only detects the fault vibration signals with better performance but also provides additional information about the frequency range in which the anomaly occurred (see Figure 8). This information can be used to predict the type of facility failure.

7. CONCLUSIONS AND FUTURE WORK

In this paper, we proposed the N-segmentation algorithm, which uses segmented frequency ranges to enhance facility fault detection performance. To measure the algorithm performance, we collected the frequency domain data of the vibration signal with the fault vibration simulator using the IEPE-type sensor. We trained the normal vibration data in the collected vibration signal using the 1-D CAE model and performed AD for the normal vibration data and four types of fault vibration data: imbalance, misalignment, looseness, and bearing faults. We detected up to 15 times more anomalies with the proposed algorithm than without it. The results show that the proposed algorithm is effective in AD for fault vibration signals. However, this study has limitations in applying only the 1-D CAE model and experimenting in the simulation environment. In future research, we aim to improve the proposed algorithm by comparing other machine learning models, and we will adopt it to facilities and equipment operating in real manufacturing sites.

ABSTRACT

Understanding the current health condition of complex systems and their temporal evolution is an important step in prognostics and health management (PHM). However, when managing a fleet of complex systems, variations arising from manufacturing, environmental factors, mission profiles, and maintenance practices result in diverse health index (HI) trajectories. Therefore, in PHM, it is essential not only to identify common fleet-wide trends but also to account for individual asset-level variations when inferring HIs.

While several data-driven approaches exist for inferring individual asset-level HIs from unsupervised run-to-failure degradation data (see e.g. (Djeziri, Benmoussa, & Zio, 2020)), little research has been devoted to deriving analytical probabilistic representations of HIs that encompass both fleet-level trends and individual asset-level fluctuations. This paper aims to bridge this gap by addressing the research question of how to obtain an analytical representation of probability distributions for the time to reach intermediate degradation levels, using run-to-failure data or incomplete degradation trajectories from a fleet of complex systems.

In this work, it is assumed that suitable, asset-specific HI curves have been inferred through a fusion of deep learning techniques and prior expert knowledge of degradation physics (e.g., (Bajarunas, Baptista, Goebel, & Chao, 2023)). Given this context, we derive an analytical probabilistic description of the health index (HI) that reflects both fleet-wide trends and asset-specific conditions in the cases of Gamma or Weibull time-to-failure (TTF) distributions. Our approach involves defining HIs with a power law function, enabling the modeling of TTF and time to reach intermediate degradation levels. Moreover, we also detail the procedure for estimating the power law exponent from field data through regression analysis and conduct a sensitivity analysis regarding this exponent.

To illustrate our methodology, we present two case studies based on the N-CMAPPS dataset of turbofan engines and Li-ion batteries, validating the aforementioned assumptions and illustrating our methodology steps.

1. INTRODUCTION

An important step in prognostics and health management of complex industrial systems is inferring their current health condition. To this end, a normalized health index is often defined as a metric that measures the degree of degradation of equipment. Conventionally, a value of 1 for the health index corresponds to perfect health, and a value of 0 to a failed state. An intermediate value characterizes a state where the item is still operating but less than perfectly. If the health index captures the physical condition of the asset correctly, the time evolution of the health index is an appropriate means for performing prognostics, i.e., predicting the evolution of a degradation, eventually up to a failure, and the time until that failure, or remaining useful life (RUL). Therefore, the health index for an asset constitutes a key tool for maintenance decision-making, as it enables health assessment (in particular, degradation severity) and prognostics.

The derivation of HIs has traditionally depended on extracting key features from condition monitoring (CM) data and integrating them with a physical understanding of the asset to create a health index (Atamuradov et al., 2020). This practice, while effective, is heavily reliant on domain-specific knowledge, presenting a significant barrier to scalability and adaptability across different systems. To address these limitations, diverse data-driven approaches have been proposed for estimating HI from condition monitoring data. For instance, supervised learning models have been applied when dealing with datasets that contain labels of HIs (Roman, Saxena, Robu, Pecht, & Flynn, 2021). Similarly, residual techniques that identify deviations from a system's expected behavior (Ye & Yu, 2021; Hsu, Frusque, & Fink, 2023) offer another pathway, albeit contingent on the existence of a representative dataset of "healthy" state labels- an often challenging prerequisite in industrial settings due to difficulties in obtaining a representative data for complex systems. Recently, unsupervised methods combining deep learning methodologies with traditional reliability engineering principles in the form of explicit, analytical representation of the health index have shown promise in inferring asset-specific HI (Bajarunas et al., 2023; Yang, Habibullah, & Shen, 2021; Qin, Yang, Zhou, Pu, & Mao, 2023). Therefore, these recent works highlight the potential of leveraging the extensive body of reliability engineering theory, alongside deep learning algorithms, to model RUL dynamics effectively. An in-depth study of RUL dynamics and uncertainty, based on reliability theory, is reported in (Dersin, 2023).

In this work, our objective is to provide a theoretical foundation for constructing a robust analytical HI that reflects both fleet-wide trends and asset-specific conditions. By doing this, we aim to enable the integration of reliability engineering models in machine learning algorithms by providing an analytical probabilistic description of the HI. Addressing this objective involves answering the following question: *How to find an analytical description for a time-dependent health index integrating random parameters to capture asset variability and align with observed times to reach various degradation severity levels including the time to failure?*

Hence, in this work, we assume the availability of time-to-failure (TTF) distributions for a fleet of assets. Given this assumption, we formulate the problem in a general context and provide an analytical solution when the TTF follows a Gamma distribution or a Weibull distribution. In this scenario, with a health index defined by a power law featuring either an inverse-Gamma or a Fréchet-distributed coefficient, as the case may be, we demonstrate that the time to reach any intermediate degradation level follows a Gamma or Weibull distribution, respectively, sharing the same shape parameter as the TTF. Moreover, the scale parameter explicitly depends on the degradation level. We also detail the procedure for estimating the power law exponent from field data through regression analysis and conduct a sensitivity analysis regarding this exponent.

To validate our methodology, we present case studies focusing on the N-CMAPPS turbofan and randomized usage Li-ion batteries datasets. The results confirm the proposed methodology and highlights its practical applications. Obtaining an explicit, analytical representation of the health index, including the random variability among assets, is a definite advance over the state of the art that offers a major advantage. The proposed approach enables maintenance decision-making with minimal computational demand.

The paper is organized as follows: Section 2 presents the methodology used in this work; we first formulate the problem in Section 2.1 and present a resolution method in Section 2.2. We then delve into specific cases involving Gamma (Section 2.3) and Weibull distributions (Section 2.4), followed by a discussion on estimating the power law exponent controlling the shape of degradation for both analyzed distributions (Section 2.5) . Case studies from the N-CMAPSS and randomized battery usage datasets illustrate our approach (Section 3), with sensitivity analysis on the power law exponent (Section 4). The paper concludes with a summary of our findings and suggestions for future research in Section 5.

2. METHOD

This section provides a detailed explanation of the methodology used to derive an analytical description of the HI. The process is divided into several steps, which are outlined below and visually summarized in Figure 1

2.1. Problem Statement

A degradation phenomenon can be described by an HI, which evolves with time i.e., $HI(t)$, usually monotonically, from a perfect health condition to a failed state. Perfect health corresponds to a value $HI(t) = 1$, and failure is deemed to occur at the first time t, for which $HI(t)$ hits 0.

Given a plausible probability distribution for the time to failure, denoted T, which is derived from available data or prior knowledge, it is desired to find a family of probability distributions for the times T_s needed for the HI to reach any intermediate health level s,

$$0 < s < 1 \tag{1}$$

In other words, given a prior probability distribution, conditional upon $HI(0) = 1$, for the time to failure T,

$$T = \inf[t : HI(t) = 0] \tag{2}$$

find, for any intermediate level s, the probability distribution for T_s:

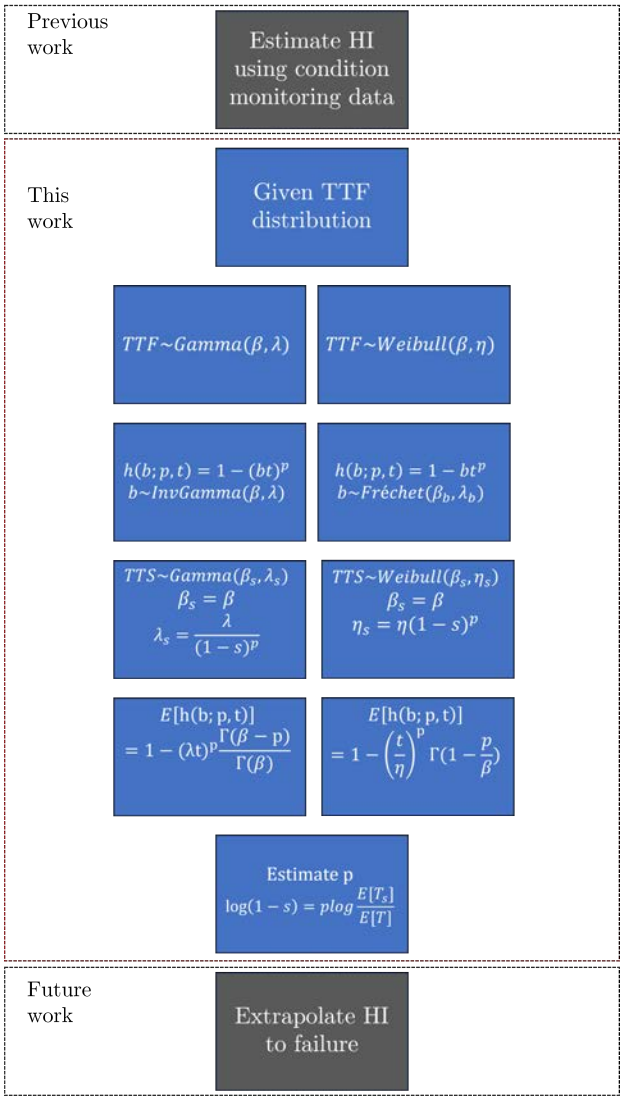

Figure 1. Flowchart illustrating the different steps of the proposed method along with the context of its applicability. (*Previous work*) The methodology assumes the availability of asset-specific Health Index (HI) derived from CM data, for instance, based on Bajarunas et al. (*This work*) The process of estimating begins with the assumption of a prior plausible Time to Failure (TTF) distribution (Gamma or Weibull models) and a probabilistic parametric model of a Health Index ($h(b, p, t)$). Based on these assumptions, we derive the analytical forms of the distributions describing the time required for the HI to reach any specified intermediate health level (TTS), thus providing a comprehensive statistical framework to model a degradation process. (*Future work*) The estimation of probabilistic, asset-specific failure times through extrapolation of individual HI's is suggested as a possible application of the derived analytical HI.

2.2. Resolution Method: General Principle

Let $R(t)$ denote an assumed reliability function. Then a probabilistic model for $HI(t)$, as a non-increasing function of t, is selected, and the condition $P[T > t] = R(t)$ is imposed. Finally, Eq. (3) is applied to obtain the distribution of T_s:

$$R_s(t) = P[T_s > t] \tag{4}$$

Let us consider the following parametric model for the health index:

$$HI(t) = h(p_1, p_2, ...p_n; t) \tag{5}$$

with an assumed functional form h, where some of the parameters $p_1, p_2, \ldots, p_n$ are random variables.

Then, it should be noted that

$$h(p_1, p_2, ...p_n; t) > 0 \tag{6}$$

is equivalent to

$$T > t \tag{7}$$

therefore the following condition is imposed:

$$P[h(p_1, p_2, ...p_n; t) > 0] = R(t) \tag{8}$$

with the right-hand side of Eq. (8) known.

Similarly, the condition $T_s > t$ is equivalent to $HI(t) > s$ and hence from Eq. (8), one derives

$$P[h(p_1, p_2, ..., p_n; t) > s] = R_s(t) \tag{9}$$

for any value of s between 0 and 1.

The method is quite general and can be applied to any TTF distribution. In the next two subsections, the method is detailed and illustrated on two frequently encountered families of TTF distributions: Gamma and Weibull, respectively.

2.3. Gamma Case

Let us consider the case when the time to failure follows a Gamma distribution with shape parameter β and rate parameter λ. The Gamma reliability function for time T (Nachlas, 2017) can be expressed as:

$$R(t) = 1 - \frac{\gamma(\lambda t; \beta)}{\Gamma(\beta)} \tag{10}$$

where $\gamma(\lambda.t; \beta)$ stands for the incomplete Euler gamma function.

A health index is sought, $HI(t)$, such that the time for the HI to reach the value 0 is Gamma-distributed.

We shall now show that a solution is provided by the following power law for the health index:

$$T_s = \inf[t : HI(t) = s] \tag{3}$$

$$h(b; p; t) = 1 - (bt)^p \tag{11}$$

with a positive exponent p and a random variable b with an inverse-gamma distribution with shape parameter β and scale parameter λ (b has the dimension of a frequency, i.e., the inverse of a time, so does λ). The health index defined by Equation (11) decreases monotonically from 1 to 0 as the time or usage variable t increases from 0 to $\frac{1}{b}$. It is a convex function of t if $p < 1$ and a concave function if $p > 1$ (and linear in the limit case of $p = 1$). The property that b has an inverse-Gamma distribution is equivalent to $\frac{1}{b}$ having a Gamma distribution with parameters β (shape) and λ (rate).

Denoting by T the time to failure, there follows from the above health index definition that

$$P[T > t] = P[(bt)^p < 1] = P[bt < 1] = P[\frac{1}{b} > t] \quad (12)$$

Since $\frac{1}{b}$ is Gamma distributed , the right-hand side of (12) is the Gamma reliability function at time t, with shape and rate parameters respectively equal to β and λ. Therefore, it has been proved that the definition (11) for the health index leads to a Gamma-distributed time to failure. .

Now let us look at the distribution of the time for the health index to reach a level s, between 0 and 1.

Let us denote that first hitting time T_s.

$$P[T_s > t] = P[h(b; p; t) > s] = P[1 - (bt)^p > s] \quad (13)$$

Equation (13) is equivalent to:

$$P[T_s > t] = P[(bt)^p < 1 - s] = P[\frac{1}{b} > \frac{t}{(1-s)^{\frac{1}{p}}}] \quad (14)$$

Since $\frac{1}{b}$ is Gamma (β,λ) distributed, it follows from (10) that,

$$R_{T_s}(t) = P[T_s > t] = 1 - \frac{\gamma(\frac{\lambda t}{(1-s)^{\frac{1}{p}}}; \beta)}{\Gamma(\beta)} \quad (15)$$

Therefore it has been shown that T_s has a Gamma distribution with shape factor β, and rate parameter λ_s given by the following function of s and the exponent p:

$$\lambda_s = \frac{\lambda}{(1-s)^{\frac{1}{p}}} \quad (16)$$

The problem stated in the beginning has thus been solved in the case when the time to failure has a Gamma distribution. The mathematical expectations of T_s and that of the health index $HI(t)$ are then derived explicitly, as follows, from the properties of the gamma distribution and the inverse-gamma distribution (Llera & Beckmann, 2016):

$$E(T_s) = \frac{\beta}{\lambda_s} = \frac{\beta}{\lambda}(1-s)^{\frac{1}{p}} \quad (17)$$

which can also be written as :

$$E(T_s) = E(T)(1-s)^{\frac{1}{p}} \quad (18)$$

To derive the expectation of the health index $HI(t)$; we now use properties of the inverse-gamma distribution. If X has an inverse-gamma distribution with parameters β and λ, the nth-order moment of X is given (Llera & Beckmann, 2016) by:

$$E(X^n) = \lambda^n \frac{\Gamma(\beta - n)}{\Gamma(\beta)} \quad (19)$$

as long as

$$n < \beta$$

Therefore

$$E[HI(t)] = 1 - E(b^p)t^p = 1 - (\lambda t)^p \frac{\Gamma(\beta - p)}{\Gamma(\beta)} \quad (20)$$

assuming the exponent p to be smaller than the shape factor β.

2.4. Weibull Case

We shall now consider the case where the time to failure follows a 2-parameter Weibull distribution. Denoting β and η the shape and scale parameters, respectively, this corresponds to the well-know reliability function:

$$R(t) = e^{-(t/\eta)^\beta} \quad (21)$$

For the health index, let us take the following power law, slightly different from the one taken in the Gamma distribution case, for reasons which will become apparent:

$$h(b; p; t) = 1 - bt^p \quad (22)$$

where p is a positive exponent, and b is a random variable. It will be seen that, if b has a Fréchet distribution (Fréchet, 1927; Ramos, Louzada, Ramos, & Dey, 2020), then the time to failure is Weibull distributed.

Indeed, by definition of the Fréchet (also known as "inverse Weibull") distribution, if the random variable b is Fréchet-distributed with scale parameter λ_b and shape parameter β_b, then:

$$P[b > u] = 1 - exp[-(\frac{u}{\lambda_b})^{-\beta_b})] \quad (23)$$

The shape parameter β_b is dimensionless, and the scale parameter λ_b has the dimension of t to the power of $(-p)$, just as the coefficient b.

Then, by substituting

$$u = t^{-p} \quad (24)$$

in (23), the following is obtained :

$$P[HI(t) > 0] = P[b < t^{-p}] = exp[-(\lambda_b t^p)^{\beta_b}] \quad (25)$$

and this expression must be equated to $P[T > t]$, which is assumed to be the reliability function of a two-parameter Weibull variable (η ,β).

Therefore, the parameters of the Fréchet distribution for b are obtained as follows:

$$\lambda_b = 1/\eta^p \quad (26)$$

$$\beta_b = \beta/p \quad (27)$$

as it can be verified by substituting the right-hand sides of (26) and (27) respectively for λ_b and β_b in (25). Then the distribution of T_s, the first hitting time of level s, can be derived as well, for any value of s between 0 and 1.

$$P[Ts > t] = P[HI(t) > s] \quad (28)$$

$$= P[1 - bt^p > s] = P[b < (1-s)t^{-p}] \quad (29)$$

Therefore, by substituting for u in (23) the value $(1-s)t^{-p}$ and using (26) and (27),

$$P[Ts > t] = exp[-(t^p/\eta^p(1-s))^{\frac{\beta}{p}}] \quad (30)$$

or

$$P[Ts > t] = exp[-(1-s)^{-\frac{\beta}{p}}(\frac{t}{\eta})^{\beta}] \quad (31)$$

It is seen that (31) describes the reliability function of a Weibull random variable with: 1) the same shape factor β as the distribution of T; 2) A scale factor η_s expressed as follows as a function of s , the scale factor η of T and the exponent p:

$$\eta_s = \eta(1-s)^{\frac{1}{p}} \quad (32)$$

Thus, the problem stated in the beginning has also been solved in the Weibull distribution case.

Accordingly, the mathematical expectation of the first hitting time T_s is obtained:

$$E(T_s) = \eta(1-s)^{\frac{1}{p}}\Gamma(1+\frac{1}{\beta}) \quad (33)$$

Equation (33) can also be formulated as

$$E(T_s) = E(T)(1-s)^{\frac{1}{p}} \quad (34)$$

which is the same as in the Gamma-distribution case (18). Also, the expectation of the health index $HI(t)$ at time t can be derived from the expectation of the random coefficient b, assumed Fréchet distributed:

$$E(b) = \frac{1}{\eta^p}\Gamma(1-\frac{p}{\beta}) \quad (35)$$

Therefore

$$E(HI(t)) = 1 - E(b)t^p = 1 - (\frac{t}{\eta})^p\Gamma(1-\frac{p}{\beta}) \quad (36)$$

The quantiles of b can also be derived. The x-percent quantile is B_x:

$$B_x = \frac{1}{\eta^p(-lnx)^{\frac{p}{\beta}}} \quad (37)$$

In particular, the median (50-percent quantile) is given by:

$$B_{0.5} = \frac{1}{\eta^p(ln2)^{\frac{p}{\beta}}} \quad (38)$$

2.5. Estimation of Exponent p from Data

From (32), there follows, by taking logarithms,

$$\log(1-s) = p\log(\frac{\eta_s}{\eta}) \quad (39)$$

Therefore, after estimating η_s from the data sample for various values of s, the regression coefficient of $\log(1-s)$ with respect to $\log(\frac{\eta_s}{\eta})$ will provide an estimation of p. Also, taking (34) into account,

$$log(1-s) = p\log(\frac{E(T_s)}{E(T)}) \quad (40)$$

Therefore, in order to estimate p, it is equivalent to estimate $E(T_s)$ from the data samples corresponding to several values of s and then run the linear regression of $\log(1-s)$ with respect to $\log(\frac{E(T_s)}{E(T)})$. The regression coefficient (slope) is the best estimate of p. The same method applies in the Gamma distribution case since the dependence of E(T_s) on s is the same in both cases (see Section 2.3).

2.6. Incomplete Degradation Trajectories

Our method for obtaining an analytical form of the HI does not require run-to-failure condition monitoring data [1]. Let us

[1] If no failures are observed the HI has a different meaning as it is normalized with respect to the most degraded unit in the fleet.

consider u as the smallest threshold of $HI(t)$ observed for all units in the fleet. Then in equation (34), instead of considering the expected TTF, $E(T)$, we would consider the expected time to hit the common threshold $E(T_u)$. The revised equation would be:

$$E(T_s) = E(T_u)\frac{(1-s)^{1/p}}{(1-u)^{1/p}} \tag{41}$$

Where $E(T_s)$ is the sample arithmetic mean for each value $s > u$. When $u = 0$, this is equivalent to Eq. 34. The exponent p can be estimated from linear regression in

$$\log(1-u) - \log(1-s) = p(\log(E(T_u)) - \log(E(T_s))) \tag{42}$$

3. Case Studies

3.1. Turbofan

The New Commercial Modular Aero-Propulsion System Simulation (N-CMAPSS) dataset (Arias Chao, Kulkarni, Goebel, & Fink, 2021) offers comprehensive degradation trajectories of turbofan engines until failure. Among the dataset's eight subsets, we focus on DS003, characterized by a failure mode impacting the efficiency and flows of both low-pressure and high-pressure turbines.

The N-CMAPSS dataset characterizes degradation at the component level across initial, normal, and abnormal degradation stages. Consequently, an HI is calculated through a non-linear mapping of operational margins under reference conditions. System failure is determined when the HI reaches 0. The dataset also accounts for between-flight maintenance by allowing improvements in engine health parameters within specified limits. The ground truth HI is shown in Figure 2, and will be used to verify the findings of Section 2.3 and 2.4. Estimating the HI using condition monitoring data as highlighted in (Bajarunas et al., 2023) is also possible.

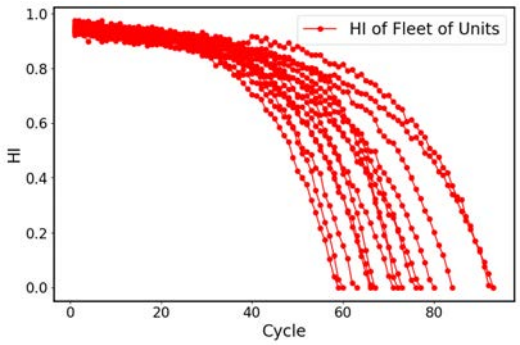

Figure 2. Observed HI in N-CMAPSS DS03 Dataset

The Akaike Information Criterion (AIC) (Akaike, 1974) was used to compare the goodness of fit with different probability distributions (Weibull, Gamma, Exponential), see Table 1. When a statistical model is used to represent the process that generated some data, some information is lost. The AIC, based on information theory, estimates the amount of information lost. It deals both with overfitting and underfitting by taking model simplicity into account as well as goodness of fit. The AIC is defined by

$$AIC = -2log(maxL) + 2P \tag{43}$$

where the term log(maxL) denotes the maximum value of the log-likelihood function, and P is the number of parameters in the model (for instance,for Weibull or Gamma, P is equal to 2). In our example, the best value of the AIC was obtained with the Gamma distribution for the time to failure as well as the time to reach level s for s ranging from 0 to 0.8. The AIC value for Weibull distribution is almost identical. In contrast, the AIC value for the exponential distribution is much higher.

Using the Maximum Likelihood Estimation technique, we estimated the best-fit Gamma parameters for various s thresholds. Figure 3 shows the estimated β_s and λ_s values for $s = [0, 0.1, 0.2, ..., 0.8]$. The results validate the conclusion presented in Section 2.3: the distribution of the first hitting time T_s shares the same shape factor $\beta = 52.83$ as the distribution of failure times T. Additionally, the rate parameter λ_s is a function of s and λ of T. We determined $p = 3.35$ following the description provided in Section 2.5. The wide confidence intervals of β_s and λ_s can be primarily attributed to the limited number of observations (15 run-to-failure curves), rather than to the choice of the Gamma distribution, which we have demonstrated to be the most suitable among the alternative distributions investigated.

We then estimated the best-fit Weibull parameters for various s thresholds. In Figure 4, we estimated β_s and η_s using $s = [0, 0.1, 0.2, ..., 0.8]$. The results validate the conclusion presented in Section 2.4: the distribution of the first hitting time T_s shares the same shape factor $\beta = 7.32$ as the distribution of failure times T. Additionally, the scale parameter η_s is a function of s and η of T.

Figure 5 illustrates the mean, median, and 90% quantile of $HI(t)$, as described by equations (36) and (37). Notably, we observe that the median closely aligns with the ground truth HI within the dataset.

3.2. Battery

The methodology proposed in this study was further validated using a dataset obtained from the NASA Ames Prognostics Center of Excellence repository, specifically focusing on battery usage patterns (Bole, Kulkarni, & Daigle, 2014). This dataset includes information collected from individual 18650 LCO cells undergoing various charging and discharging cycles following randomized protocols.

Batteries commonly exhibit several physical aging mecha-

0.9	116	113	127

nisms such as graphite exfoliation, electrolyte loss, solid electrolyte interface layer formation, continuous thickening, and lithium plating, among others (Sui et al., 2021). These aging processes lead to two primary changes in battery behavior: capacity degradation and increased internal resistance. In this analysis, our focus will be on capacity degradation as the key health index for the batteries under investigation.

The HI of a battery is defined as the ratio between its current capacity and the nominal capacity (Q/Q_{nominal}). The battery's capacity can be determined by reference discharge cycles conducted at a constant current (I). The current capacity is calculated as the integral of current over the entire

reference discharge cycle, denoted as $\int_t I$.

In this work, the failure of a battery (HI = 0) is defined once the capacity ratio is less than 60%. The initial HI of the battery is equal to the initial capacity ratio. Figure 6 shows the estimated HI of the NASA battery dataset.

The AIC values of three different distribution fits are shown in Table 2. The best fit was obtained with Gamma distribution for the time to failure as well as the time to reach level s for s ranging from 0 to 0.9. The AIC value for Weibull dis-

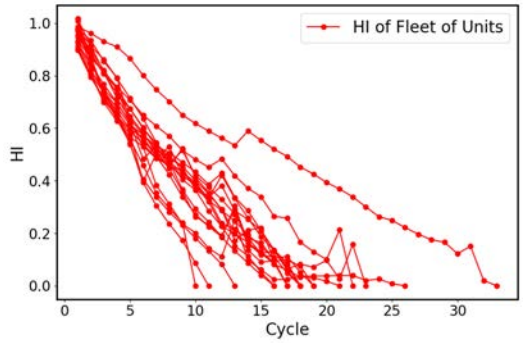

Figure 6. Observed HI in NASA battery dataset

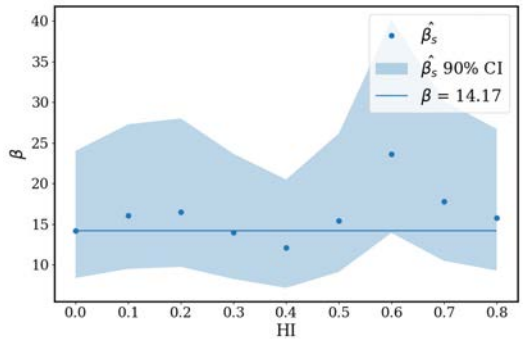
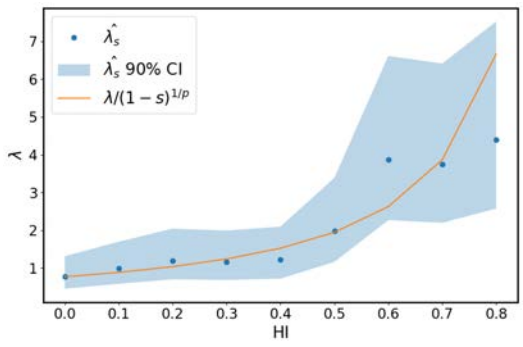
tribution is almost identical,in contrast with the exponential distribution AIC, much higher.

We employed the Maximum Likelihood technique to estimate the best-fit Gamma parameters for various s thresholds. In Figure 7, we estimated β_s and λ_s using $s = [0, 0.1, 0.2, ..., 0.8]$. Once more, we illustrate that a reasonably good approximation for the shape parameter β_s of the first hitting time is the shape parameter β of T. Following the estimation of $p = 0.94$, we demonstrate that the rate parameter λ_s varies with s and λ. Since $p < 1$, the HI curve is now convex, as observed.



(a) β_s



(b) λ_s

Figure 7. The Gamma distribution shape factor β_s and the rate parameter λ_s for various HI thresholds for NASA battery dataset.

The best-fit Weibull parameters for various s thresholds are shown in Figure 8. Once again, we show that a reasonably good approximation for the shape parameter of the first hitting time β_s is the shape parameter β of the failure time T and that the scale parameter η_s varies with s and η as expected.

0.8	54	60	89
0.9	44	50	71

4. Sensitivity Analysis

Sensitivity analysis has been conducted on the N-CMAPSS dataset, to investigate the effect of the exponent p in the parametric model of the health index.

For the Gamma case, it is immediate from (16) that, for given

s, λ_s is a decreasing function of p (for p greater than, or equal to 1). In the limit of p going to infinity, λ_s converges to λ. For the Weibull case, a similar conclusion is drawn, but instead from (32) it follows that, for given s, η_s is an increasing function of p.

From (18) and (34) it follows that for both considered distributions the average time to reach threshold s, $E(T_s)$, is an increasing function of p, as illustrated in Figure 9.

For both distributions, when p increases, the average value of the HI is first higher than, and subsequently (for greater values of the time variable t), lower than, the HI corresponding to a lower value of p. Increasing p corresponds to delaying the decrease in HI, i.e., delaying the onset of the degradation; but, once the degradation occurs, it is more sudden. See Figure 10 for an illustration.

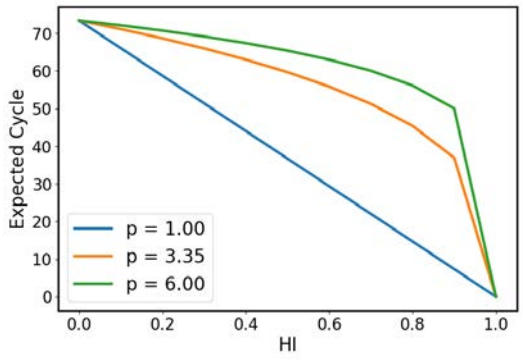

Figure 9. Gamma and Weibull distribution $E[T_s]$ as a function of s for three values of p. N-CMAPSS dataset.

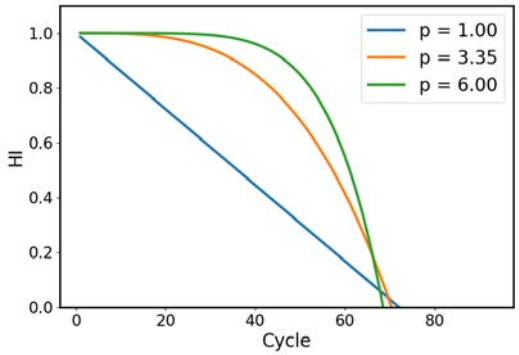
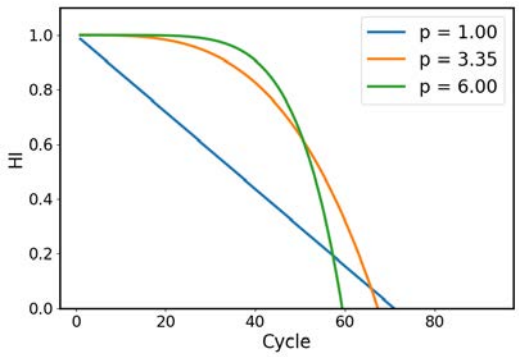
5. Conclusion and Perspectives

This study has successfully addressed the problem of analytically modeling health indices (HI) in cases where the time-to-failure follows either a Gamma or Weibull distribution. By leveraging observed health index trajectories over time and specifically the failure times, we have derived an analytical form for the health index that is consistent with these observations. Additionally, we provided an analytical expression for the distribution of the time to reach any intermediate degradation level.

The availability of closed-form expressions for the health index is highly beneficial for implementing predictive maintenance strategies, particularly for estimating the remaining useful life (RUL) distribution. Furthermore, once a health index function is derived for a particular application, it can potentially serve as a foundation for similar applications, such as the same asset under different operating conditions or a slightly modified asset. Without an analytical characterization, a new health index would need to be learned from scratch for each new dataset.



(a) Gamma distribution $E[HI(t)]$ as a function of t for three values of p. N-CMAPSS dataset.



(b) Weibull distribution $E[HI(t)]$ as a function of t for three values of p.

Figure 10. Sensitivity to various p for the turbofan case study. N-CMAPSS dataset.

Future work could extend this approach to other TTF distributions and other HI formulations by applying the general methodology outlined in Section 2.2. Additionally, an important extension of this work could be the use of quantile regression and extrapolation of the HI from individual degradation trajectories. More broadly, the analytical health index approach represents a significant advancement in survival analysis, offering opportunities to integrate machine learning techniques, particularly 'deep survival' methods, with traditional reliability engineering.

BIOGRAPHIES

Dr.Pierre Dersin: Dr. Dersin is currently Adjunct Professor at Luleå University of Technology (Sweden) in the Operation and Maintenance Engineering Division. He is also the president and founder of Eumetry sas, Louveciennes,France, a consulting firm in the fields of RAMS, PHM and AI. He holds a Ph.D. in Electrical Engineering from the Massachusetts Institute of Technology (MIT),as well as a Master's degree in Operations Research, also from MIT, and math and E.E. degrees from Université Libre de Bruxelles (Belgium). From 1990 to 2021, he was with Alstom Transport, France, where he occupied several technical and managerial positions, including RAM (Reliability-Availability-Maintainability) Director and RAM Master Expert,and founded the "RAM Center of Excellence".In 2015, he contributed to the launch of the predictive maintenance activity at ALSTOM and became PHM (Prognostics and Health Management) Director of ALSTOM Digital Mobility, St-Ouen, France. From 2014 to 2018, he was also the co-director of the joint Alstom-Inria Research Lab on Digital Mobility, and supervised several Ph.D. theses. Prior to joining Alstom, he was employed in the USA ,first as a research scientist in the US DOE large-scale system effectiveness program; and subsequently,with Belgian engineering firm Fabricom's US subsidiary, involved with fault detection and diagnostics in industrial systems. He has contributed a number of conference and journal papers in the fields of RAMS, PHM, automatic control, electric power systems, and AI. He was the keynote speaker at the 2014 European Conference of the PHM Society . Dr.Dersin is the author of the book " Modeling Remaining Useful Life Dynamics in Reliability Engineering" , CRC Press, Taylor and Francis, June 2023. His current interests focus on the confluence between RAMS and PHM as well as complex systems resilience and asset management.

Kristupas Bajarunas: Kristupas Bajarunas is a Ph.D. candidate at Delft University of Technology (Netherlands) and Zurich University of Applied Sciences (Switzerland). He holds an M.Sc. in Machine Learning from the Royal Institute of Technology (Stockholm). His current research is concerned with developing generic hybrid models for prognostics.

Dr. Manuel Arias Chao: Dr. Arias Chao is a Senior Lecturer at Zurich University of Applied Sciences and a visiting researcher at the Air Transport and Operations of the Delft University of Technology in the Netherlands. He has a PhD in Physics-informed Machine Learning for Prognostics and Health Management from ETH Zurich, a Master's degree in

Thermal Power from Cranfield University, and a Bachelor's degree in Aeronautical Engineering from the Technical University of Madrid. Manuel has gained valuable industrial and research experience as a visiting researcher at the Diagnostics & Prognostics Group at NASA Ames, Thermodynamics & Performance Lead Engineer at General Electric and ALSTOM Power, and Aero Engine Maintenance Engineer at ITP. In his current role, Manuel also co-leads the Expert Group Smart Maintenance from the Swiss Alliance for Data-Intensive Services. He focuses on teaching & research for a broad range of application fields, including power generation, marine and aircraft propulsion, and manufacturing equipment.

Anomaly Detection of a Cooling Water Pump of a Power Plant Based on its Virtual Digital Twin Constructed with Deep Learning Techniques

ABSTRACT

This paper aims to explore the use of recent approaches of deep learning techniques for anomaly detection of potential failure modes in a cooling water pump working in a gas-combined cycle in a power plant. Two different deep learning techniques have been tested: neural networks and reinforcement learning. Two virtual digital twins were developed with each family of deep learning techniques, able to simulate the behavior of the cooling water pump in the absence of pump failure modes. Each virtual digital twin consists of several models for predicting the expected evolution of significant behavior variables when no anomalies exist. Examples of these variables are bearing temperatures or vibrations in different pump locations. All the data used comes from the SCADA system. The main features and hyperparameters in the virtual digital twins are presented, and demonstration examples are included.

1. INTRODUCTION

The early anomaly detection of failure modes in a power plant is a key factor in mitigating their effects on its operation, maintenance, and, in general, potential costs not planned. This problem has been studied intensively in the scientific literature for some time. Today, the availability of a large amount of data and the development of different machine learning techniques have propitiated their increasing use for early anomaly detection. References (Chavan & Yalagi, 2023), (Pang, Shen, Cao, Van Den Hengel (2021)), or (Nassif, Talib, Nasir & Dakalbab (2021)) are some examples of literature reviews in this area.

Also, anomaly detection with respect to the expected normal behavior is a crucial input for a data-driven, efficient prognostics and health management program (PHM) as is inferred from references (Maior, Araújo, Lins, Moura &. Droguett, 2023), (Ochella, Shafiee & Dinmohammadi, 2021) and (Calvo-Bascones, Sanz-Bobi & Welte, 2021). These references are based on machine learning techniques as the main tools to reach their objectives.

In line with these principles, this paper presents a digital twin of a cooling water pump (CWP) working in a power plant able to emulate normal behavior through a set of characteristic variables when the pump is in normal operation. The variables predicted are those that were considered important for the detection of anomalies that could cause failure modes. The digital twin was developed using two different families of deep learning techniques (Bishop & Bishop, 2024): neural networks and reinforcement learning. The use of reinforcement learning techniques in this field is less known, and this paper explores its potential by comparing the results obtained with a more extended method based on deep neural networks.

The paper is organized as follows: Section 2 describes the foundations of the study. Section 3 presents the digital twins developed and the methodology used. Section 4 shows the anomaly detection results based on the digital twins. Finally, Section 5 presents the more relevant conclusions reached.

2. STUDY FOUNDATIONS

The objective of the analysis presented in this paper is to detect anomalies as soon as possible in the behavior expected for a Cooling Water Pump (CWO) working in a combined

cycle of a power plant. Even when the paper is focused on the case of a CWP, the idea is to develop a procedure that can be easily extended to other components in the power plant. A CWP (Bowman & Bowman, 2021) is an important component whose objective is to cool the steam from the water turbine in an enthalpic process that contributes to the improvement of the water-steam cycle efficiency in the power plant. The process of monitoring if the pump is working as expected in normal behavior for any working condition is based on the consideration of the most typical failure modes that could appear in this type of pump. A Failure Mode and Effects Analysis (FMEA) (Huang, You, Liu & Song, 2020) suggested the main observable variables that could indicate the presence of an anomaly and that can be summarized by monitoring the vibrations in the pump axes, temperature in bearings, and currents in the electrical motor. As it is known, all of these potential failure modes have an important critical impact on keeping the pump in healthy condition.

This information has been used to support the development of a virtual digital twin to predict, in any working condition, the expected values of the vibrations in the axes of the pump, the temperature in its main bearings, and the currents in the electrical motor. This virtual digital twin is based on several models that characterize the relationships between variables to monitor for possible anomalies and the working conditions of the power plant. The list of variables predicted by the models developed follows:

- Prediction of vibration in axis X
- Prediction of vibration in axis Y
- Temperature of the bearing on the electrical motor side
- Temperature of the bearing on the pump side
- Temperature of pump thrust bearing
- Current in the electrical motor

The inputs to all the models correspond with the power generated by the steam turbine of the combined cycle power plant, which is the most important flow to cool, and the temperature in the electrical motor representing the work developed by the pump. The CWP is a high-pressure pump that is horizontal, centrifugal, and multistage. The pump and its motor are mounted on a common structural steel bedplate. Its behavior is monitored from a control room of the power plant where the variables measured in the CWP are accessible.

3. DIGITAL TWIN MODELS

Two redundant virtual digital twins (Jones, Snider, Nassehi, Yon & Hicks, 2020) were developed for the CWP. Both aim to simulate the CWP when it works in normal conditions. The emulation of the expected values for anomaly detection of the target variables is based on a double redundant strategy that uses two different families of deep learning algorithms supporting the models cited: deep learning neural networks and deep reinforcement learning. The datasets used for the creation of the models behind the digital twin correspond to three years of the CWP operation that here will be called year 1, year 2, and year 3. Year 1 will be used for learning the relationships to model, and the other two years will be used for checking the behavior of the digital twin of the pump, simulating its behavior. Python is the programming language used in both versions of the CWP digital twin.

The following subsections will present the results reached by these two types of algorithms.

3.1. CWP digital twin based on Deep Learning Neural Networks (DLNN)

As previously mentioned, six models were created using deep learning neural networks. The procedure followed was similar in all the cases; for this reason, only one case will be described as an example of the method followed. If the whole set of models is used, more than one type of anomaly related to one failure mode could be detected. The example case described here is the estimation of the bearing temperature at the mechanical axis on the side of the connection to the electrical motor. The dataset used for training is Year 1. The input variables were the power generated by the steam water and the temperature in the electrical motor, which represents the working conditions of the CWP. After preprocessing and scaling the data, the *Optuna* open software tool (Akiba, Sano, Yanase, Ohta & Koyama, 2019) was used to find a convenient architecture and hyperparameters of the deep learning neural network. Tables 1 and 2 present the main characteristics of the neural network architecture and the most significant hyperparameters.

Table1. Deep Learning Neural Network. Architecture

Layer	Layer type	Number of neurons	Activation function
1	Dense	40	Sigmoid
2	Dense	25	Sigmoid
4	Dense	1	Sigmoid
4	Output	1	Linear

Table 2. Algorithm Implemented

Language	Python
Main Library	Keras and Tensorflow
Loss function	Mean Squared Error
Optimiser	Adam, learning_rate=0.001, epsilon=1^{e-8}
Training	Epochs=500, steps per epoch=100

Figure 1 shows the result of the relationship learned between the input and output variables based on data from Year 1. Both real and predicted values of the bearing temperature are very close. Their difference or error is in Figure 2. It shows that the most part of the error is the interval [-1, 1] ºC. It suggests a good simulation performance for this part of the digital twin. The axis X is in samples separated by 10 minutes.

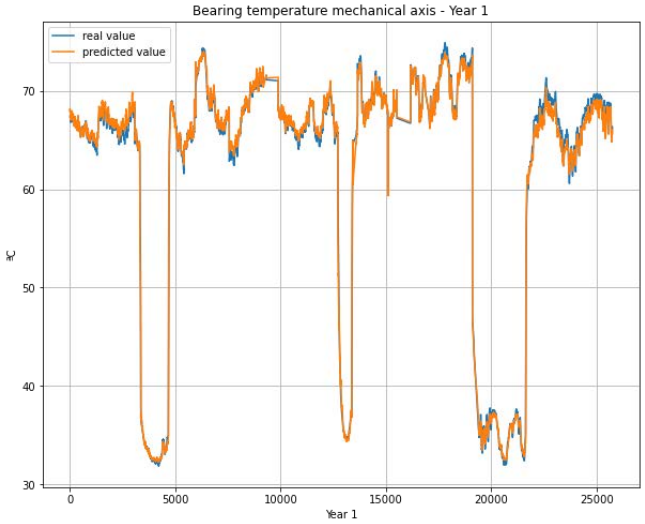

Figure 1. Real and predicted values for the bearing temperature using Year 1 data.

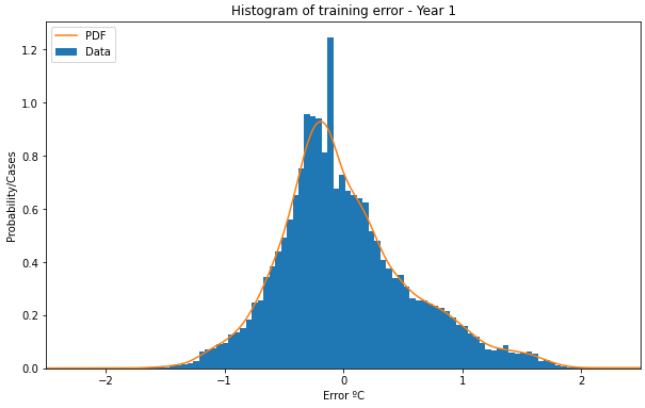

Figure 2. Error observed between real and predicted values for the bearing temperature using Year 1 data.

As a confirmation of the goodness of the model obtained to predict the bearing temperature, Figure 3 presents how good the prediction of this variable is when data used were not included during the creation of the model. Once again, the real and predicted values are very close, concluding that the model created is valid to simulate the bearing temperature in the normal behavior of the CWP. Also, this confirms that no overfitting issues are present. The errors observed are in the same range of values observed with the training dataset, and the same conclusion is reached for the Year 2 dataset. This confirms that this model can be used as a virtual twin of part of the CWP.

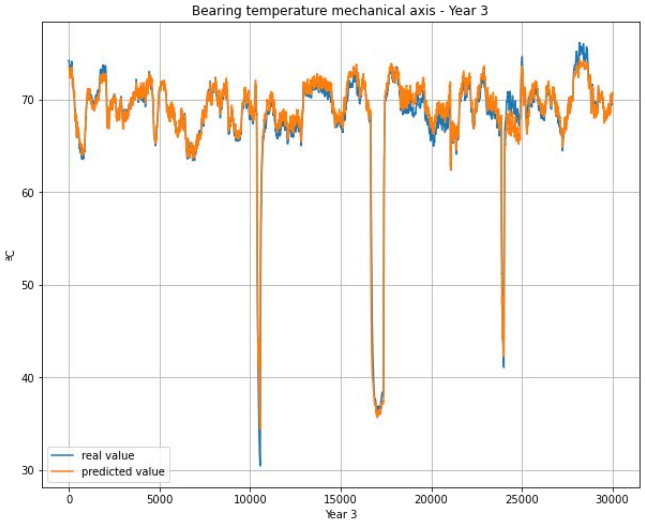

Figure 3. Real and predicted values for the bearing temperature of the dataset Year 3 not used in training.

3.2. CWP digital twin based on Deep Reinforcement Learning (DRL)

Once the CWP digital twin was developed using DLNN, a completely different type of algorithm was studied to cover the same objective. The idea was to explore Reinforcement Learning (RL) techniques for elaborating a digital twin of the CWP. At present, these techniques are not used very often in diagnosing industrial processes, and the number of publications about them is very limited.

Reinforcement Learning (Sutton & Barto, 2018) is a technique where an agent acts in an environment. It has a state, and it can make an action. After each action, the environment provides it with its new state and a reward corresponding to how good the action was. Therefore, the agent learns the parameters of a Quality function and makes new actions according to it. The agent has a multidimensional state space and a multidimensional action space. Figure 4 represents a schema of the basic cyclic process used in RL.

Figure 4 represents the correspondence between the main elements of RL. The objective is to build the same models described for the case DLNN. Here, the state is the input data used by the models. The action is the prediction of the behavior of the pump, considering its different working conditions. The environment gives a reward to penalize how far the prediction is from the real value and gives a new state, which is the new entrance data. The action space is continuous because a real value represents it. There are several RL algorithms; however, due to the continuous nature

of the problem to be managed, a Twin Delayed Deep Deterministic Policy Gradient algorithm (TD3) was selected. Details of the method and a pseudocode can be found in (Fujimoto, van Hoof & Meger, 2018).

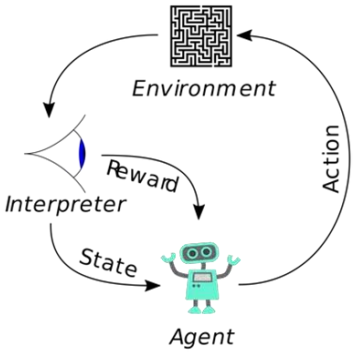

Figure 4. Basic learning cycle of Reinforcement Learning.

With the TD3 algorithm, the agent needs two deep neural networks to decide on its action. The PolicyNetwork determines an action to take. It takes the input data and returns the action, and the Q_network determines the Q_value of the action. It takes the input data and the action and returns the Q_value. During the training phase of the algorithm, the gradient for training the Q_network is calculated based on a linear combination between the reward and the prediction of the algorithm. The PolicyNetwork is trained based on the variation of the Q_network. The Q_Network weights are initialized between -3 and 3. The PolicyNetwork weights are initialized between -0,3 and 0,3. The networks are composed of three linear dense layers with a *relu* activation function.

Table 3. TD3 Hyperparameters

Algorithm Hyperparameter	Value
Training episodes	100
Steps per episode	100
Exploration factor	0.1
Replay buffer size	1032
Batch size	1024
Delayed steps for updating the policy network and target networks	10
Size of hidden layers for networks	64
Learning rate Q_network	3e-4
Learning rate Polocy_network	3e-4
Reward scale	100.

Table 3 presents the values used for the main hyperparameters of the TD3 algorithm. *Keras* and *tensorflow* were used for the implementation of the TD3 algorithm. The reward in RL is essential to guide the correct learning process. The reward design is based on a function of 6 levels depending on the absolute difference between the real and predicted values observed for the output variable of the model. The reward ranges from 100 for differences lower than 0.001, till -1500 for differences higher than 0.3.

Figure 5.a shows the result of the relationship learned between the input and output variables based on data from Year 1. Both real and predicted values of the bearing temperature are very close. Their difference or error is in Figure 5.b It shows that the most part of the error is the interval [-1, 1] ºC. It suggests a good simulation performance for this part of the digital twin.

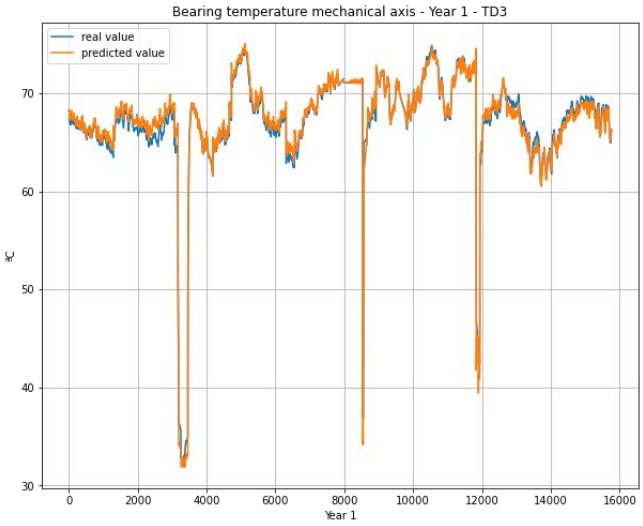

Figure 5.a. Real and predicted values for the bearing temperature using Year 1 data and TD3 algorithm.

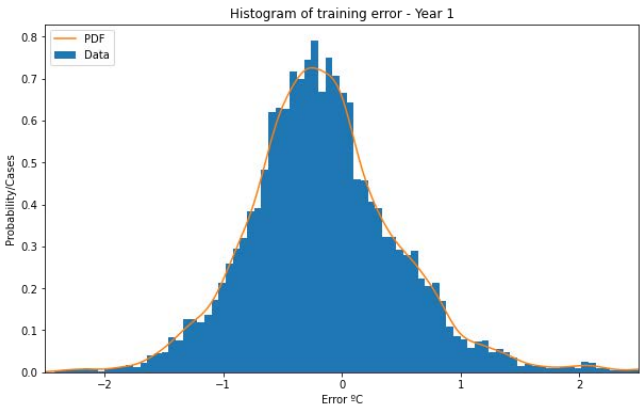

Figure 5.b. Error observed between real and predicted values for the bearing temperature using Year 1 data and TD3 algorithm.

Figure 6 confirms the model goodness using RL to predict the bearing temperature when the data used, Year 2, were not included in the model training process. Once again, the real and predicted values are very close, concluding that the model created with the RL algorithm TD3 is also appropriated to simulate the bearing temperature in the normal behavior of the CWP. The errors observed are in the same range of values observed with the training dataset, and the same conclusion is reached for the Year 3 dataset. This confirms that this model can be used as a virtual twin of part of the CWP.

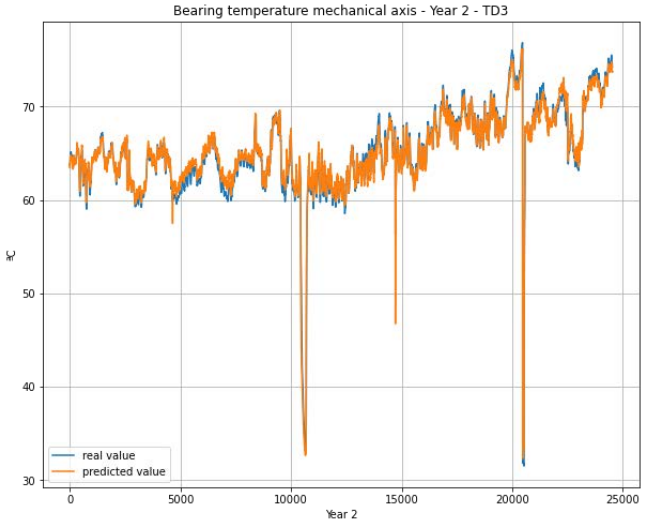

Figure 6. Real and predicted values for the bearing temperature using Year 2 data and TD3 algorithm.

3.3. Comparative results of both CWP digital twins: DLNN and DRL

Once both virtual digital twins were obtained to simulate the CWP performance, one of the objectives of this study was reached, which was the comparison between the use of DLNN and DRL techniques. As mentioned, the use of DRL for this type of problem is not too extended. The results obtained have demonstrated that DRL is a reasonable option in terms of simulation of the behavior of a real industrial component. Table 4 shows the mean and standard errors obtained in °C degrees in all the cases studied with both deep learning methods. It can be observed that the values are within the accuracy of any temperature sensor used in industry, and both methods can be used with similar confidence for detecting deviations concerning the normal behavior expected.

However, the main objective of this study is the early detection of possible anomalies that can cause failures. The next section will show how the digital twins can be used for that.

Table 4. Mean and standard errors obtained

	Year 1	Year 2	Year 3
Mean_DLNN	0,03600	-0,26709	0,16897
Std_DLNN	0,71556	1,36557	1,24222
Mean_TD3	-0,14583	-0,04837	-0,04837
Std_TD3	0,68032	0,04842	0,99234

4. ANOMALY DETECTION AND RISK ASSESSMENT

The digital twins described in the previous section and their good performance permit the application of a redundant strategy for robust anomaly detection. It is important to note that the algorithms used for both digital twins are completely different, even when they observe the same information. It seems clear that if both coincide in detecting an anomaly in the behavior expected, its certainty should be high. Also, if both observe normal behavior. In the case of a discrepancy, careful monitoring must be observed for the new coming data. Redundancy is key for preventing false alarms in anomalies detected.

Another important point to note is that the digital twins were developed to learn the normal behavior in the CWP operation expressed by several values of variables observed in the SCADA system. If, for some of these variables, the value observed is not similar to the value predicted by the digital twin, then an abnormal behavior is present that has to be investigated. In fact, the variables observed and predicted were selected as direct indicators of the presence of possible failure modes.

The models obtained by DLNN and DRL techniques simulate very well the normal behavior expected for the output variables; however, they show small discrepancies between real and predicted values, such as those presented in Table 4. In order to prevent false alarms in both cases, confidence bands, according to the error observed in the training models, were defined for monitoring new data differently from those used for training. These confidence bands were adopted around the ±3 times the standard deviation of the error observed in training. Any new prediction inside these bands means that there is no behavior different from this expected for the variable predicted.

Figure 7 shows an example of the upper and lower confidence bands (straight lines) for the error observed in the prediction of Year 3 data that were not used for learning. In this figure, the error is inside the confidence bands, concluding that the temperature in this pump bearing is as expected and no anomaly is present. The same approach of confidence bands is applied to any model inside each digital twin.

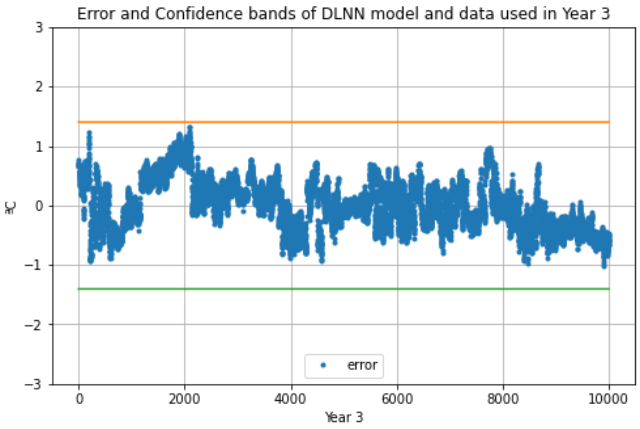

Figure 7. Error inside confidence bands: the behavior observed is similar to the expected one.

The main objective of this section is to present the ability of both digital twins to detect anomalies. In order to reach this goal, an artificial abnormal behavior was introduced in Year 3, simulating an increase in the temperature in the bearing studied in the previous section that could be the result of an incipient failure mode due to the wearing of balls in the bearing or weak lubrication. In this case, only an isolated possible failure mode is considered, leaving the problem of simultaneous failure modes open for further studies. Figure 8 shows the predicted and real values of the bearing temperature in the mechanical axis of the CWP digital twin based on DLNN. In the right part of the figure, there is a significant deviation between real and predicted values that alert about abnormal temperature behavior for the observed working conditions.

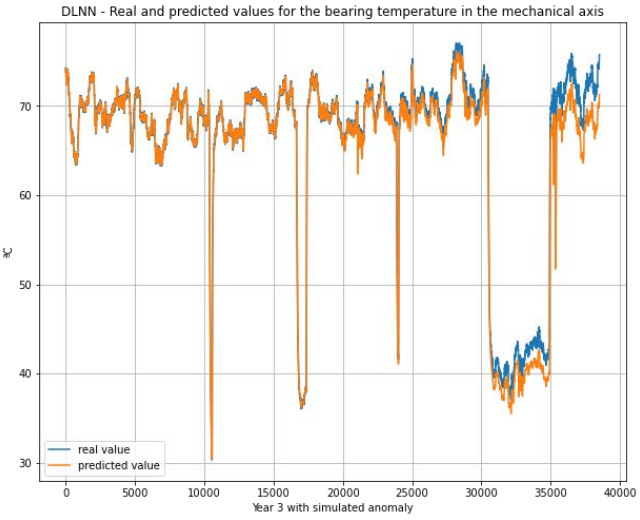

Figure 8. Real and predicted values by the DLNN digital twin. An anomaly is detected at the end of the period.

The deviation with respect to the normal behavior is observed in detail in Figure 9, where the confidence bands of the error are also represented. On the left part of the figure, there is a very clear deviation with respect to the normal behavior expected, meaning that the temperature in the bearing is higher than normal for the current working conditions. Also, it is possible to observe the current fingerprint of the detected anomaly, keeping only the information in Figure 9 that is out of the upper confidence band. This is presented in Figure 10, where an increase of about 2.5 ºC degrees in the last 50 days (6000 samples) is observed, and its trends will be called "risk of the failure mode" in this paper. This information is precious for an approach to implement a data-driven maintenance program.

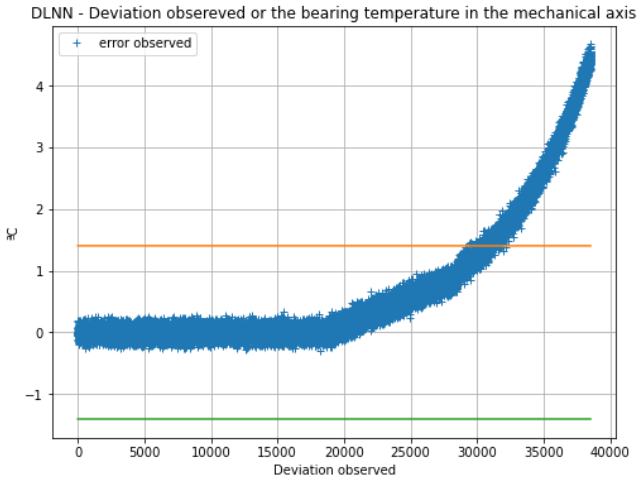

Figure 9. Error inside confidence bands: the behavior observed is similar to the expected one. DLNN case.

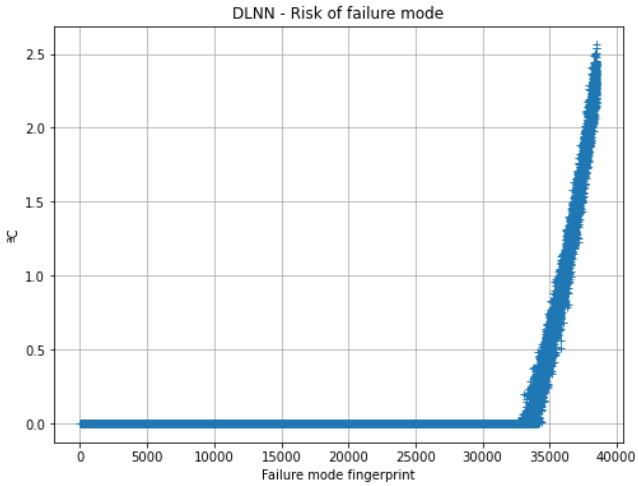

Figure 10. Risk of failure mode based on DLNN digital twin.

The performance of the digital twin based on DRL is similar to that described for the digital twin based on DLNN. Figures 11, 12, and 13 present these results.

Figure 14 presents the superposition of the risk presented in Figures 10 and 13. The objective is to check if some digital twin detects the anomaly condition presented earlier. According to this figure, both virtual digital twins are able to detect the anomaly at the same time. The error observed from the DLNN digital twin seems to be slightly higher, but in any case, it is not significant in ºC units. This confirms the reliability and robustness of the method for anomaly detection based on these digital twins built using different deep learning techniques.

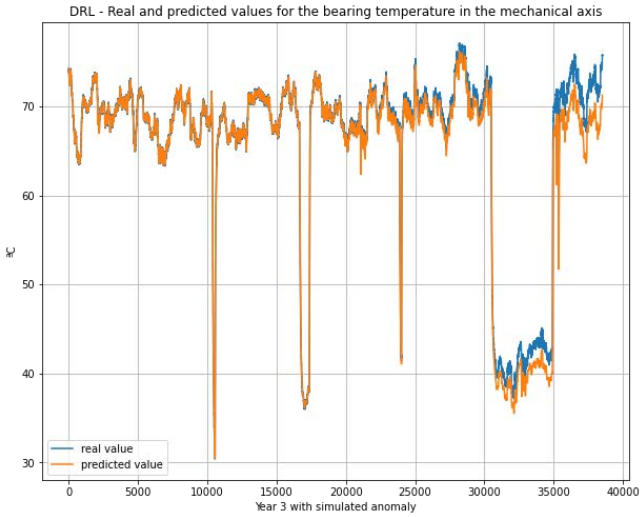

Figure 11. Real and predicted values by the DRL digital twin. An anomaly is detected at the end of the period.

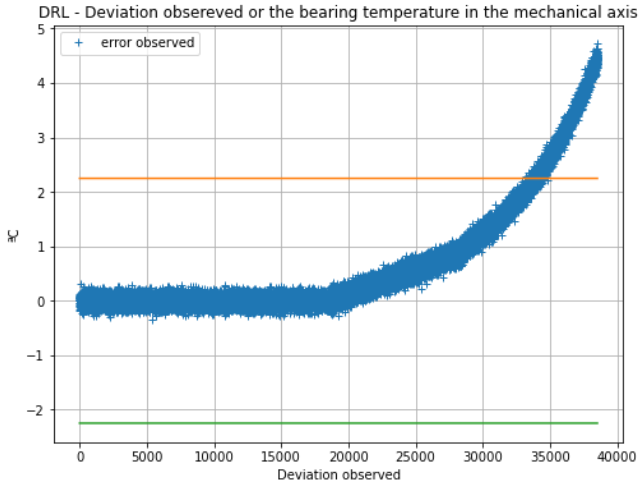

Figure 12. Error inside confidence bands: the behavior observed is similar to the expected one. DRL case.

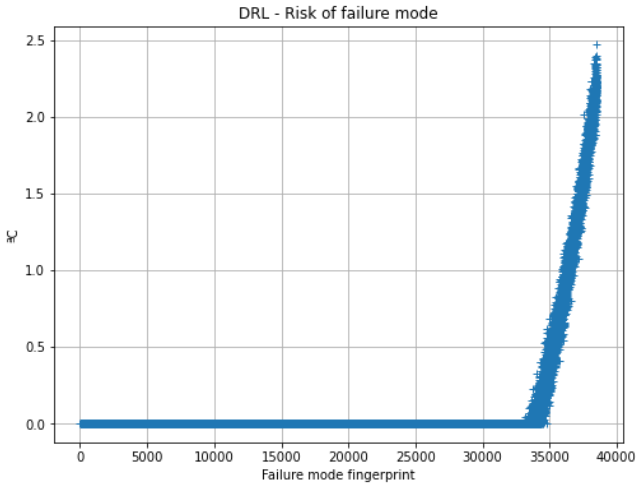

Figure 13. Risk of failure mode based on DRL digital twin.

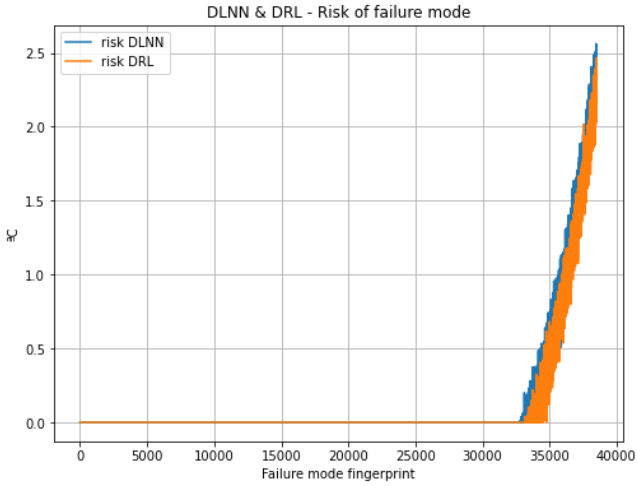

Figure 14. Comparison of risks observed with DLN and DRL digital twins.

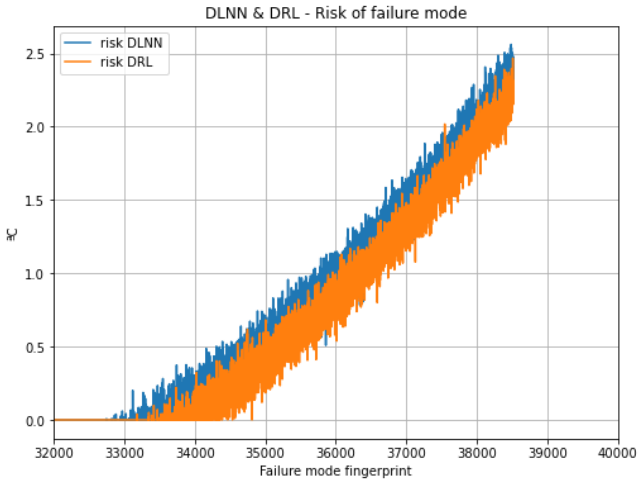

Figure 15. Zoom of the interest zone of Figure 14.

5. CONCLUSION

This paper has presented two virtual digital twins for anomaly detection in a CWP. The objective of creating two digital twins was double. First, the performances between DLNN and DRL were compared because the use of DRL is not well-known yet in this field, and it could have some advantages over the well-known DLNN method because it would need less data for training. The conclusion is that DRL techniques can be used as an alternative option for the DLNN. Second, using two digital twins based on different techniques could robust the anomaly detection process, preventing false alarms. This was verified and confirmed with an example of isolated failure. Additionally, the fingerprint of the detected anomaly can be used as an indicator of risk for a failure mode and alert maintenance people about this fact, giving the basis for a data-driven approach supporting the maintenance and asset management of industrial processes.

The results of this paper open several future studies, such as the analysis of the performance of the digital twins when several failure modes appear simultaneously and the propagation of their effects. Also, the use of the profiles of the risk of failure modes and their integration in maintenance promises to implement new maintenance plans.

ACKNOWLEDGEMENT

The study has been developed with the scientific and economic support of the ENDESA Chair of Artificial Intelligence Applications to Data-driven Maintenance.

BIOGRAPHIES

Miguel A. Sanz-Bobi is currently a Professor with the Computer Science Department, and also a Researcher with the Institute for Research and Technology (IIT), both within the Engineering School, Comillas Pontifical University, Madrid, Spain. He shares his time between teaching and research in topics related to the artificial intelligence field applied to diagnosis and maintenance of industrial processes. He has been the main researcher in an important number of industrial projects related to the diagnosis of industrial processes, incipient detection of anomalies based on models, knowledge acquisition and representation, and reliability and predictive

maintenance. All these projects have been based on a combination of artificial intelligence, new information technologies, and machine learning techniques.

Sarah Orbach is currently a student in the Engineering School CentraleSupelec. She mainly studied physics and computer science. During a gap year, she did two internships. The first one in collaboration to an Open Source web development project and the second in artificial intelligence with the Institute for Research and Technology (IIT) within the Engineering School, Comillas Pontifical University, Madrid, Spain. She is now specializing in bioengineering.

F. Javier Bellido-Lopez is an Electrical and Automatic-Electronic engineer from the Polytechnic University of Madrid (UPM). He is currently studying Physics and is a Researcher with the Institute for Research and Technology (IIT) of the ICAI Engineering School, Comillas Pontifical University, Madrid, Spain. His areas of interest include the application of Artificial Intelligence techniques to the monitoring and diagnosis of industrial processes, Data Analysis, Machine Learning.

Antonio Muñoz San Roque is currently a Professor with the Electronics and Communications Department, and also a Researcher with the Institute for Research and Technology (IIT), both within the ICAI Engineering School, Comillas Pontifical University, Madrid, Spain. His areas of interest include the application of Artificial Intelligence techniques to the monitoring and diagnosis of industrial processes, Time series forecasting, Machine Learning, and Electricity markets analysis.

Daniel González-Calvo is currently responsible for data-driven maintenance in the centralised maintenance unit at Iberia at ENEL/ENDESA. He obtained his master's degree in industrial engineering from the University of La Laguna and his PhD in industrial engineering (industrial doctorate) from the same university. He has worked on data projects for insular power generation systems and research on related data analysis techniques. His scientific and technical work has resulted in several publications and conferences. His areas of interest include predictive maintenance, industrial process optimisation and artificial intelligence applied to the energy sector.

Tomás Alvarez-Tejedor is currently Head of Thermal Maintenance Iberia at ENEL/ENDESA. He obtained his BSc, PhD degree in Engineering and MBA - Master in Business Administration at the Polytechnic University of Madrid (Spain) and his MSc - Master Science in The Gas Turbine Engineering Group at Cranfield University (UK). He has been working in the Spanish Electricity Market for more than thirty years and his background covers R&D projects on Advanced Power Generation Systems, Power Generation Asset Management and Combined Cycle and Gas Turbine Technology. His scientific and technical work are summarized in more than one hundred technical publications and conferences (EPRI, ASME, ETN, PowerGen,..etc). His areas of interest include the application of Artificial Intelligence techniques to power generation asset management.

Contrastive Metric Learning Loss-Enhanced Multi-Layer Perceptron for Sequentially Appearing Clusters in Acoustic Emission Data Streams

ABSTRACT

Conventional structural health monitoring methods for interpreting unlabeled acoustic emission (AE) data typically rely on generic clustering approaches. This work introduces a novel approach for analyzing sequential and temporal acoustic emission (AE) data streams by enhancing a Multi-Layer Perceptron (MLP) with a contrastive metric learning loss function (MLP-CMLL)and Time Series K-means (TSKmeans) clustering. This dual approach, MLP-CMLL with TSKmeans, is crafted to refine cluster differentiation significantly. This method is designed to optimize cluster differentiation, bringing similar acoustic patterns closer and distancing divergent ones, thereby improving the MLP's ability to classify acoustic events over time. Addressing the limitations of traditional clustering algorithms in handling the temporal dynamics of AE data, MLP-CMLL with TSKmeans approach provides deeper insights into cluster formation and evolution. It promises enhanced monitoring and predictive maintenance capabilities in engineering applications by capturing the complex dynamics of AE data more effectively, offering a significant advancement in the field of structural health monitoring. Through experimental validation, we apply this method to characterize the loosening phenomenon in bolted structures under vibrations. Comparative analysis with two standard clustering methods using raw streaming data from three experimental campaigns demonstrates that our proposed method not only delivers valuable qualitative information concerning the timeline of clusters but also showcases superior performance in terms of cluster characterization.

1. INTRODUCTION

Structural Health Monitoring (SHM) is essential to ensuring the safety, longevity, and efficient maintenance of engineering structures across civil, mechanical, and aerospace fields. This discipline employs advanced technologies to proactively detect and address damages, aiming to avert catastrophic failures and optimize maintenance efforts. Among various SHM applications, the precision monitoring of bolted connections is particularly critical, given its profound impact on the structural integrity and stability of significant constructions such as bridges, aerospace structures, and wind turbines (Bolognani et al., 2018).

The vulnerability of bolted connections to loosening—and the profound implications of such—was dramatically underscored by the 2015 collapse of a 129-meter wind turbine in Sweden (Swedish Accident Investigation Authority, 2017). This incident, attributed to bolt looseness, resulted not only in significant financial loss but also highlighted the urgent need for early detection systems to prevent such disasters. While traditional bolt inspection techniques are effective, they are notably labor-intensive and can significantly interrupt operational workflows. This has led to a shift toward non-destructive testing (NDT) methods (Hoła & Sadowski, 2022), particularly the use of acoustic emission (AE) sensors (Sun, Yang, Li, & Xu, 2023; P. Xu, Zhou, Liu, & Mal, 2021; D. Xu, Liu, Li, & Chen, 2019), as more efficient alternatives.

AE sensors are distinguished by their ability to detect stress-induced changes within materials, offering a sophisticated means of identifying potential damages or loosening. Research, such as that conducted by Wang et al. (Wang, Song, Wang, & Li, 2013), demonstrates a correlation between AE signal energy and the axial load of bolts, enabling precise detection of bolt looseness through analysis of energy dissipation and signal amplitude. However, AE signals' complexity, marked by significant variations in amplitude and energy, coupled with susceptibility to environmental noise and interference, poses a significant challenge (Fu, Zhou, & Guo, 2023). Relying solely on a single AE characteristic often falls short in accurately reflecting bolt tightness. Therefore, there's a pressing need to develop innovative methods capable of quantifying AE signals' nonlinear characteristics and accurately interpreting bolt looseness, underscoring the demand for advanced analytical techniques.

The vast quantities of AE signals within data streams present a significant challenge in identifying ground truth, rendering supervised learning methods impractical for AE data interpretation or anomaly detection (Ramasso, Denoeux, & Chevallier, 2022; Ramasso, Placet, & Boubakar, 2015). This necessitates a pivot towards unsupervised learning techniques, such as K-means, fuzzy C-means (FCM), and Gaussian Mixture Models (GMM), to extract actionable insights from AE data. Among these approaches, Gaussian Mixture Models sequentially (GMMSEQ), introduced by Emmanuel Ramasso et al. (Ramasso, Denoeux, & Chevallier, 2022), stands out by incorporating temporal dynamics into the clustering of unlabeled AE data, thereby significantly enhancing parameter estimation related to damage progression.

Recent advancements highlight the growing significance of unsupervised and self-supervised learning methods, with a notable focus on contrastive metric learning. This approach harnesses the inherent similarities and contrasts within data to facilitate learning without the necessity for explicit labels, marking a pivotal shift toward more efficient representation learning (Saunshi, Plevrakis, Arora, Khodak, & Khandeparkar, 2019). By comparing input samples and manipulating their representations within the embedding space—drawing similar samples closer and distancing dissimilar ones—contrastive representation learning streamlines the learning process. It sidesteps the conventional need for labeling each sample, instead utilizing a pre-established similarity distribution to classify inputs into positive or negative pairs (Hassani & Khasahmadi, 2020).

Building on these insights, we propose a novel method that leverages the power of a Multi-Layer Perceptron (MLP) enhanced with a contrastive metric learning loss (MLP-CMLL), to adeptly handle AE data streams, particularly those exhibiting sequentially appearing clusters. The proposed MLP-CMLL approach, rooted in the principles of contrastive metric learning, aims to differentiate between similar and dissimilar features within the AE data, generating robust feature embeddings without the need for explicit labels. These embeddings serve as a powerful foundation for clustering, enabling our system to dynamically identify and group sequentially appearing clusters of AE data. By applying time series k-means clustering algorithm (TSKMean) (Huang et al., 2016), we can effectively cluster AE events based on both their feature similarities and their temporal characteristics. This integration enables the detection of sequentially appearing clusters, a common occurrence in AE data streams, thereby providing deeper insights into the material's behavior and the efficacy of the monitoring system.

The remainder of this paper is organized as follows: Section 2 introduces the proposed MLP-CMLL method, along with their respective data preprocessing methods. Section 3 describes the dataset and provides an analysis of experimental results. Finally, the main findings of this study are summarized in Section 4 along with a description of future work perspectives.

2. Proposed method

In this section, we delineate the architecture of the proposed framework, which aims to classify bolt tightening levels through the analysis of acoustic emission data streams. Figure 1 illustrates the overarching architecture of our proposed approach, specifically designed for clustering bolt tightening levels based on acoustic emission data streams. Subsequently, we will elaborate on the intricacies and functional components of the proposed framework, detailing each block's contribution to the overall system.

2.1. AE signal Preprocessing & Feature Extraction

The preprocessing and feature extraction of AE signals is a critical step in analyzing the raw data stream, performed through a three steps, initially outlined in (Kharrat, Ramasso, Placet, & Boubakar, 2016). The process begins with the data stream undergoing an initial filtration stage, employing a fifth-order high-pass filter with a cutoff frequency of 10 kHz and a passband ripple of 0.2 dB, effectively eliminating the DC component from the data.

- **Step 1**: **Wavelet filtering** Utilizing wavelet denoising on 250,000 sample frames achieves an optimal balance between computational efficiency and denoising quality. The chosen Daubechies "dB45" wavelet, featuring 90 coefficients and 14 decomposition levels, effectively identifies AE signal onsets (Kharrat et al., 2016). This step includes applying the soft Donoho-Johnstone universal threshold to the wavelet coefficients and adjusting for level-dependent noise, alongside correcting for any group delay introduced by the filtering process. Figure 2 displays the raw signal and denoised signal.

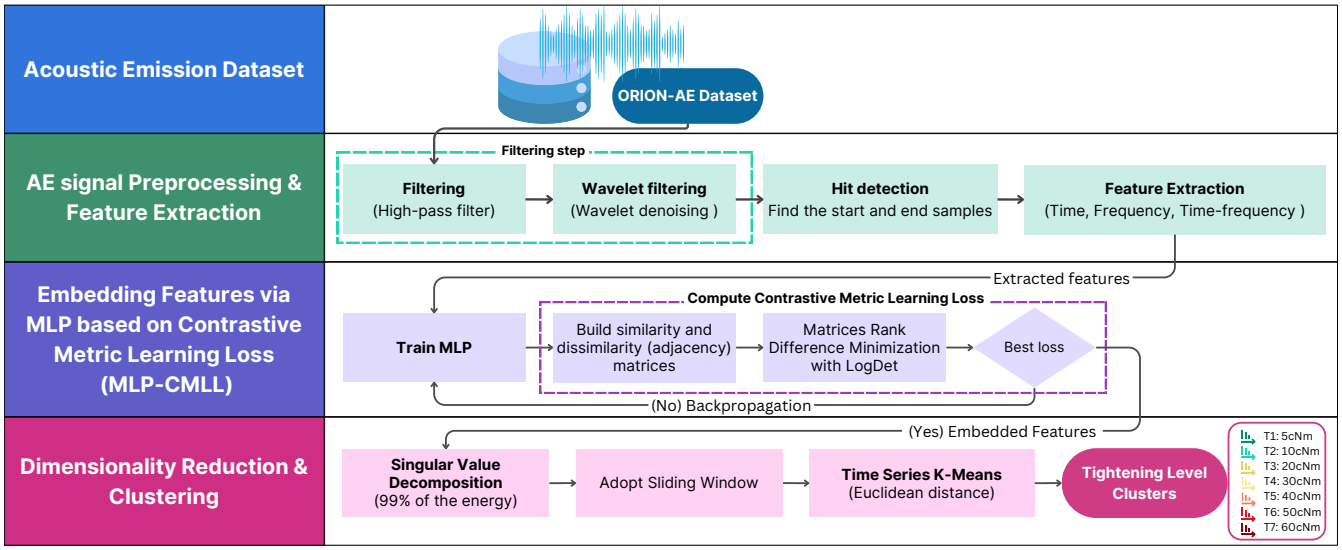

Figure 1. The general architecture of the proposed approach for bolt tightening level clustering.

- **Step 2**: **Hit Detection Procedure** aims to identify the start and end of each AE signal post-filtering based on amplitude thresholds (1.2 mV in this case). This step ensures that only relevant AE events are selected for analysis, utilizing specific counters ("HDT" 1100 μs and "HLT" 80 μs) to accurately demarcate signal boundaries (Kharrat et al., 2016).

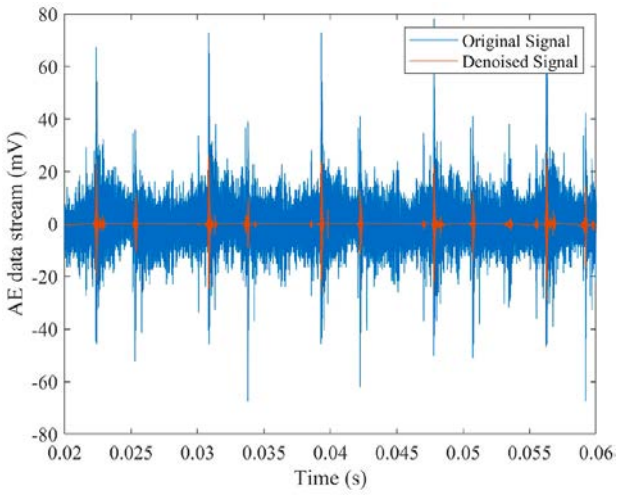

Figure 2. Raw signal and denoised signal.

- **Step 3 Feature Extraction**: Each detected AE signal is then analyzed to extract an extensive set of features, encompassing time-based and frequency-based characteristics (Kharrat et al., 2016; Sause, Gribov, Unwin, & Horn, 2012; Gonzalez Andino et al., 2000) such as rise time, counts, PAC-energy, amplitude, frequency metrics, signal strength, and energy distributions across specified frequency intervals. Figure 3 shows an AE signal and some typical features. Additional features include the Renyi number from the scalogram analysis using a Morlet wavelet and the frequency at maximum energy, providing a detailed signal characterization suitable for further analysis.

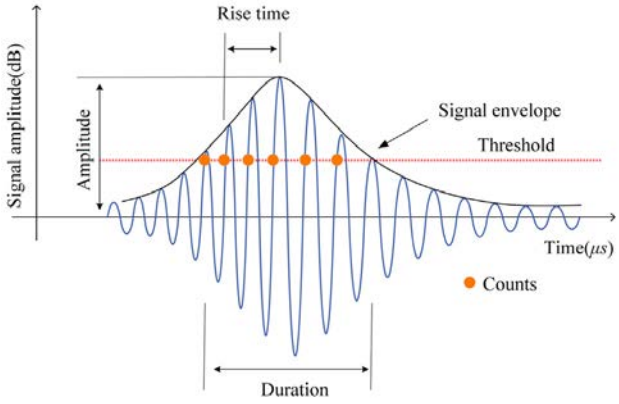

Figure 3. AE signal and some typical characteristics.

2.2. Embedding Features via MLP based on Contrastive Metric Learning Loss (MLP-CMLL)

This subsection will describe the proposed MLP based on the Contrastive Metric Learning Loss (MLP-CMLL) method. In the following, we will mention the details of our algorithm for learning a best loss metric based on an unsupervised metric learning with unlabeled data. The proposed contrastive metric learning framework is based on the combination of two methods, unsupervised EASE metric learning (Zhu & Koniusz, 2022a) and Generalized Laplacian Eigenmaps (Zhu & Koniusz, 2022b).

Let $\mathbf{X} \in \mathbb{R}^{n \times m}$ be an unlabeled AE data of n samples and m features. We propose a new MLP based on Contrastive Metric Learning Loss (MLP-CMLL) framework for unsupervised network embedding. To compute the loss function of the MLP framework, we calculate the logdet of scatter matrices based on the similarity and the dissimilarity (adjacency):

$$\mathbf{\Theta}^* = \arg\min_{\mathbf{\Theta}} \operatorname{Rank}\left(\mathbf{S}_{sim}\left(\mathbf{X}\right)\right) - \operatorname{Rank}\left(\mathbf{S}_{dis}\left(\mathbf{X}\right)\right) \quad (1)$$

Eq. (1) aims to compute a metric loss $\mathbf{\Theta}$ for each epoch that maximizes the similarity between similar features and minimizes the dissimilarity between dissimilar features.

Let:
$\mathbf{S}_{dis} = f_{\mathbf{\Theta}}(\mathbf{X})^\top \mathbf{L}_{dis} f_{\mathbf{\Theta}}(\mathbf{X})$ and $\mathbf{S}_{sim} = f_{\mathbf{\Theta}}(\mathbf{X})^\top \mathbf{L}_{sim} f_{\mathbf{\Theta}}(\mathbf{X})$
Then the LogDet relaxation becomes:

$$\begin{aligned}\mathbf{\Theta}^* &= \arg\min_{\mathbf{\Theta}} \log\det\left(\mathbf{I} + \alpha f_{\mathbf{\Theta}}(\mathbf{X})^\top \mathbf{L}_{sim} f_{\mathbf{\Theta}}(\mathbf{X})\right) \\ &\quad - \log\det\left(\mathbf{I} + \alpha f_{\mathbf{\Theta}}(\mathbf{X})^\top \mathbf{L}_{dis} f_{\mathbf{\Theta}}(\mathbf{X})\right) \\ &= \arg\min_{\mathbf{\Theta}} \log\det(\mathbf{I} + \alpha \mathbf{S}_{\text{sim}}) - \log\det(\mathbf{I} + \alpha \mathbf{S}_{\text{dis}})\end{aligned} \quad (2)$$

where $\mathbf{I}$ ensures $\mathbf{I} + \alpha f_{\mathbf{\Theta}}(\mathbf{X})^\top \mathbf{L} f_{\mathbf{\Theta}}(\mathbf{X}) > 0$ as $f_{\mathbf{\Theta}}(\mathbf{X})^\top \mathbf{L} f_{\mathbf{\Theta}}(\mathbf{X})$ may be $\mathbb{S}_+^m$ leading to $\det\left(f_{\mathbf{\Theta}}(\mathbf{X})^\top \mathbf{L} f_{\mathbf{\Theta}}(\mathbf{X})\right) = 0$. Thus, we use $\log\det(\mathbf{I} + \alpha\mathbf{S})$ as a smooth surrogate for $\operatorname{Rank}(\mathbf{S})$.

$$\begin{aligned}\mathbf{L}_{\text{sim}} &= \mathbf{I} - \tilde{\mathbf{A}}_{\text{sim}} \in \mathbb{S}_+^n, \\ \mathbf{L}_{\text{dis}} &= \mathbf{I} - \tilde{\mathbf{A}}_{\text{dis}} \in \mathbb{S}_+^n.\end{aligned} \quad (3)$$

Let us also define normalized graph Laplacian matrices in Eq. (2) as in Eq. (3). Let $\mathbf{D}^{-1/2}\mathbf{A}\mathbf{D}^{-1/2} = \tilde{\mathbf{A}}$ and $\mathbf{D} = \operatorname{diag}\left(d_1, \cdots, d_n\right)$, where $d_i = \sum_j \mathbf{A}_{ij}$. We explain how we obtain $\mathbf{A}_{sim}$ and $\mathbf{A}_{dis}$ later in the text. From equations Eq. (3) and Eq. (2) we have:

$$\begin{aligned}\mathbf{L}_{\text{sim}} - \mathbf{L}_{\text{dis}} &= (\mathbf{I} - \tilde{\mathbf{A}}_{\text{sim}}) - (\mathbf{I} - \tilde{\mathbf{A}}_{\text{dis}}) \\ &= \tilde{\mathbf{A}}_{\text{dis}} - \tilde{\mathbf{A}}_{\text{sim}},\end{aligned} \quad (4)$$

As $\mathbf{L}_{\text{sim}} - \mathbf{L}_{\text{dis}} = \tilde{\mathbf{A}}_{\text{dis}} - \tilde{\mathbf{A}}_{\text{sim}}$, we obtain:

$$\begin{aligned}\mathbf{\Theta}^* = \arg\min_{\mathbf{\Theta}} &\log\det\left(\mathbf{I} + \alpha f_{\mathbf{\Theta}}(\mathbf{X})^\top \tilde{\mathbf{A}}_{\text{dis}} f_{\mathbf{\Theta}}(\mathbf{X})\right) \\ &- \log\det\left(\mathbf{I} + \alpha f_{\mathbf{\Theta}}(\mathbf{X})^\top \tilde{\mathbf{A}}_{\text{sim}} f_{\mathbf{\Theta}}(\mathbf{X})\right),\end{aligned} \quad (5)$$

where $\mathbf{A}_{\text{sim}}$ and $\mathbf{A}_{\text{dis}}$ are two different measurements with the opposite effect. Thus, we introduce parameter $\alpha > 0$ to balance the impact of these both terms.

Dissimilarity Matrix. Although one might design a linear projection based on the similarity relationship alone, we use both the dissimilarity information and the similarity matrix for learning a metric loss. Intuitively, in the context of a K-clustering task with n unlabeled samples and M_i queries for each cluster, we are addressing a problem where ($\mathrm{n} = \mathrm{K} \times \mathrm{M_i}$) samples are to be clustered into K groups. Here, off-diagonal entries are understood to signify distinct entities, whereas on-diagonal entries indicate identical entities. Thus, we form a dissimilarity matrix as the adjacency matrix of a densely connected graph:

$$\mathbf{A}_{dis} = \frac{1}{n}\mathbf{e}\mathbf{e}^\top - \mathbf{I}, \quad (6)$$

where $\mathbf{e}$ is an (n)-dimensional all-ones vector and $\mathbf{I}$ is the identity matrix.

Similarity Matrix. To measure the similarity between the pairs of samples, one has to choose a distance (or similarity measure) that will perform well in the clustering setting.

The typical choice for the measure of similarity is the RBF function $Z_{ij} = \exp\left(-\left\|f_\theta\left(\mathbf{x}_i\right) - f_\theta\left(\mathbf{x}_j\right)\right\|_2^2 / \sigma\right), \sigma > 0$ but the RBF function alone does not capture the structure of data. In this work, we claim that for the K-cluster learning task, the expected similarity matrix should be a K-block diagonal matrix. However, the similarity matrix based on the RBF kernel has no blockdiagonal structure.

Low-Rank Representation (LRR) (Liu, Lin, & Yu, 2010) expresses each data point $\mathbf{x}_i$ as a linear combination of other points, $\mathbf{x}_i = \sum_{j \neq i} Z_{ij}\mathbf{x}_j$, and uses the representational coefficient $\left(|Z_{ij}| + |Z_{ji}|\right)/2$ to measure the similarity between $\mathbf{x}_i$ and $\mathbf{x}_j$. LRR takes the correlation structure of data into account, and finds a low-rank representation instead of a sparse representation. In this work, the LRR is applied in the following rank minimization problem:

$$\arg\min_{\mathbf{Z}} \left\|f_\theta(\mathbf{X}) - f_\theta(\mathbf{X})\mathbf{Z}\right\|_F^2 \quad \text{s.t. } \operatorname{rank}(\mathbf{Z}) = K. \quad (7)$$

Eq. (7) is solved in two stages: 1) $\mathbf{Z} = \mathbf{V}^\top\mathbf{V}$, where $\mathbf{V}$ is obtained from the skinny SVD of $f_\theta(\mathbf{X}) = \mathbf{U}\mathbf{\Sigma}\mathbf{V}^\top$, and 2) for each row of $\mathbf{V}$, one only keeps top-K absolute largest entries of $\mathbf{\Sigma}$. Given the feature matrix $f_\theta(\mathbf{X})$, we obtain the representation matrix $\mathbf{Z}$ by solving Eq. (7). The similarity matrix is defined as $\mathbf{W}_{\text{sim}} = |\mathbf{Z}| - \operatorname{diag}(|\mathbf{Z}|)$.

We provide our implementation in Alg. 1. The proposed algorithm targets unsupervised network embedding by employing contrastive metric learning loss to enhance similarity among similar features while reducing dissimilarity among different ones. Central to this framework are the LogDet relaxation and Low-Rank Representation (LRR), both aimed at achieving an embedding that accurately captures the inherent structure of unlabeled data. This structured approach outlines a comprehensive step-by-step methodology for implementing the MLP-CMLL method, specifically designed to optimize metric learning loss in scenarios involving unlabeled datasets.

2.3. Time Series K-Means for clustering

Following the generation of high-dimensional embedded features via MLP-CMLL, with each feature vector comprising

Algorithm 1 MLP based on Contrastive Metric Learning Loss (MLP-CMLL)

Input: $\mathbf{X} \in \mathbb{R}^{n \times m}$: Unlabeled AE data of n samples and m features.
Initialize: Predefined MLP architecture, $\alpha > 0$.

Compute Similarity and Dissimilarity Matrices based on Laplacian Matrices:
$\mathbf{S}_{\text{dis}} = f_{\mathbf{\Theta}}(\mathbf{X})^\top \tilde{\mathbf{A}}_{\text{dis}} f_{\mathbf{\Theta}}(\mathbf{X})$
$\mathbf{S}_{\text{sim}} = f_{\mathbf{\Theta}}(\mathbf{X})^\top \tilde{\mathbf{A}}_{\text{sim}} f_{\mathbf{\Theta}}(\mathbf{X})$

Optimization:
while not converged **do**
    Solve for $\mathbf{\Theta}^*$ minimizing:

$$\begin{aligned}\mathbf{\Theta}^* &= \arg\min_{\mathbf{\Theta}} \log\det\left(\mathbf{I} + \alpha f_{\mathbf{\Theta}}(\mathbf{X})^\top \tilde{\mathbf{A}}_{\text{dis}} f_{\mathbf{\Theta}}(\mathbf{X})\right) \\ &\quad - \log\det\left(\mathbf{I} + \alpha f_{\mathbf{\Theta}}(\mathbf{X})^\top \tilde{\mathbf{A}}_{\text{sim}} f_{\mathbf{\Theta}}(\mathbf{X})\right) \\ &= \arg\min_{\mathbf{\Theta}} \log\det(\mathbf{I} + \alpha \mathbf{S}_{\text{sim}}) - \log\det(\mathbf{I} + \alpha \mathbf{S}_{\text{dis}})\end{aligned}$$

    Update MLP parameters.

    Adjust Matrices ($\mathbf{S}_{\text{sim}}$ and $\mathbf{S}_{\text{dis}}$) Based on MLP-embedded features.
end while

Output: MLP-embedded features $\mathbf{F}$ (transform $\mathbf{X}$ into feature-embedded space using best $f_{\mathbf{\Theta}}(.)$).

1024 dimensions, the next crucial step involves dimensionality reduction and the application of time series k-means for effective clustering. Singular Value Decomposition (SVD) (Wall, Rechtsteiner, & Rocha, 2003; Furnas et al., 2017) is employed to reduce the dimensionality of these embeddings, enhancing computational efficiency and preserves the essential characteristics of the embedded features.

Upon completing the dimensionality reduction, we employ a sliding window technique to integrate the time series k-means algorithm, a pivotal step for clustering AE data streams that exhibit temporal dependencies. This method involves segmenting the reduced feature set into overlapping windows, allowing for the dynamic nature of AE data to be captured over time. The sliding window approach (SW) organizes the data into sequences of a specified window size. We empirically choose the SW size as 50, with a step size (1) dictating the overlap between consecutive windows. This structuring is essential for maintaining the temporal continuity of AE events, facilitating the identification of clusters that evolve over time.

By applying time series k-means (Huang et al., 2016) to these windowed sequences, we can effectively cluster AE events based on both their feature similarities and their temporal characteristics. This integration enables the detection of sequentially appearing clusters, a common occurrence in AE data streams, thereby providing deeper insights into the material's behavior and the efficacy of the monitoring system.

3. Experimentation and Results

3.1. Acoustic emission dataset Description

The ORION-AE dataset (Ramasso, Verdin, & Chevallier, 2022) was obtained through a test rig known as ORION. The ORION is specifically designed to mimic the loosening phenomena commonly observed in bolted joints of structures in various industries, including aeronautics, automotive, and civil engineering. It is composed of two metallic plates linked together by three M4 bolts (as shown in Figure 4, enabling the simulation of bolt loosening under vibrational stress.

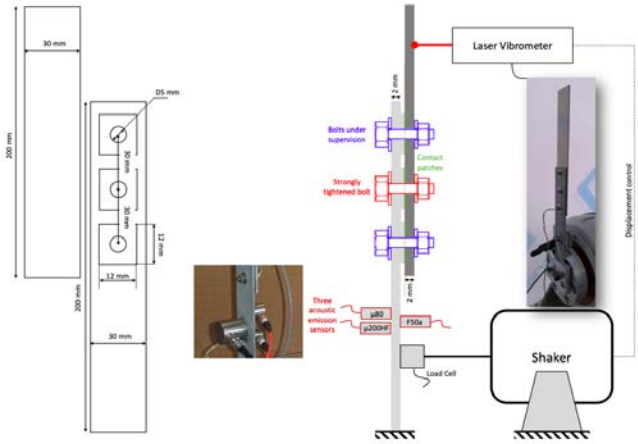

Figure 4. Setup description: part dimensions, sensors positions, bolts positions

The ORION-AE data are dynamically loaded with a vibration shaker and monitored with a laser vibrometer for velocity measurements and three AE sensors (micro80, F50A, micro200HF). The sensors sampled data at a rate of 5 MHz, producing datasets ranging from approximately 1.4 to 1.9 GB.

The ORION-AE dataset was generated by manually loosening a bolt on a test assembly and then subjecting it to 120 Hz harmonic vibrations, to simulate operational conditions. The experiment explored seven levels of bolt tightness (T1: 5cNm, T2: 10cNm, T3: 20cNm, T4: 30cNm, T5: 40cNm, T6: 50cNm, T7: 60cNm), with AE transients recorded for 10 seconds at each level. This procedure was repeated five times, resulting in five campaigns/datasets (B, C, D, E, and F), each with seven classes with 70 s of data for different sensors. Each campaign recorded varying numbers of signals, totaling 10,866; 9,461; 9,285; 15,628; and 17,810 signals, respectively. Note that, for campaign C, the level of bolt tightness 20 cNm is missing.

The seven tightening levels can be used as a ground truth when designing learning methods. This makes this dataset useful for developing and testing clustering and classification

methods for interpreting acoustic emission data.

For the purposes of this paper, analysis was focused exclusively on the micro-200-HF sensor, and only campaigns B, C and E were utilized to measure the performance of the clustering method. Figure 5 displays the tightening levels, acoustic emission and laser vibrometer data superimposed for measurements ”B” and sensor micro-200-HF (variable C).

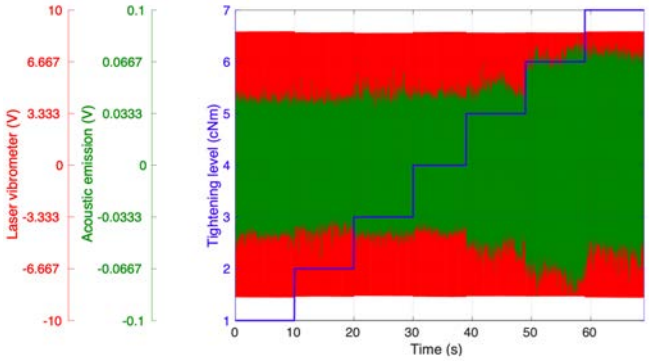

Figure 5. Tightening levels, acoustic emission and laser vibrometer data superimposed for measurements ”B” and sensor micro-200-HF (variable C).

3.2. Evaluation metrics

To properly evaluate the performance of clustering algorithms, such as TimeSeriesKMeans, on our test dataset, we use a variety of metrics. These metrics, as suggested by literature (Maulik & Bandyopadhyay, 2002), include:

- **Silhouette Score** evaluates cohesion within clusters and separation between them.
- **Davies-Bouldin Index** measures the average similarity between each cluster and its most similar cluster.
- **Adjusted Rand Index**, **Normalized Mutual Information (NMI)**, **Homogeneity**, **Completeness**, and **V-Measure** compare the clustering results to a ground truth, providing a measure of how well the clustering matches actual categories in the data.

3.3. Performance analysis

To demonstrate the effectiveness of the proposed unsupervised MLP-CMLL, we conduct numerous experiments to show the effectiveness of our embedded features compared to three different features, including raw data (AE signal Preprocessing & Feature Extraction), PCA (Kherif & Latypova, 2020) and SVD (Wall et al., 2003; Furnas et al., 2017). Tables 1, 2, and 3 show performance metrics for Campaigns B, C and E using different features over the TSKMeans cluster with sliding window.

Table 1. Performance metrics for Campaign B using different features over TSKMeans cluster with sliding window.

Method	ARI	Silhouette	DBI	NMI	Completeness
RAW	0.818	0.296	**1.394**	0.842	0.844
SVD	0.818	0.296	**1.394**	0.842	0.844
PCA	0.818	0.296	**1.394**	0.842	0.844
MLP-CMLL	**0.875**	**0.335**	1.278	**0.884**	**0.884**

Table 2. Performance metrics for Campaign C using different features over TSKMeans cluster with sliding window.

Method	ARI	Silhouette	DBI	NMI	Completeness
RAW	0.700	0.317	1.244	0.784	0.786
SVD	0.700	0.317	1.244	0.784	0.786
PCA	0.700	0.320	1.230	0.784	0.786
MLP-CMLL	**0.949**	**0.418**	**1.079**	**0.929**	**0.929**

Table 3. Performance metrics for Campaign E using different features over TSKMeans cluster with sliding window.

Method	ARI	Silhouette	DBI	NMI	Completeness
RAW	0.738	0.228	**1.743**	0.800	0.805
SVD	0.738	0.228	**1.743**	0.800	0.805
PCA	0.738	0.228	**1.743**	0.800	0.805
MLP-CMLL	**0.854**	**0.300**	1.700	**0.866**	**0.867**

In the three tables 1, 2, and 3, the consistent outperformance of MLP-CMLL across all campaigns underscores the potential of sophisticated neural network-based feature extraction methods in enhancing clustering performance. It suggests that MLP-CMLL can adaptively learn and highlight the most relevant features for clustering, outpacing traditional dimensionality reduction techniques in capturing the essential structures of various datasets. Furthermore, the relatively close performance of SVD, PCA, and RAW methods across the campaigns might reflect their limitations in dealing with complex data structures or their potential redundancy when the raw data is already amenable to effective clustering. Analyzing three campaigns using various feature extraction methods within a TSKMeans cluster with a sliding window approach reveals consistent trends across performance metrics. The MLP-CMLL method consistently outperforms the other methods (RAW, SVD, PCA) in all evaluated metrics — Adjusted Rand Index (ARI), Silhouette score, Davies-Bouldin Index (DBI), Normalized Mutual Information (NMI), and Completeness—indicating superior clustering effectiveness. The RAW, SVD, and PCA methods display nearly identical performance across most metrics and campaigns, suggesting similar capabilities in handling clustering tasks. MLP-CMLL's higher scores across all metrics highlight its ability to capture more complex patterns and nonlinearities that linear methods might miss, resulting in better-defined and more accurately clustered data groups. This underlines the importance of method selection in data clustering to achieve optimal re-

Table 4. Performance metrics of different clustering methods for Campaign B using MLP-CMLL embedded features with (w/) and without (w/o) sliding window.

Method	ARI	Silhouette	DBI	NMI	Completeness
GMM (w/o)	0.676	0.406	1.007	0.810	0.809

MLP-CMLL+TSKMeans (w/o)	0.657	0.410	0.997	0.796	0.795
MLP-CMLL+TSKMeans (w/)	**0.875**	0.335	**1.278**	**0.884**	**0.884**

Table 5. Performance metrics of different clustering methods for Campaign C using MLP-CMLL embedded features with (w/) and without (w/o) sliding window.

Method	ARI	Silhouette	DBI	NMI	Completeness
GMM (w/o)	**0.975**	0.420	1.050	**0.962**	**0.962**
Kmeans (w/o)	0.919	0.423	1.036	0.904	0.904
MLP-CMLL+TSKMeans (w/o)	0.919	**0.424**	1.037	0.904	0.905
MLP-CMLL+TSKMeans (w/)	0.949	0.418	**1.079**	0.929	0.929

sults based on specific campaign characteristics and objectives. Therefore, these observations suggest that while traditional methods like SVD and PCA have their merits, especially in contexts where computational simplicity and interpretability are key, advanced neural network-based approaches like MLP-CMLL offer a promising avenue for tackling more complex clustering challenges. Future work could explore further optimizations of the MLP-CMLL architecture, comparisons with other advanced machine learning techniques, and applications to a broader range of data types and clustering scenarios.

For Campaign B, MLP-CMLL shows the best performance across almost all metrics, highlighting its ability to extract meaningful embedded features that contribute to effective clustering. This suggests that the MLP-CMLL approach, with its presumably more nuanced understanding of the data structure, is particularly well-suited for the types of datasets represented in Campaign B. RAW, SVD, and PCA show similar performance in terms of ARI, Silhouette score, and other metrics. This could indicate that for Campaign B's dataset, the simpler dimensionality reduction techniques (SVD and PCA) do not provide significant advantages over using RAW data. This might be due to the nature of the data where the intrinsic data structure is either too complex for simple linear transformations to capture or perhaps is already in a form where raw data clustering is relatively effective.

For Campaign C, MLP-CMLL again outperforms other methods significantly in ARI and Completeness, reinforcing the value of advanced feature extraction methods in improving clustering outcomes. The improvement in the Silhouette score and DBI suggests that MLP-CMLL leads to more distinct, well-separated clusters than other methods. The performance gap between MLP-CMLL and other methods (SVD, PCA, and RAW) is notable, especially in terms of ARI and Completeness. This could imply that the Campaign C dataset contains complex patterns or high-dimensional structures that are better captured by the MLP-CMLL's feature extraction capabilities.

For Campaign E, MLP-CMLL's superiority is evident but less pronounced compared to Campaign C. It still leads in Adjusted Rand Index and Completeness, indicating its consistent effectiveness across different datasets. The similarity in performance between SVD, PCA, and RAW methods suggests that for Campaign E's data, the simple dimensionality reduction does not significantly impact the clustering performance, similar to Campaign B. However, the overall lower scores compared to Campaign B could indicate that Campaign E's dataset is inherently more challenging to cluster effectively, possibly due to noise, less distinct groupings, or more complex data structures.

Tables 4, 5, and 6 show performance metrics using different clustering methods for Campaigns B, C, and E with (w/) and without (w/o) sliding window.

Table 4 shows the performance metrics for Campaign B. The performance metrics for Campaign B provide a nuanced view of algorithm effectiveness. The Gaussian Mixture Model (GMM) showcases strong performance with an ARI of 0.676, suggesting a high degree of accuracy in clustering with respect to the true classifications. This is supported by an NMI of 0.810 and a Completeness score of 0.809, indicating a robust alignment between cluster assignments and actual data labels. The introduction of a sliding window with Time Series K-Means enhances its performance significantly, as evidenced by a jump in ARI to 0.875 and NMI to 0.884, underscoring the method's ability to capture temporal dependencies within the data. The Silhouette Score and DBI provide additional insights; despite a lower Silhouette Score (0.335) with the sliding window, indicating less clear separation between clusters, the method's overall effectiveness is not notably diminished, suggesting that the sliding window compensates by capturing temporal patterns not evident in spatial metrics alone.

Table 5 shows the performance metrics for Campaign C. Campaign C's analysis reveals the exceptional capability of the

Table 6. Performance metrics of different clustering methods for Campaign E using MLP-CMLL embedded features with (w/) and without (w/o) sliding window.

Method	ARI	Silhouette	DBI	NMI	Completeness
GMM (w/o)	0.626	0.311	1.453	0.716	0.718
Kmeans (w/o)	0.546	0.336	1.284	0.642	0.644

MLP-CMLL+TSKMeans (w/)	**0.854**	0.300	**1.700**	**0.866**	**0.867**

GMM algorithm, achieving near-perfect ARI (0.975) and NMI (0.962) scores, which imply an almost flawless clustering outcome compared to true labels. This campaign highlights the impact of using a sliding window with Time Series K-Means, which achieves an ARI of 0.949 and an NMI of 0.929. These results suggest that the temporal structure captured by the sliding window significantly enhances clustering fidelity. The Silhouette Score (0.418 with the sliding window) and DBI (1.079 with the sliding window) indicate a balance between cluster cohesion and separation, affirming the effectiveness of incorporating temporal context in clustering analysis.

Table 6 shows the performance metrics for Campaign E. In Campaign E, the stark contrast in performance metrics between methods with and without sliding windows becomes even more pronounced. The use of the sliding window with Time Series K-Means propels its ARI to 0.854 and NMI to 0.866, suggesting a high degree of clustering accuracy that leverages temporal information effectively. Despite a lower Silhouette Score (0.300) with the sliding window, indicating potential overlap among clusters, the high NMI and Completeness scores (0.866 and 0.867, respectively) with the sliding window imply a successful capture of the intrinsic data structure. This campaign showcases the critical role of temporal analysis in clustering, especially for data where temporal patterns significantly influence the underlying structure.

Across campaigns B, C, and E, the analysis underscores the nuanced performance of GMM and Time Series K-Means, particularly when enhanced with a sliding window technique, across various clustering quality metrics. While simpler algorithms like Kmeans show competitive performance in specific metrics such as the Silhouette Score, the added complexity and temporal awareness of the sliding window modification in Time Series K-Means generally translate into superior clustering outcomes, especially in terms of aligning with true cluster structures and maintaining class completeness.

Advantages of MLP-CMLL Time Series K-Means (MLP-CMLL with TSKMeans)

From all tables 4, 5 and 6, the introduction of Contrastive Metric Learning Loss-Enhanced Multi-Layer Perceptron with Time Series K-Means (MLP-CMLL with TSKMeans) marks a significant advancement in clustering complex time-series data. This novel approach leverages the strength of contrastive learning to fine-tune the feature representation, significantly enhancing the clustering capability of TSKMeans by ensuring that similar instances are brought closer while dissimilar ones are distanced in the feature space. Our results underscore the efficacy of this method, particularly in achieving superior clustering performance metrics across all campaigns when compared to traditional approaches. Notably, the MLP-CMLL with TSKMeans exhibits remarkable improvements in metrics such as ARI and NMI, indicating not only an enhanced alignment with the true cluster structures but also a comprehensive capture of the intrinsic data relationships. This methodological enhancement introduces a powerful tool for time-series analysis, offering robustness against the challenges posed by the dynamic nature of temporal data and paving the way for more accurate, interpretable clustering solutions.

Our MLP-CMLL with TSKMeans vs. GMMSEQ (Ramasso, Denoeux, & Chevallier, 2022). In a comparative analysis between the novel MLP-CMLL+TSKmeans method and the GMMSEQ (Ramasso, Denoeux, & Chevallier, 2022) method across three experimental campaigns labeled B, C, and E, the performance is quantitatively measured using the Adjusted Rand Index (ARI). The ARI scores indicate the similarity between the clustering results and the true classifications, with a range from -1 to 1, where 1 denotes perfect agreement. For Campaign B, the MLP-CMLL+TSKmeans method significantly outperforms GMMSEQ, achieving an ARI of 0.875 compared to GMMSEQ's 0.772. This suggests a superior ability of the MLP-CMLL+TSKmeans to accurately match the true cluster structures. In Campaign C, both methods exhibit exceptional performance with MLP-CMLL+TSKmeans slightly leading (0.949 vs. 0.947), indicating that both are very capable but MLP-CMLL+TSKmeans shows a slight edge in capturing the clustering structure accurately. Campaign E again sees MLP-CMLL+TSKmeans outperforming GMMSEQ (0.854 vs. 0.799), reinforcing the method's robustness and accuracy in analyzing the complex dynamics of acoustic emission data streams. Overall, MLP-CMLL+TSKmeans consistently surpasses GMMSEQ in clustering performance across all campaigns, evidencing its effectiveness and the significant benefits it offers for structural health monitoring applications through better differentiation and handling of temporal dynamics within AE data.

4. CONCLUSION

This work introduced a new method for the analysis of acoustic emission (AE) data streams, which are inherently sequen-

tial and temporal. The study proposes a unique approach by enhancing a Multi-Layer Perceptron (MLP) with a contrastive metric learning loss function (MLP-CMLL) and time series kmeans, aiming to efficiently identify and analyze sequentially appearing clusters within the data. This novel loss function is meticulously designed to optimize the MLP by improving the differentiation between distinct clusters. The approach primarily concentrates on embedding sequences in a manner that clusters with similar acoustic patterns are brought closer together, while those with divergent patterns are distanced, thereby augmenting the MLP's capability to recognize and classify acoustic events based on their emission signatures over time.

The importance of this work lies in its ability to address the challenges associated with the precise characterization of dynamically forming clusters within AE data streams. Traditional clustering algorithms often falter in handling the temporal dynamics of AE data, where the sequencing and timing of events are crucial for a comprehensive understanding of the phenomena being monitored. By integrating a contrastive metric learning loss with an MLP architecture tailored to the specifics of sequentially appearing clusters in AE data streams, our method aims to unveil deeper insights into the formation and evolution of clusters. This approach promises to enhance monitoring and predictive maintenance in engineering applications by capturing the complex dynamics of AE data more effectively.

Through extensive experimentation and comparative analysis against conventional techniques, we validate the superiority of our proposed method in discerning the intricate dynamics of AE data. This work presents a robust analytical tool for the investigation of sequential clusters and their implications in the domain of structural health monitoring, offering significant advancements over existing methods in terms of cluster detection, characterization, and temporal analysis.

ABSTRACT

Prognostics and Health Management (PHM) offers the potential to increase the acceptance of adaptive structures and to operate them in an optimal way. With suitable design and proper operation, adaptive high-rise structures enable significant increases in sustainability and service life extensions compared to passive high-rise buildings. The control loop for PHM provides a systematic overview of the contents related to PHM and their sequence. However, a framework is required for application to a complex adaptive system. Such a framework is presented in this paper. The framework is divided into the areas of system analysis and modeling as well as the PHM solution. A systematic approach is used to analyze the system and create the basis for full integration of all functional domains. This is then used in modeling to develop an adapted model structure. Finally, the PHM solution looks at the details of the approaches for diagnosis, prognosis, and health management.

1. MOTIVATION

The construction industry consumes significant resources and is responsible for a considerable proportion of CO_2 emissions (Thibaut Abergel & Dulac, 2018; OECD, 2015). Traditional load-bearing structures are typically designed for infrequent critical load cases. Additionally, there are numerous uncertainties, which are compensated in the design by safety factors. As a result, the load-bearing structure is often significantly oversized for most of its service life, which leads to increased resource demands and CO_2 emissions (Efinger et al., 2022). Actuators can be used to induce displacements, homogenize stresses in structures, and actively dampen vibrations. This enables the structural mass of such adaptive load-bearing structures to be reduced compared to passive structures by targeted reduction of cross-sections. In addition, the actuators need to be integrated into the structure and complemented by associated systems – including measurement systems, control systems and energy supply. Adaptive load-bearing structures offer the potential to save structural mass and – through suitable operation – to be more sustainable than conventional passive load-bearing structures (Efinger et al., 2022). At the same time, ensuring sustainability should not come at the expense of safety or serviceability. On the other hand, unnecessarily frequent maintenance measures need to be avoided for both sustainability and economic reasons. However, in addition to the parameter space for maintenance, there is also the parameter space for adaptivity control. This includes determining when which actuators exert how much force on the system and in what combination. As a result, stiffness and damping are controlled locally at the individual points, but also globally in the load-bearing structure. Depending on this, static and dynamic effects develop under the respective load, and more or less damage occurs in the individual elements of the structure. For both operation and maintenance, short, medium, and long-term objectives must also be considered and balanced. This high-dimensional problem cannot be solved with conventional methods for operating or maintenance strategies.

Prognostics and Health Management (PHM) offers the potential to improve the reliability and availability of technically complex systems in line with requirements. A comprehensive understanding of the application of PHM is crucial, especially when it comes to developing customized PHM solutions for complex systems.

The challenge in developing a universally applicable PHM solution lies in the high complexity and variability of the systems. Henß (Henß, 2021) highlights this problem and proposes a PHM control loop that offers a general approach to implementing PHM. However, this still needs to be embedded in the system for the application itself. To that end, this paper provides a framework that enables the practical implementation of the PHM solution and provides a structured approach for applying PHM to the complex system of an adaptive high-rise building.

To do this, a framework is presented that is specifically designed to apply PHM to complex systems. This framework

serves as both a method and a framework to enable effective implementation of PHM strategies. It is divided into two main parts: *System analysis and modeling* as well as *PHM-solution*.

In order to achieve this objective, section 2 – **basics** – initially introduces adaptive systems, the high-rise structure that serves as an example, and the PHM control loop.

Section 3, **system analysis and modeling**, focuses on understanding and modeling the specific features and behavior of the system under consideration. This phase is fundamental for the development of accurate predictive models and for the identification of relevant system parameters that are important for condition assessment and prediction.

This is followed by the **PHM-solution** in section 4, which comprises the development and implementation of solutions based on the findings and models of the system analysis. Specific techniques and procedures are used to implement system prognostic and the optimization of the system based on this.

Finally, section 5 gives a **summary**.

2. BASICS

This section introduces relevant basics for the adaptive system and introduces the PHM control loop.

2.1. Adaptive Systems

Systems that actively change with the help of sensors and actuators are referred to as adaptive systems. The system interacts with the environment and manipulates loads, for example, in such a way that load peaks are avoided (Sobek, Haase, & Teuffel, 2000). Adaptivity is enabled by a control process, whereby the input signals are fed into the system through sensors.

2.2. The D1244

The world's first adaptive high-rise building is called D1244. D1244 is a multi-functional experimental platform and is located on the campus of the University of Stuttgart. The load-bearing structure is activated by hydraulic actuators. Hydraulic pressure accumulators close to the cylinders ensure homogenization of the system pressure and minimize the switching requirements for the hydraulic pump. A central control unit and several module control units are available to control the hydraulic actuators, which are actuated by electro-hydraulic valves. Various sensors provide the controls with information on the load-bearing structure, the actuator system, and the ambient conditions. There are strain gauges for strain measurement in a redundant arrangement on the pillars and diagonals. LEDs mounted on the outer shell in the transition between the modules of the load-bearing structure serve as measuring points for an optical measuring system that uses cameras on two sides to record relative displacements and deformations of the load-bearing structure. The change in displacement of the actuators is recorded using displacement measuring systems on the hydraulic cylinders. There is a weather station on the roof of the building that records wind speed and wind direction.

2.3. Control of the Adaptive Structure D1244

The control loop contains the physical system, from which relevant variables such as stresses, deflection and other measured variables are recorded, a Kalman filter (KF) for condition monitoring and a linear-quadratic regulator (LQR) for controlling the adaptive components. Using the KF as an observer and estimator, the current system state $\hat{x}$ is estimated and iteratively transferred to the controller by a feedback loop. This allows unknown system variables to be determined and the system to self-adapt (Ostertag, 2021). Finite element models are used to investigate the equation of motion of the mechanical structure. The finite element method is used for the dynamic analysis of structures and the equation of motion of the structure. The discretization of the FE model at the nodal points results in the equation of motion according to (Ostertag, 2021; Gienger, Schaut, Sawodny, & Tarin, 2020):

$$M\ddot{q} + D\dot{q} + Kq = F_u u_{act} + F_\nu(\nu) \tag{1}$$

with the following boundary conditions:

$$\dot{q}(0) = \dot{q}_0, \;\; q(0) = q_0. \tag{2}$$

2.4. PHM Control Loop

The PHM control loop, as introduced by Henß (Henß, 2021), represents a systematic approach to optimizing the operation and maintenance of technically complex systems. Central to the control loop is the continuous interaction between the system and its optimization based on data from measurements, diagnosis, and prognosis. The optimization is fed directly back into the system, creating a closed loop that leads to continuous improvement.

The control loop can be abstractly divided into three main areas:

1. **Condition assessment:** This includes collecting data and analyzing it to determine the current system status.
2. **Forecast approaches:** Based on the condition assessment, a prediction is made about the future condition of the system.
3. **Optimization approach:** The results of the condition assessment and forecast are used to define and implement measures to improve the system.

Figure 1, based on (Henß, 2021), illustrates the PHM control loop including the three main areas formed. This illus-

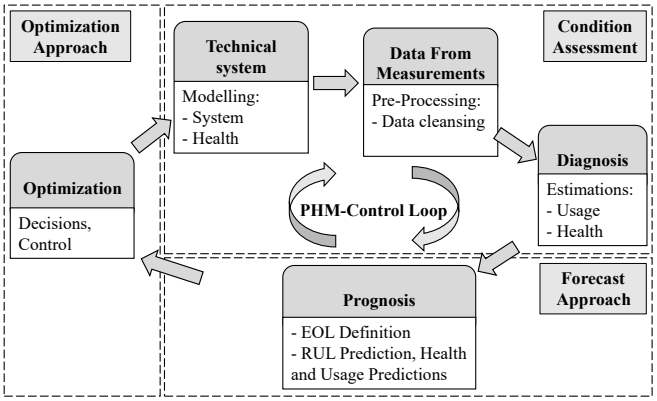

Figure 1. PHM control loop with its three main areas.

tration demonstrates the dynamic and cyclical nature of the PHM approach, which is based on continuous improvement and adaptation.

The condition assessment includes the evaluation of the system (system and health modeling), the evaluation of the data (data collection and cleansing) and the diagnosis (state estimation). This classification enables a precise assessment of the system and health statuses, based on which estimates can be made for the current state. Based on the estimates determined from the diagnosis, the predicted range within the condition forecast is determined. The downtime or, if an end-of-life definition has been selected, the remaining useful life (RUL) can be calculated. The basis for this is, among other things, the history to date. If information on future changes is available, these can also be considered. During optimization, the adjustable system settings are adjusted so that the objective function is as optimal as possible within the scope of the observation horizon. The information from the condition assessment and condition forecast is used for optimization. This holistic approach enables proactive maintenance and the optimization of operating processes, which leads to an extension of the service life and an increase in the efficiency of systems.

3. System Analysis and Modeling

This paper is built around the D1244 system, which offers ideal conditions for the application of PHM due to its complexity and adaptive capabilities. The special feature of the D1244 lies in the large number of influencing variables and the associated uncertainties. This makes the implementation of PHM a challenging task.

For a comprehensive integration of PHM into a complex system – such as an adaptive high-rise structure – a systematic approach is required. This is dealt with as part of the framework in this section. It is further subdivided into the steps of system analysis and modeling. During the system analysis in subsection 3.1, all aspects relevant for modeling the PHM application are determined. The models and their interrelationships are then built on this basis in subsection 3.2.

3.1. System Analysis

This subsection develops the content to create models for state estimation, prediction, and health management. A comprehensive system analysis is carried out for this purpose. This begins with the overall objective, which also provides target parameters, followed by the system description. In addition, the requirements and boundary conditions for operation and its optimization are extracted. From this, the dimensions of the system are derived and supplemented by further conditions. Influencing factors are then identified on this basis. Lastly, uncertainties for the target parameters and the boundary conditions can be derived from the target parameters and influencing factors.

Once these steps have been completed, all areas are available for developing models for the PHM application.

3.1.1. Objective

The objective of the PHM control loop according to Henß (Henß, 2021) is to operate and maintain the system in such a way that the target parameter is maximized, and the existing boundary conditions are met. A target parameter describes a measurable or countable variable from the objective. For the use case of the adaptive high-rise system this means:

Firstly, the environmental impact should be as low as possible, with the CO_2 equivalent being assessed. Secondly, increasing the service life of the system beyond a certain level may also be a further goal. Thirdly, this needs to be done in compliance with the requirements and boundary conditions.

There is now a conflict of interest between the goals of lowest possible CO_2 equivalence and increased service life. The lowest possible CO_2 equivalent would be achieved with the shortest possible service life and an increase in service life would presumably require additional CO_2 expenditure. For this reason, the CO_2 equivalent is used as a reference for its opposing benefit – i.e., the service life. This means that the CO_2 equivalent is normalized to the useful life. Nevertheless, it is possible that the target parameters compete. Therefore, an individual objective function needs to be formed for each use case from the existing target parameters and boundary conditions for multi-criteria optimization. This is implemented as part of the modeling in subsection 3.2.1.

3.1.2. System Description

Now that the objective is set, it is important to clearly define what it applies to. The system description serves to make the system and its components tangible and to separate the area under investigation from the environment through a defined system boundary. In addition to a physical and a signal-related system boundary, the system boundary also includes

a temporal dimension. For the example under investigation, this means:

The system of interest is the entire system of the adaptive high-rise structure, described in subsection 2.2. In addition to the load-bearing structure, this also include the functional domains of the actuators, various sensors, physical control, and transmission elements, the software control and the energy supply. Furthermore, maintenance with all its domains – including spare parts stocking, capacity planning, etc. – is also included in the system scope. Figure 2 shows the domains of the adaptive structure schematically and indicates their allocation. The temporal consideration starts from the beginning of the building usage until the end of the service life. The manner in which the adaptation function is carried out by the components of the adaptive system corresponds to the description in subsections 2.1 and 2.3. To do this, a functional adaptation function is required. If the adaptation function is to be performed and it is not functional, the adaptation function fails.

3.1.3. Requirements and Boundary Conditions

The first question that arises for a defined system or its optimization is that of the general requirements and boundary conditions. They are set externally or internally and need to be fulfilled. There are elementary requirements for a structure such as a high-rise building. These include the fact that they have to enable their intended use and that they have to have a certain geometrical shape. Standards such as the Eurocodes formulate further requirements. There are also project-specific, definable requirements that the building has to fulfill. The probability of partial or total failure of the structure or its function is of central importance. Suitable measures must be taken to ensure that the probability of occurrence is lower than the limit values defined as acceptable. Typical design measures for this are redundancies in the functional structure or the oversizing of relevant structural components. The limit values to be fulfilled are, on the one hand, limit values for the designed service life and, on the other hand, limit values for failure at any time. The Eurocodes typically work with two different safety levels for buildings. The stricter one deals with the risk of structural failure. Whereas the less stringent one concerns, for example, the occurrence of non-failure-critical cracks or the occurrence of building vibrations that could potentially be perceived as unpleasant by users. While the stiffness – and therefore the vibration behavior – of passive load-bearing structures cannot be actively changed, this is possible with adaptive structures. This means that compliance with building vibrations defined for user comfort could be linked to the presence of users in the building. In this way, the limit value would change over time – if there were people in the building, it would take effect, if there are no people in the building, it could be raised.

3.1.4. Dimensions

The existing dimensions can be developed based on the requirements and can be further enhanced based on the objective and the boundary conditions. To fulfill the requirements, the system has to perform functions, but these are not always requested in the same way.

For the D1244, this gives rise to the three existing dimensions – the function request dimension, the function availability dimension, and the temporal dimension. These are supplemented by additional criteria from the objective and the boundary conditions. From the objective, this are the target parameter of CO_2 equivalent and the extension of the service life. The boundary conditions provide the time-variable risk limit for the failure of the adaptation function.

The dimensions can be examined in more detail. The aspects to be found there can influence each other within the dimension as well as between the dimensions or are dependent on each other. For example, the temporal dimensions consist of endless gradations between the past, the present and the future. The dimension of function request is composed of the aspects of building usage, external influences such as wind and weather as well as the limits of safety levels.

However, the most comprehensive dimension is that of function availability. It can be divided into the physical system, non-adjustable and adjustable system properties, and system monitoring. The following lists show some of the contents.

Physical system:

- *Load-bearing structure:* Load capacity; Statics; Dynamics; Health
- *Actuators:* Dynamics; Fault; Failure; Health
- *Sensors:* Fault; Failure; Health
- *Physical control elements:* Dynamics; Fault; Failure; Health
- *Physical transmission elements:* Fault; Failure; Health
- *Energy supply:* Fault; Failure; Health

Non-adjustable system properties:

- *Function structure:* Redundancy; Compensation possibilities
- *Failure behavior individual elements:* Reliability; Health; Damage factor; Failure behavior

Adjustable system properties:

- *Control options:* Control limits; Control models; Actuators; Ph. control el.; Energy supply
- *Maintenance:* All physical domains; Spare parts; Tools; Personnel; Measures

System monitoring:

- *State detection:* Position; Force; Stress; Pressure; Motion; Acceleration; Control; Health; Maintenance; Usage; External influences; function request

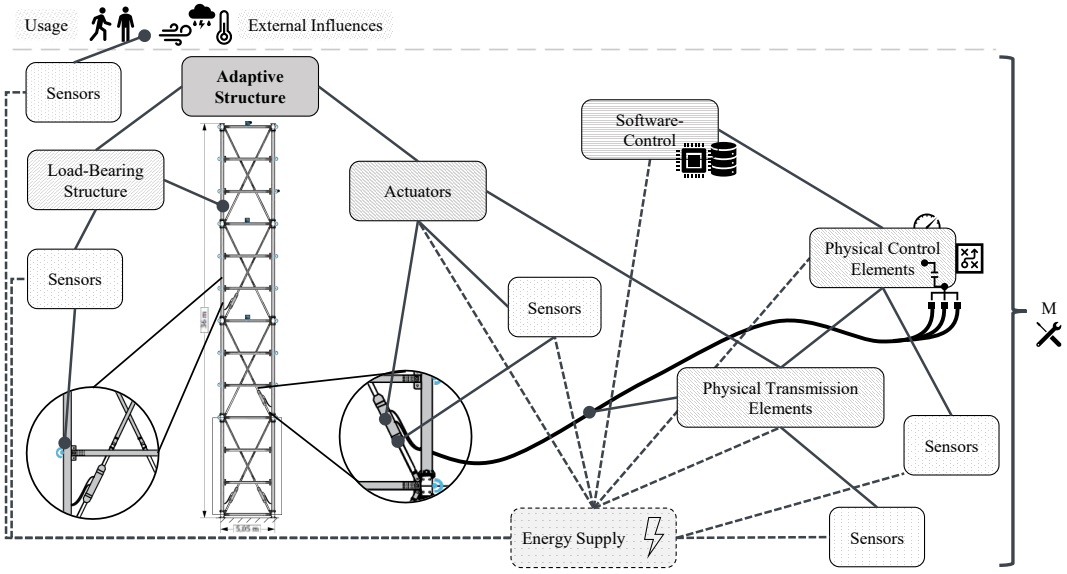

Figure 2. Schematic illustration of the system.

- *Fault detection:* All physical domains with exception of load-bearing structure; Control
- *Failure detection:* All physical domains; Control

Using the dimensions, the subsequent steps of the system analysis can be systematically examined for all existing aspects of the system. The dimensions can also be used to systematize the interconnection of aspects and dependencies in the functions for subsequent modeling. Aspects with identical themes can therefore be found in different dimensions.

3.1.5. Influencing Factors

This step collects all existing influencing factors. Influencing factor is anything that influences the fulfillment of the requirements, the boundary conditions, or the objective at any point in time. For the PHM application, the influencing factors needs to be divided into those that cannot be adjusted during operation, those that can only be adjusted indirectly and those that can be adjusted directly by PHM.

3.1.6. Uncertainties

Uncertainties describe a lack of or imprecise knowledge about something. To utilize the existing knowledge, it is necessary to quantify the uncertainty. Otherwise, unknown risks would be taken. These can be of an economic, social, or ethical nature. Uncertainties can be determined from the combination of target parameter and influencing factor as well as their relationship and classification in the existing dimensions.

Generalized uncertainties of the respective influencing factors from the following areas have to be taken into account. This applies to each measurement and model level and influences dependent model and system areas.

- Measurement uncertainties: Measurement errors, measurement data noise, etc.
- Model uncertainties: Model errors, model inaccuracies, etc.
- Stochastic effects
- Time

From the levels of the measured variables to the sub-models and the models, more influences of uncertainties are added. Some of these can be reduced using appropriate models to reduce uncertainties. An example of this is checking for measurement errors from sensor signals using a model that checks several sensor signals for plausibility and can perform error identification.

The temporal dimension plays a crucial role in uncertainties. In a present state, uncertainties from the areas of measurement uncertainty and model uncertainty can be present. If the corresponding data is available for the past, the situation is the same there. When considering future points in time, however, the uncertainty from the temporal development is always added. Figure 3 shows an uncertainty space that spans the areas of measurement and model uncertainties and the temporal dimension. There is no temporal uncertainty for the past and the present, provided that the data from the past is still fully available. For the future, however, the temporal uncertainty increases more with increasing temporal distance. The measurement uncertainty and the model uncertainty do not have a generalizable function from lower to greater uncertainty. They must be estimated individually for each case under consideration.

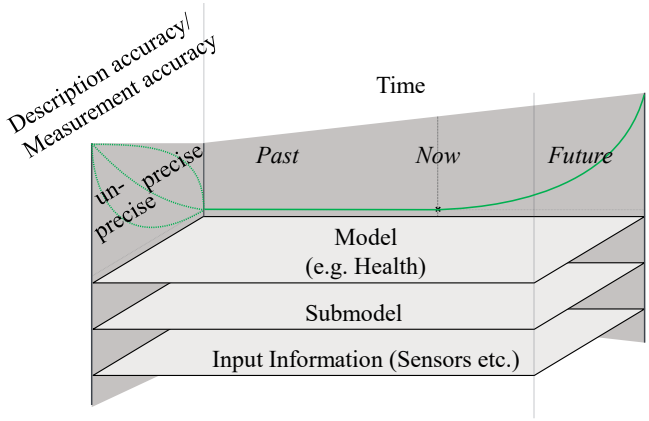

Figure 3. Illustration of a dimension model with dimensions of uncertainties.

3.2. Modeling

Subsection 3.2.1 establishes the target space and objective function based on results, requirements, and boundary conditions. The creation and interconnection of model structures across various levels are detailed in 3.2.2. System integration for the structural control of an adaptive high-rise structure is discussed in 3.2.3.

3.2.1. Target Space and the Objective Function

The target space represents the scope in which all specifications and requirements are met. It therefore describes permissible solutions. The objective function defines the weighting of the target parameters in relation to each other. Permissible solutions fulfill all requirements, the best possible solutions achieve the highest values for the objective function. In concrete terms, this means that the probabilities of partial or total failure of the structure or its function must be always kept below the limit values and for the entire planned service life of the structure. Some of the limit values can change over time, depending on factors such as building occupancy. At the same time, the overriding objective is to achieve the lowest possible CO_2 equivalent and possibly an increase in the service life of the building. The weighting of the two target parameters needs to be described by way of a relationship. Further boundary conditions and target parameters are possible and could be added in the same way. The optimization of such an objective function is not trivially solvable for such a complex system. Therefore, the use of fuzzy logic is proposed in section 4 in order to enable an assessment of all influencing factors based on the information about the system using the hybrid approach described there.

3.2.2. Model Structure

The development of the model structure relates to two designations of models and their structure. On the one hand, it is about the dimensional models and their interconnections. On the other hand, it is about functional models and their interaction.

Function Models The function models are divided into the three areas of condition assessment, forecast assessment and optimization approach introduced in subsection 2.4. Figure 4 also shows an overview of the structure of some function models for the PHM solution of the adaptive high-rise building. In accordance with the PHM control loop according to Henß and figure 1, the diagnosis in the condition assessment provides input for the prognosis in the forecast assessment and this for the optimization. Optimization continues until an accepted condition forecast is reached, for which the instruction to adjust the relevant influencing factors is given. In addition to these optimized adjustment instructions described above, there are also system variables that are also provided externally by the condition assessment from the PHM solution. The adjustment instructions contain parameters with different change behavior over time. For example, the instruction of a maintenance measure after several years of operation and with an execution time of several days or weeks. But also, the current state of stress on an element of the load-bearing structure or the pressure in one of the actuators.

- The **diagnostics** includes function models for the detection, determination or estimation of
  - Failures: for example of individual actuators, sensors, valves or load-bearing elements
  - Faults: for example in the measurements of sensors, the control behavior of valves or the control instructions of the control system
    For example, (Stiefelmaier, Böhm, Sawodny, & Tarín, 2023) provides a concept for detecting sensor or actuator faults that can be integrated.
  - System states: for example, for the individual parts of the load-bearing structure, actuators, sensors, feed and control systems, or maintenance processes in relation to their positions, mechanical or electrical stresses or hydraulic pressure, the dynamic state or the state of damage
- The **prognostics** contains function models for forecasting all states of the condition assessment. It is fed with information from the diagnostics. External predictions are also included. These include forecasts for wind and weather, personnel capacity, spare parts capacity and, if applicable, utilization and the planned remaining service life.
- **Optimization** takes place in Health Management. Function models are available to evaluate the optimized solution and to optimize the adjustable influencing factors.

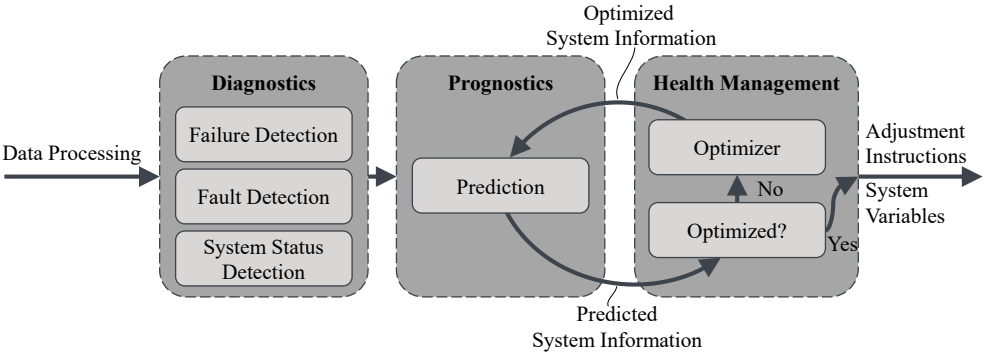

Figure 4. Some feature models of the PHM-solution.

Dimension Models The dimensional models or models of dimension aspects form different layers on top of the function models. They interact with each other and with the function models. Figure 3 shows such a dimension model using the example of health and taking the temporal dimension into account. The dimension model uses various input information, which is prepared and processed in sub-models before being merged in the dimension model.

The correlations can be illustrated using a simple example of a fault in the measured value of a sensor. In the case of fault detection in the measured value of a sensor, the function model for the fault detection is used to handle an influence from the dimension aspect of sensors. To assess whether or with which other sensor information an evaluation is possible, the model for the dimension aspect of function structure is used to work on redundancies or compensation options. These may be reduced in number by the results of the function model for failure detection. The temporal dimension may also be used to detect changes in the data history.

3.2.3. System Integration on the Example of Structural Control

This subsection uses the example of structure control to describe how system integration can be carried out with the PHM solution. To do this, we refer back to Figure 4 in the previous subsection. The PHM solution provides adjustment instructions. These must then be processed – for structural control in the control of the actuators. The system integration for structural control can be divided into two higher-level subareas if this is abstracted:

- Intelligent control model
- Intelligent monitoring and assessment model

The conventional approach from subsection 2.3 for controlling the high-rise demonstrator involves using a linear-quadratic controller in a closed control loop with feedback and a Kalman filter as an observer. This means that only a limited adaptation of the control behavior is possible.

In (Dakova, Heidingsfeld, Böhm, & Sawodny, 2022) the authors present an agent-based fatigue level controller through the use of a model predictive control (MPC) and the use of a cost function for the damage in the elements. This controller is adopted for structural control as a so-called score MPC. The PHM solution provides it with the control difference $e(t)$ and the optimized scores for each actuator as adjustment instructions. In this way, the PHM solution defines the intensity of the control and the distribution between the actuators in the system. The block diagram for the control loop is shown in Figure 5. The score MPC thus forms the intelligent control model, and the PHM solution forms the intelligent condition monitoring and evaluation model.

4. PHM-SOLUTION

This section covers the diagnostics and prognostics approach, detailing the use of a hybrid model and a health management agent that utilizes optimized system information for improved control behavior. It also introduces a data-driven strategy employing fuzzy neural networks (FNN) to manage the complexity of the D1244 system. This method facilitates the efficient analysis of extensive, multi-layered data, enhancing decision-making in maintenance and operations. Fuzzy neural networks enable the PHM solution to adapt and refine predictions, crucial for addressing challenges in complex systems like the D12444.

4.1. Diagnostics and Prognostics Approach

The effective assessment and prediction of the health of complex systems have requirements that cannot be met by conventional approaches. As described by Kim et al. (Kim, An, & Choi, 2017), Goebel et al. (Goebel et al., 2017), and Si et al. (Si, Zhang, & Hu, 2017), hybrid approaches offer a promising solution. These approaches combine data-driven algorithms with physical degradation models to improve the accuracy of condition assessment and prediction.

Such a hybrid approach is made up of various sub-models, each of which depicts individual dimensions of the system,

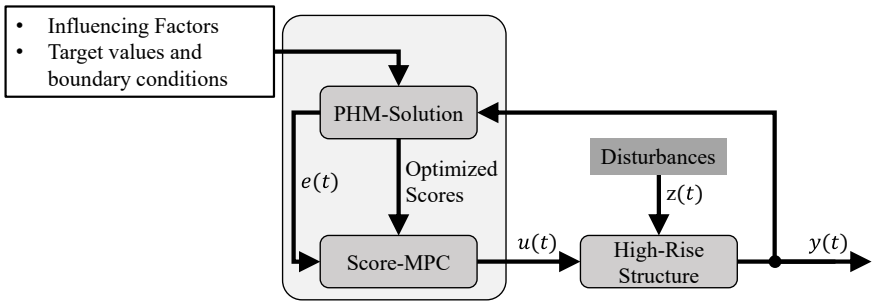

Figure 5. Control loop for the D1244 optimized for PHM application.

and which are linked together. Training and experience data are essential for the development and refinement of these approaches. This data includes not only the current measured values recorded by sensors, but also historical data that is used to calibrate and train the algorithms.

4.1.1. Design of the Hybrid Approach

The hybrid approach combines data-driven and physically based models to enable a comprehensive analysis of the failure behavior of system components. Pure data-driven models based on mathematical functions can only approximate reality without taking underlying physical models into account. The integration of a physical model, on the other hand, enables a deeper insight into the behavior of the system. This combination not only increases the accuracy of the predictions, but also expands the database for training the algorithms and promotes a holistic understanding of the overall system.

A schematic setup for the application of such an hybrid approach to a complex adaptive system, such as the D1244, is shown in Figure 6. Data- and physics-based methods are used to both estimate the current state and predict the future state.

A degradation model forms the basis for making valid statements about the system based on sensor data and minimizing inaccuracies. The combination of data-driven findings and physical models provides a robust basis for the reliable evaluation and prediction of system performance.

To optimize the informative value of this approach, continuously recorded training data is integrated into the prediction models over the system's service life. This enables a flexible and effective response to unexpected system changes.

This approach distinguishes between two sub-models, which are discussed in detail in the following sections. These submodels are the state estimation and the state prediction.

4.1.2. State Estimation

The state estimation serves as the basis and data foundation for the forecasting approaches. For this purpose, system and condition modeling is carried out and data from the technical system is recorded by sensors. The degradation model plays a key role here, as it provides a basis for the estimates. Degradation modeling is conducted using damage mechanisms on the components or estimates of the system modeling, for example using KF. The assessment of the condition takes place in the diagnosis: Through data, states that affect the use and health of a technical system are estimated in diagnostics based on collected information.

4.1.3. State Prediction

In addition to current sensor data, the hybrid approach can also incorporate training data from past measurements for the state prediction. This allows the forecast to be improved. This therefore represents a continuously learning process.

4.2. Health Management Agent

During optimization, the predicted system information is finally optimized iteratively, and a decision is made for the system. Optimization goals such as fault tolerance, sustainability and fault prevention are considered, for example to enable proactive and environmentally friendly maintenance planning. Based on the optimized system information, the control behavior of the system can be adapted and improved.

Calculating the score is therefore one of the most important tasks of optimization and can be achieved by using fuzzy methods in combination with NN. The use of FNN has the advantage that a more precise classification and assignment of the optimized system variables is possible and thus a more precise score calculation can be realized for the respective actuators.

4.2.1. Optimization of System Information

The optimization of the predicted system information as part of health management aims to improve the service life and added value over the entire life cycle by integrating optimization factors. This strategic adjustment affects both maintenance planning and the efficiency of use of the system components. Through targeted control, component functions can be adapted not only to extend the service life but also to

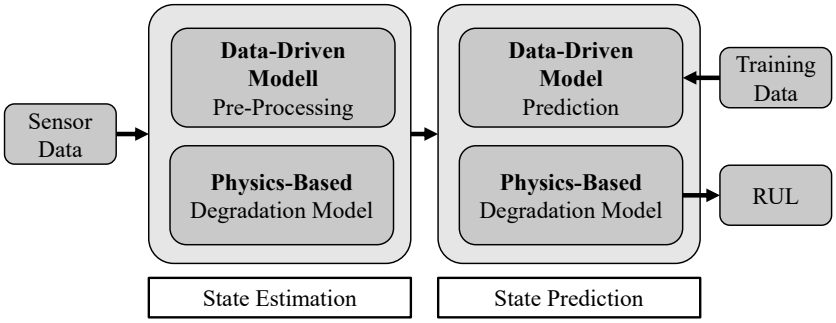

Figure 6. Schematic setup of the hybrid approach for a complex system.

prevent premature failures. The process is iterative and is based on the continuous analysis of the remaining useful life (RUL), which considers both risk factors and life cycle analysis (LCA) factors. This comprehensive approach enables dynamic adaptation of maintenance strategies and a flexible response to changing operating conditions or new findings about the condition of the components. By integrating both data-driven insights and physical model assumptions, a more precise forecast and thus more effective planning and control of maintenance measures is achieved.

The continuous improvement of the management system through this iterative approach not only supports an extended service life and increased reliability of the system components, but also helps to reduce maintenance costs and increase overall efficiency. This methodical approach is therefore an essential part of strategic maintenance and operational management, creating a balance between preventive maintenance and operational flexibility.

4.2.2. AI-Supported Optimization Using Fuzzy Neural Networks

At the core of the Prognostics and Health Management solution is the implementation of fuzzy neural networks, which use the hybrid approach to make adaptive decisions regarding the system components and adjust the control behavior accordingly. Embedding fuzzy logic (FL) in neural networks enhances their ability to precisely interpret and process complex system states and dynamics. FL mimics human thinking by making it possible to represent complex relationships in an understandable form. In addition, the use of FL enables a sophisticated analysis of uncertainties and ambiguities within the system data, allowing FNNs to make efficient decisions even in the presence of incomplete or fuzzy information. Fuzzy sets and rules are directly integrated into the structure of the neural networks, resulting in a synergetic architecture of fuzzy neural networks (de Campos Souza, 2020; Mishra, Sahoo, & Mishra, 2019).

The special feature of this approach lies in the improved interpretability of complex systems and the effective handling of data uncertainty. The use of FNNs enables a deep understanding and clear interpretability of system dynamics and state evaluations, which is crucial for the optimization of PHM solutions (de Campos Souza, Lughofer, & Guimaraes, 2021).

4.3. Fuzzy-Based Score Calculation

The interface between the PHM solution and the controller from 2.3 requires a control difference to be defined and transferred to the control system. For this purpose, a PHM solution is added to the control system, which calculates a score value for the individual actuators using extended optimization. The score calculation can be performed using various methods, including simple weighting or the application of complex logical operations using fuzzy rules in fuzzy neural networks (FNNs). The objective function from subsection 3.2.1 and the influencing factors from subsection 3.1.5 are included in the calculation of the score. For example, deferring maintenance to reduce CO_2 emissions can increase the risk of failure. All of these factors needs to be considered as part of an iterative optimization, as illustrated in Figure 4. The influencing factors can be integrated into a calculation function as weights. One implementation option is the formulation of fuzzy rules, whereby the weighting of the individual factors within the FNN is included in the evaluation. This allows complex logical relationships based on the data to be considered and the result to be interpreted as a score value.

The main objective of using an FNN is to make the score calculation for adaptive control efficient and effective. By integrating fuzzy rules, the various influencing factors are categorized and evaluated by fuzzification layers in the network. This allows not only a specific weighting of the factors, but also a flexible adjustment of these weightings within the layers. Training data from previous calculations or empirical values can also be used to train the network. A particular advantage of fuzzy networks is that they do not require an explicit model and that they can simplify the score calculation despite complex mathematical relationships through fuzzification.

4.3.1. Design of a Fuzzy Network

A fuzzy-based neural network consists of several core components. These are:

- **Fuzzy logic:** Enables the processing of uncertainties and ambiguities through the use of fuzzy sets and fuzzy operators.
- **Membership Functions:** Each fuzzy set is represented by a membership function, which specifies the degree to which an input value belongs to a set.
- **Fuzzy Rules:** Fuzzy rules, formulated as "IF-THEN" statements, define how input values should be processed based on their membership of different fuzzy sets.
- **General neural network structure:** Similar to traditional neural networks, including layers of neurons that are interconnected by weighted connections.

4.3.2. Definition of Fuzzy Rules

As the decisions of the adaptive system are based on the fuzzy rules, it is important to define the most precise boundaries possible when recording the rules. The rules should represent the characteristics of the training data sets as accurately as possible. To define precise fuzzy rules, approaches such as the improved Wand-Mendel method can be used. This tool makes it possible to determine fuzzy rules directly from the data sets. However, as this leads to further uncertainties, it is important to determine the fuzzy rules iteratively to keep the uncertainties as low as possible. And use methods such as the WM method as an additional option.

Since the determination of fuzzy rules is a continuous process, it is essential that the fuzzy rules within this framework can be adapted flexibly and adaptively to changes to be able to react effectively to modifications of the underlying rules.

4.3.3. Example Use Case of Fuzzy Neural Network

To demonstrate the practical application and effectiveness of FNNs across various adaptive control systems, we explore an example using the D1244. This use case illustrates how FNNs can be seamlessly integrated into complex environments to manage and improve system responses dynamically.

FNN Implementation: The FNN architecture in this scenario consists of several key layers, each tailored to handle the specifics of sensor data interpretation and decision-making in a fuzzy context:

- **Input Layer:** Directs raw sensor data into the network.
- **Fuzzification Layer:** Converts numeric sensor inputs into fuzzy values using membership functions. These functions define linguistic terms such as low, medium, high, which are easier to handle in rule-based logic processing.
- **Inference Layer:** Implements fuzzy logic rules that determine the control responses based on the fuzzy inputs. This layer combines the fuzzy terms using logical operators and forms the backbone of decision-making within the network.
- **Defuzzification Layer:** Converts the fuzzy conclusions back into precise control outputs, such as adjustment levels for actuators.

Input: The FNN receives real-time input from the sensor array, which is continuously monitoring the process variables:

- **Temperature sensors** provide data that are vital for preventing overheating and ensuring chemical processes proceed at optimal rates.
- **Pressure sensors** monitor the integrity of containment vessels and pipelines, preventing leaks and ruptures.

These inputs are sampled at a frequency high enough to allow real-time responses from the control system.

Results Interpretation: The outputs from the FNN directly influence the operational controls of the D1244. They are interpreted as follows:

- **Control actions:** Adjustments made by the control system based on FNN outputs are implemented immediately to optimize processes and reduce energy consumption.
- **Operational efficiency:** By continuously adapting to changing conditions, the D1244 maintains optimal performance with minimal waste of resources.
- **Safety:** The system enhances safety by maintaining all process variables within safe operational limits, reducing the risk of accidents.

All these features are summarized in a score value, which can be managed in the PHM solution for the prediction of future states.

4.3.4. Advantages and Future Prospects of Fuzzy Neural Networks

FNNs represent a significant advancement over traditional NNs in that they provide interpretable relationships despite the increased complexity of systems and data. This capability makes FNNs particularly valuable for modeling and controlling complex systems. The score generated by FNNs enables a simplified yet comprehensive representation of system states and interactions, which are summarized in a value that can be interpreted by the controller. This not only reduces complexity, but also lays the foundations for improved decision-making and system control.

The combination of the adaptability of fuzzy logic and the learning capacity of neural networks allows FNNs to process

imprecise and uncertain information effectively. This is particularly advantageous in decision-making processes where traditional methods reach their limits. FNNs show their strengths especially in scenarios characterized by high uncertainty and fuzziness and offer a robust solution to the challenges of the real world.

The future of FNNs in application methodology aims to achieve real-time data processing and interpretability. The further development of these technologies will enable even more precise decision-making, which will significantly improve the adaptivity and autonomy of the system components. This direction of development promises to increase efficiency and effectiveness in the processing of complex data structures and at the same time create the basis for innovative control and monitoring systems that are able to react dynamically to changes and make proactive decisions (Talpur et al., 2022).

The integration of FNNs with advanced data processing techniques, such as Long Short-Term Memory (LSTM), could further enhance the ability to analyze and adapt to newly added information in real time. This not only increases system performance, but also lays the foundation for extensive use of FNNs in a variety of applications, from predictive maintenance to optimization of operations (Wang, Shao, & Jumahong, 2023).

5. Conclusion

This paper provides a framework for the comprehensive realization of Prognostics and Health Management for a complex system of an adaptive high-rise building. This includes not only the load-bearing structure, but all domains involved in the system such as actuators, sensors, the control system as well as maintenance with all sub-domains such as spare parts stocking and maintenance resources.

Adaptive load-bearing structures offer the potential to increase the sustainability and service life of high-rise buildings. However, this integrates many other functional domains into the system that can fail and whose optimal use may require regular adjustments. Prognostics and Health Management offers the potential to reduce uncertainties about the current state of the system and to optimize it for use.

The PHM control loop consisting of five modeling elements – system, data, diagnosis, prognosis, and optimization – is used as the basis for the structure in the application of PHM. However, since embedding in a system is required for implementation, a framework is introduced here that does this under the requirements of the complex system of an adaptive structure.

The framework is divided into the areas of system analysis and modeling and the description of the PHM solution. The comprehensive nature of the framework and the systematic approach support the consideration and accurate integration of all functional areas of the adaptive structure into the PHM.

The system analysis consists of six sub-steps. First, the system is described, and the relevant system scopes are defined. On this basis, existing dimensions are identified. With the help of the dimensions and the system description, specifications, boundary conditions are determined. The target parameters for operation and its optimization are defined on the same basis. This is followed by the derivation of influencing factors on the target parameters and for compliance with boundary conditions. At the end of the system analysis, uncertainties are identified for compliance with the boundary conditions and optimization of the target parameters.

Modeling begins with the development of the target space and objective function. The target space describes all permissible solutions, as the boundary conditions are met. The objective function weights the individual target parameters in relation to each other if there are several target parameters. The next step is to develop the model structure. Here, the results of the system analysis are used again to map and link all the necessary functions. Finally, system integration is presented using the example of structural control for an adaptive high-rise building.

The PHM solution section covers details of the approaches for diagnosis, prognosis, and health management. A hybrid approach of physically based and data-driven models is recommended for diagnosis and prognosis to meet the requirements of the complex system. For the health management agent, the use of fuzzy neural networks is discussed to enable precise interpretation and processing of complex system states and dynamics.

Through the presented content, the paper provides, besides the framework for the implementation, the structure in terms of system sizes and models for the application of PHM to the complex system of the first adaptive high-rise building.

ABSTRACT

Bearings and gears are components most susceptible to failure in electromechanical systems, especially rotating machines. Therefore, fault detection becomes a crucial step, as well as fault diagnosis. Over decades, substantial progress in this field has been observed and numerous methods are now proposed for feature extraction from monitoring data. Among these data, vibration signals are most used. However, in the presence of non-Gaussian noise, most conventional methods may be inefficient. In this paper, a hybrid methodology is proposed to address this potential issue. The proposed methodology uses a combination of the Maximal Overlap Discrete Wavelet Packet Transform (MODWPT) and Principal Component Analysis (PCA) techniques. First, the MODWPT technique decomposes the vibration signal with uniform frequency bandwidth, facilitating effective signal processing and introducing diversity for enhanced time-frequency signals. Then, to identify significant patterns and characteristics related to faults, PCA is used for 3D dimensional representation of system health state by capturing the variance in the extracted features. Subsequently, a self-organizing map (SOM) is used for system state classification for diagnostics. This technique is applied to open-access test bench data containing vibration signals with non-Gaussian noise.

Keywords: Signal processing, Fault diagnosis, Gearbox, Feature extraction, Rotating machines, MODWPT.

1. INTRODUCTION

Bearings and gears have significant roles in both traditional and modern manufacturing processes due to their extensive applicability (A. Soualhi et al., 2014; Benaggoune et al., 2020). As technology progresses rapidly, bearings and gears are often used in industrial equipment and systems (Gougam et al., 2021). Consequently, any bearing or gear failure can have a profound impact on the entire production process, resulting in economic losses and potentially fatal accidents. Consequently, early bearing and gear failure diagnosis becomes a critical step in preventing premature and catastrophic failures throughout the manufacturing process. Detecting and addressing gear failures is fundamental in preventing serious economic losses and potential accidents. A robust failure detection and isolation technique is required to monitor the rotational components and identify any damage (Abdeltwab & Ghazaly, 2022). Currently, many researchers are focusing on monitoring conditions using vibration signals. Various conventional methods, such as the Fast Fourier Transform, the Wigner Ville distribution (Dhok et al., 2020), short-time Fourier transform (S. Zhou et al., 2020), and cyclo-stationary analysis (Gilles, 2013; Adel et al., 2022; Patel & Upadhyay, 2020), have been employed. However, background noise often obscures defect-characteristic information, resulting in non-stationary, non-linear behavior of the data signal. Hence, such methods are regarded as ineffective in extracting features indicating early defects. Several adaptive decomposition methods have been introduced in recent decades for feature extraction. As a promising example, empirical mode decomposition (EMD), proposed by Huang, has been widely explored and applied to mechanical fault diagnosis (Meng et al., 2022). EMD decomposes a discrete-time signal into in-

dividual components called intrinsic mode functions (IMFs). Each IMF includes an oscillating component with several frequency levels, and the determination of the sifting iteration number is determined by a sifting stop criterion (SSC) (Fan et al., 2020). In the decomposition process, EMD uses a specialized filter with a bandwidth and center frequency that adjust dynamically according to the signal's characteristics.

Nevertheless, HHT presents two major drawbacks derived from EMD: mode mixing, in which waves of the same frequency are assigned to different intrinsic mode functions (IMFs), and end effects, which lead to incorrect instantaneous values at both ends of the signal (Afia, Gougam, Rahmoune, et al., 2023). A more appropriate decomposition method needs to be considered. Consequently, wavelet analysis has returned to the center of attention, in particular the discrete wavelet transform (DWT), widely used in condition monitoring and fault diagnosis to extract time-frequency features (Syed & Muralidharan, 2022). Unfortunately, DWT requires the sample size to be precisely 2 (down-sampling) during the analysis (Wang et al., 2021). An enhanced version of the discrete wavelet transform, known as the Maximal Overlap Discrete Wavelet Transform (MODWT), handles the sampling reduction process, yet still remains plagued by inadequate frequency resolution, similar to that of the discrete wavelet transform [14]. To address such limitations, the Maximal Overlap Discrete Wavelet Packet Transform (MODWPT) has replaced both MODWT and DWT, providing improved resolution. MODWPT decomposes the complex signal into single components of instantaneous amplitude and frequency, ensuring circular shift equivariance to monitor the gear's working condition (Afia et al., 2024a). For automated health monitoring, various machine learning techniques are used to provide more accurate predictions (M. Soualhi et al., 2021; Lourari et al., 2024; Benaggoune et al., 2022; M. Soualhi et al., 2019; Gougam, Afia, Aitchikh, et al., 2024; M. Soualhi et al., 2020; Afia, Gougam, Touzout, et al., 2023; Tahi et al., 2020; Touzout et al., 2020; A. Soualhi et al., 2012; Gougam, Afia, Soualhi, et al., 2024; Afia et al., 2024b). The self-organizing map (SOM) belongs to the artificial neural network (ANN) category, trained by unsupervised learning. SOM objective is to generate a low-dimensional - typically two-dimensional - discretized representation called a map, offering a dimensionality reduction method in the input space of training samples (Z. Zhou et al., 2020; Zhang et al., 2020). In this context, SOM offers a significant advantage, as it improves data interpretability. By clustering in grids and reducing dimensionality, data become more accessible, facilitating the identification of underlying patterns (Fan et al., 2021). In this paper, MODWPT was used as the signal processing method for decomposition. Afterwards, PCA was applied to reduce the dimensions while preserving the stable signal features. A comparison with EMD-PCA is presented to assess the advantages of the proposed approach. The final step in the proposed methodology incorporates the use of the self-organizing map (SOM) for defect clustering. SOM, a neural network-based algorithm, categorizes faults on the basis of extracted features, providing a sophisticated clustering process. This enhances defect detection and analysis by offering a nuanced exploration of relationships and patterns in vibration data.

2. PROPOSED METHODOLOGY

This section aims to present the different steps of the proposed methodology. First, raw data are injected to the Maximal Overlap Discret Wavelet Packet Transform (MODWPT) to extract features by filtering the signal and enhance their dimensionality. Then, the obtained new data passes through Principal Component Analysis (PCA) for reducing dimensionality by converting intricate vibration signals into a collection of uncorrelated principal components. After that, a 3D representation of the three principal components (PCs) of different health state under variable working conditions will be generated. Finally, a self-organizing map (SOM) is used to classify the different patterns for faults diagnosis. And overall view of the proposed technique is presented in Figure 1.

3. MAXIMAL OVERLAP DISCRET WAVELET PACKET TRANSFORM

The raw data is initially segmented into 25 groups, each consisting a length of 10024 samples. This segmentation is carried out as a preliminary step for data augmentation, a process aimed at enhancing the dataset's diversity and robustness by generating additional instances. The MODWPT uses segmented raw data as input for multi-stage filtering, resulting in a greater number of vibration time-frequency bands.Similar to Mallat's algorithm (Afia et al., 2024a), MODWPT relies on quadrature mirror filters. The filters, denoted as and, represent a low-pass and a high-pass filter, each with a length of L=10024 samples (assumed to be even). For this purpose, 16 resulting wavelet coefficients (decomposed signals) are obtained from MODWPT filters, as presented in Equation 1.

$$\left\{\begin{array}{l} \sum_{l=0}^{L-1} \tilde{h}_l^2 = \frac{1}{2} \\ \sum_{l=0}^{L-1-2k} \tilde{h}_l \tilde{h}_{l+2k} = 0, \quad k = 1, 2, ..., \frac{1}{2}(L-2) \\ \tilde{g}_l = (-1)^{l+1} \tilde{h}_{L-l-1}, \quad l = 0, 1, ..., L-1 \end{array}\right\} \quad (1)$$

MODWPT diverges from Mallat's method by employing interpolation two-based decimation operation. More precisely, at each MODWPT level, $(2^{j-1} - 1)$ zeros are introduced between two consecutive adjacent coefficients of $\widetilde{g}_l$ and $\widetilde{h}_l$. This ensures that the wavelet coefficients generated (WT) for each wavelet sub-band maintain an equivalent length to that

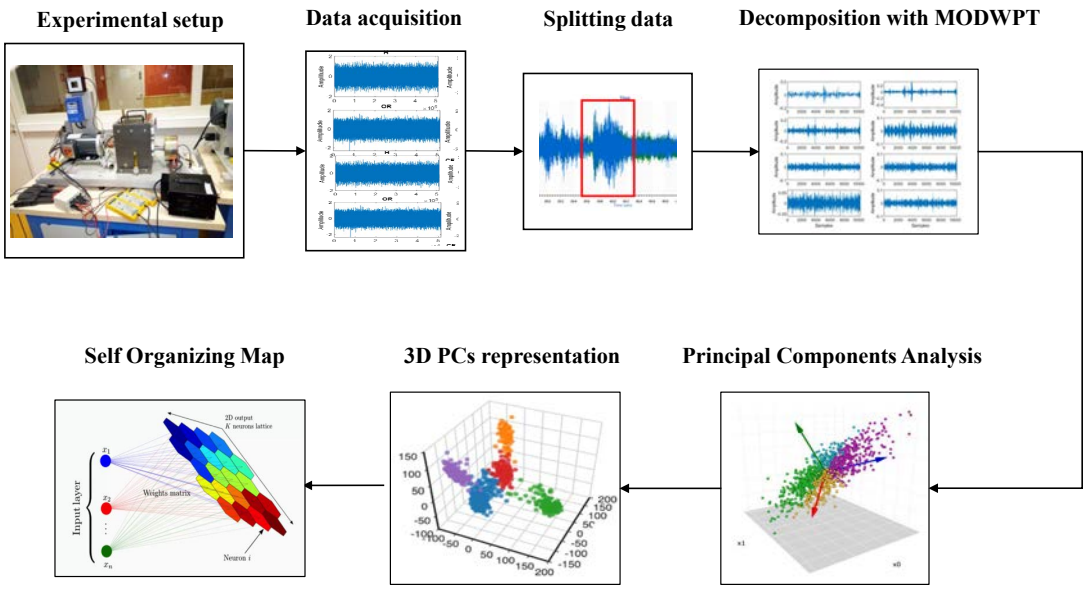

Figure 1. Overall view of the proposed technique.

of the input signal (Afia et al., 2024a). Considering a discrete-time sequence $x(t), t = 0, 1, \ldots\ldots, , N-1$, where N represents the sequence length, the wavelet coefficients $W_{j,n,t}$ of the nth sub-band at level j are computed using the following equations, with n taking values from $0 to 2^j - 1$. The initial condition is given by $W_{0,0,t} = x(t)$ [14]. For a discrete-time sequence$x(t), t = 0, 1, \ldots\ldots\ldots, , N-1$, where N is the sequence length, the wavelet coefficients$W_{j,n,t}$ of the nth sub-band at level j are calculated according to the following equations in which $n = 0, 1, ..., 2^j - 1, W_{0,0}, t = x(t),\ t = 0, 1, ..., N-1$ (Afia et al., 2024a):

$$W_{j,n,t} = \sum_{l=0}^{L-1} \tilde{f}_{n,l}\ W_{j-1,[n/2](t-2^{j-1}l) \bmod N} \tag{2}$$

$$\tilde{f}_{n,l} = \begin{cases} \tilde{g}_l, & \text{if } n \bmod 4 = 0 \text{ or } 3 \\ \tilde{h}_l, & \text{if } n \bmod 4 = 1 \text{ or } 2 \end{cases} \tag{3}$$

4. Principal Components Analysis

This step of the methodology aims to exploit the wavelets coefficients data for anomaly detection. For this purpose, the obtained data matrix, comprising 16 wavelet coefficients with 10024 samples(16,10024), is fed into PCA for dimensionality reduction and 3D visualization. In fact, conventional literature works aims to use extracted features and directly train Machine Learning (ML) models for classification. This procedure lacks efficiency with regard to train a ML model, already considered as a black box, with no verified and reliable feature. In such a scenario, PCA generates stable Principal Components from various vibration health state signals. PCA is proving advantageous in vibration signal analysis for fault diagnosis due to its multiple benefits (Shi et al., 2020). PCA excels in dimensionality reduction, transforming complex vibration signals into a set of uncorrelated principal components. This simplifies subsequent analysis, improves computational efficiency and provides a concise representation of essential information. PCA contributes to noise reduction in vibration signals. By emphasizing the principal components associated with the greatest variances, PCA actually mitigates the noise impact, making it particularly useful in environments where the signal-to-noise ratio is a significant concern. PCA can be conceptualized as an unsupervised learning problem. The process of deriving principal components from a raw dataset can be simplified into six steps:

1. **B**egin with the entire dataset, initially comprising d+1 dimensions, and disregard the labels, resulting in a new dataset of d dimensions.
2. **C**alculate the mean for each dimension across the entire dataset.
3. **C**ompute the covariance matrix for the complete dataset; where i is the samples number of signal X. are the mean of X,Y signals.

$$Cov(X,Y) = \frac{\sum_{i=1}^{n} \left(X_i - \overline{X}\right)\left(Y_i - \overline{Y}\right)}{n-1} \tag{4}$$

4. **D**etermine the eigenvectors and their corresponding eigenvalues.

$$Cov(X,Y) \times \sum\nolimits_{Value} = \sum\nolimits_{Value} \times \sum\nolimits_{Vector} \tag{5}$$

5. **A**rrange the eigenvectors in descending order based on eigenvalues, selecting k eigenvectors with the highest

eigenvalues to create a d×k dimensional matrix, denoted as W.

6. Utilize this d × k eigenvector matrix (W) to transform the samples to obtain the new set of uncorrelated variables.

5. Self Organizing Map

A Self-Organizing Map (SOM) is an unsupervised machine learning algorithm used for clustering and visualization of high-dimensional data. SOM is employed to identify patterns and anomalies in complex systems. SOMs consist of a grid of nodes (neurons) organized in two dimensions [29]. Each neuron is associated with a weight vector that is adjusted during the learning process. The best matching unit (BMU) weights and its neighboring neurons are adjusted to move closer to the input pattern. Neighboring neurons in the SOM grid respond similarly to similar input patterns, forming clusters (Figure 2).

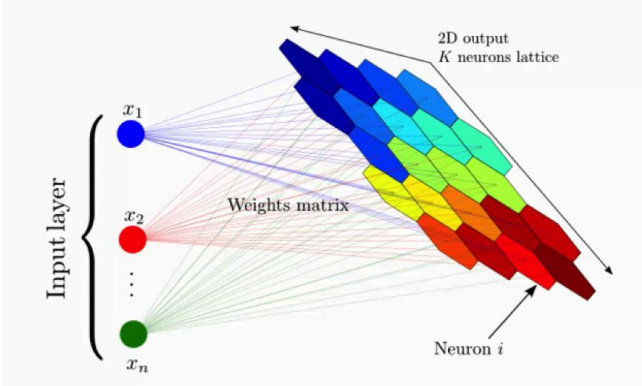

Figure 2. Self-organizing map architecture.

6. Application and Results

The described methodology is applied to experimental data, which includes various fault states as well as a healthy state. The experimental setup is designed for multi- faults classification. With the proposed methodology, our objective is to evaluate the effectiveness of the extracted features in separating the different health states.

6.1. Case Study

To verify the applicability of the proposed methodology, an open access data of test bench provided and presented in (M. Soualhi et al., 2023). The test bench chosen in this study is Laboratoire d'Analyse des Signaux et Processus Industriels (LASPI) benchmark that introduce bearing and gear fault detection and diagnostic problem(Figure 3). It consists of a three-phase inverter controlling a 1.5 kW induction motor driving the gearbox. An electromagnetic brake connected to the gearbox simulates the motor load.

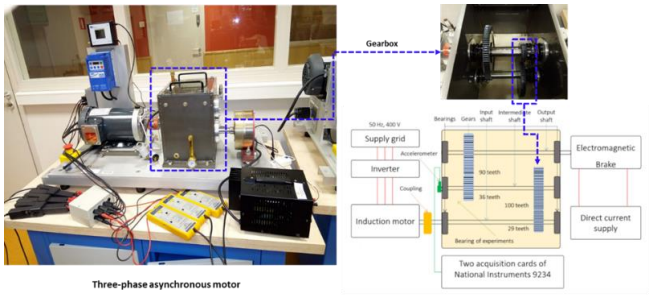

Figure 3. LASPI Benchmark.

The gearbox consists of three shafts: input, intermediate and output, with the studied bearings located on the intermediate shaft. The input shaft, connected directly to the motor, features a 29-tooth gear and two bearings with 9 balls each. The bearings have a 0.3125" diameter, a 1.5157" pitch diameter and a 0" contact angle.

Measurements are conducted in continuous mode for 10 seconds, with a 25.6 kHz sampling frequency. Vibration signals are acquired with an accelerometer sensor with a 100 mV/g sensitivity. Using the specified test rig instrumentation, a total of five distinct health states were examined, encompassing healthy bearings, inner, outer ring defects and combined bearing defects. In addition, each condition was tested at two different speeds: 25 Hz. Furthermore, each speed condition was tested at two load levels: 0%, 50% and 75%.

6.2. Result and discussion

The used raw data represent different states of bearing and gears. Each signal is first splitted into 25 segments. Figure 4 displays the different acquired vibration signals. Subsequent

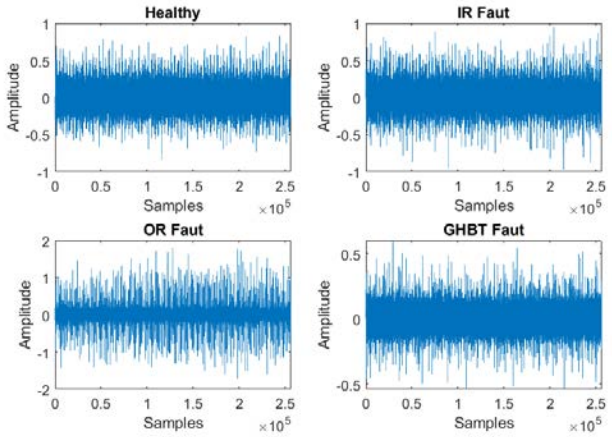

Figure 4. Vibration signals of different health states.

steps involve applying MODWPT to the segments in order to decompose each signal into its different frequency components, thus obtaining a detailed signal representation in the

time and frequency domains(Figure 5).

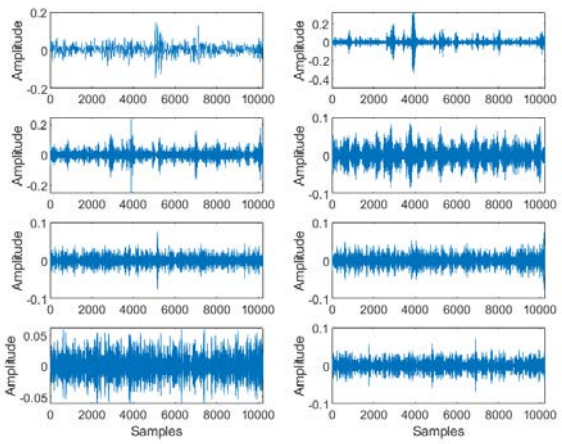

Figure 5. MODWPT decomposition.

PCA is applied to the decomposed modes, enabling a more concise data display by focusing on the dominant features. This step is crucial for simplifying the data set while retaining the essential information, thus facilitating analysis and interpretation.

Figure 6 illustrates the sample distribution under variable working conditions $(0\%, 50\% and 75\% load)$ using EMD-PCA. In the visual representation depicted in Figure 6, a noticeable level of sample confusion is obvious. This intricacy involves complex patterns and overlapping samples in the dataset, leading to a significant degree of imprecision in the extraction process. Recognizing the critical nature of this issue, our proposed solution is a hybrid MODWPT-PCA technique.

Figure 7 provides a more accurate sample distribution between the different health states. In comparison with the EMD-PCA, the advantages of the proposed approach in the feature extraction step are affirmed, demonstrating the proposed methodology's effectiveness. For automated fault diagnosis, a self-organizing map (SOM) is used to cluster neighboring neurons that respond similarly to analogous input patterns. The extracted data from MODWPT-PCA which containing 100 samples (25 samples for each 4 health states) and three columns (3 Principal Components) is used as input data for SOM model. Figure8 shows the sample clustering map using the proposed methodology for the four health states under three distinct working conditions.

After examining the map clustering (Figure 8), a significant sample separation is seen across distinct health states under different working conditions. This validates the reliability of the suggested diagnostic methodology.

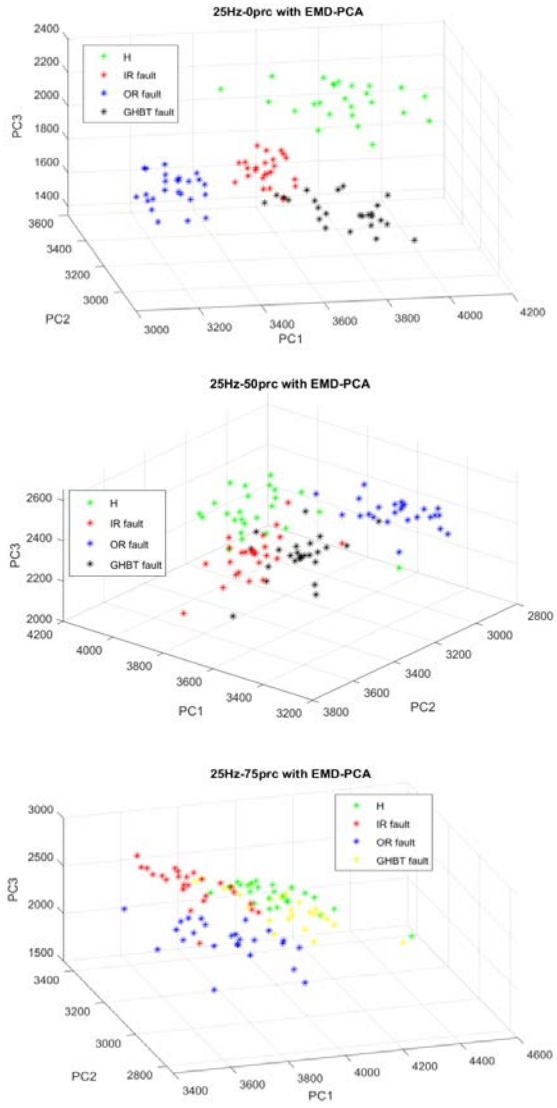

Figure 6. Samples distribution using EMD-PCA.

7. Conclusion

In this paper, the authors proposed a hybrid technique to address the inherent limitations of hidden fault characteristics in fault diagnosis. The approach integrates Maximal Overlap Discrete Wavelet Packet Transform (MODWPT) and Principal Component Analysis (PCA). MODWPT efficiently decomposes data signals with uniform frequency bandwidth, while PCA proves advantageous for feature extraction in vibration signal analysis. PCA captures variance, enabling the identification of significant defect-related patterns. A comparison with EMD-PCA is then conducted to assess the performance of the suggested algorithm. Finally, a self-organizing map (SOM) is used for machine learning to cluster the acquired data samples. The experimental results highlight that the proposed methodology is highly efficient in extract-

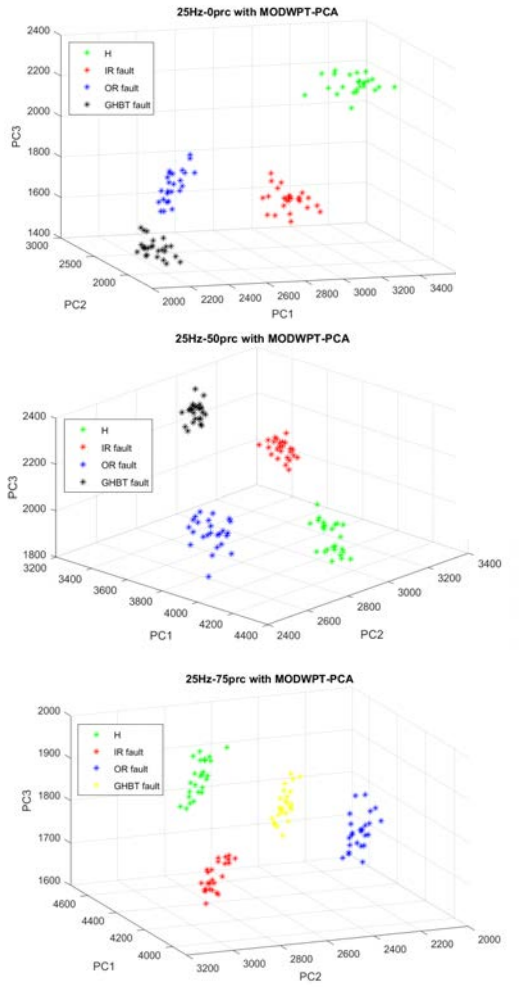

Figure 7. Samples distribution using MODWPT-PCA.

ing fault signatures from raw vibration data, even in a complex working environment.

ABSTRACT

Remaining useful life (RUL) prediction is a critical task in the field of condition-based maintenance. It is important to perform RUL prediction in a statistical sound way. However, it is not straightforward to properly combine multiple information sources about an asset, such as available statistics, measurements, derived features, and prior knowledge in the form of mathematical models and relations, including their uncertainties. Bayesian networks (BNs) are a means of graphically representing all statistical information in a comprehensible way and allow for correctly combining all information. BNs allow for inference in all directions, thereby not merely providing a RUL prediction with explicit uncertainty, but select the most informative features, diagnose which degradation mechanism is manifest if multiple mechanisms exist, provide decision support in the form of optimal condition-based maintenance points when combined with a cost model. BNs also explicitly quantify the model uncertainty arising from the scarcity of the training data. We illustrate these benefits on two real-world industrial examples: solenoids and bearings. We also provide a method to correctly include the effect of changing operating conditions.

1. INTRODUCTION

Condition-based maintenance (CBM) has gained a strong interest from the industry in recent years, both driven by the market-driven necessity of ever-increasing efficiency and sustainability of industrial systems, and the opportunity opened up by the fast growing industrial digitization and sensorization. For an extensive recent literature survey, we refer to (Quatrini, Costantino, Di Gravio, & Patriarca, 2020). The prediction of remaining useful life (RUL), which is the time at which an industrial asset will have been degraded to such extent that it can no longer perform its intended function, plays an important role in CBM to schedule maintenance, optimize operating efficiency, and above all avoid unplanned downtime.

Given the intrinsic randomness of the drivers of degradation leading up to the ultimate failure of the asset, a proper statistical treatment of these phenomena is required (Sankararaman, 2015). Indeed, because of the costly consequence of an unanticipated failure, even when its probability is small, the expected cost may become significant and requires early action. Many performance metrics for RUL prediction focus on the deviation of mean prediction from the ground truth, but the decision support for maintenance actions should rather focus on the tail of the prediction distribution.

In this paper, we aim to present a generic and systematic method using *Bayesian networks* (BNs) to incorporate all available knowledge and data in the RUL prediction. When many factors contribute to this prediction, it is a challenge to manage these relations and correctly calculate the overall statistics. BNs, although in essence nothing more than a representation of the statistics, offer a comprehensible approach. The explicit modeling and quantification of RUL prediction uncertainty has been extensively studied in literature, typically focused on a particular industrial asset, such as (Mishra, Martinsson, Rantatalo, & Goebel, 2018) for batteries and (Prakash, Narasimhan, & Pandey, 2019) for bearings.

A Bayesian network is a graphical representation of a joint distribution of a set of variables (Pearl, 1988). The joint distribution is factorized into root probabilities and conditional dependencies, which are graphically represented by a directed acyclic graph. BNs are ideal for taking an event that occurred and assessing the probability that any one of several possible known causes was the contributing factor. For example, a BN could represent the probabilistic relationships between failure mechanisms and their manifestations in the sensor data. Given sensor data, the network can be used to compute the probabilities of the presence of various failure mechanisms. This is analogous to how medical doctors need

to diagnose a patient showing symptoms of disease, see for example Fig. 1. In summary, BNs are a means for graphically representing complex statistical relations that become otherwise intractable.

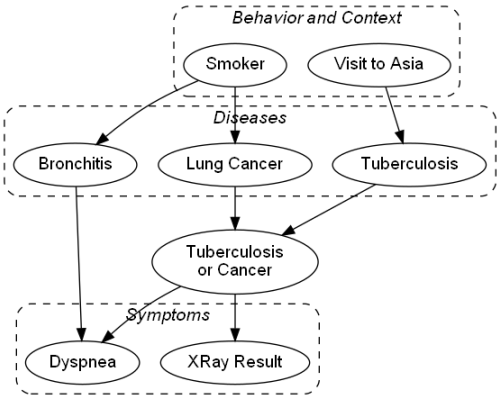

Figure 1. An example of a BN in medicine, analogous to condition-based maintenance. The intuitive (causal) understanding of how stochastic variables relate is well captured: diseases (failure mechanisms) are caused by behavior and context (settings and operating conditions) and become manifest in observed symptoms (measurements or features derived thereof). In this particular example, smoking increases the probability of bronchitis or lung cancer, whereas if a patient recently visited Asia, there is a higher probability of having contracted tuberculosis. The symptoms alone cannot distinguish tuberculosis from cancer, therefore an auxiliary variable "Tuberculosis or Cancer" is used to make this explicit.

The purpose of this paper is to show the advantages of using BNs for RUL prediction: (i) BNs naturally combine all prior knowledge, in the form of models and statistics, and data, and as such maximally exploit the available information; (ii) distributions of unknown variables can be inferred from observed variables, in all possible directions, depending on the application (parameter estimation, diagnostics, prognostics, decision support); (iii) explicit model uncertainty, which can be used to assess the (in)sufficiency of the available training data; (iv) BNs are easily extended with more variables that affect RUL and its assessment, such as operating conditions. We will illustrate how BNs are used on two examples of assets widely used in industry, a solenoid-operated valve (SOV) and a bearing, on which we conducted accelerated life testing.

This paper is organized as follows. In Section 2, we introduce the two industrial assets, SOVs and bearings, on which we validated the BN method for RUL prediction. In Section 3, we explain the methodology of BNs for RUL prediction and show how they provide the aforementioned advantages. In particular, we explain (i) how the model is built, trained and used, (ii) how a cost model can be integrated in the BN to provide *decision support for maintenance*, (iii) how *model uncertainty* is taken into account in the RUL prediction, and (iv) how the BN is adjusted to incorporate *operating conditions*. In Section 4, we illustrate the methodology by the application on the two industrial assets in four case studies, corresponding to the topics (i)-(iv). Finally, we formulate some conclusions and future directions of research in Section 5.

2. The application cases

2.1. Solenoid-operated valves

We have conducted our research on a historic dataset of accelerated life tests (ALT) on a set of 3/2-way normally closed alternating current powered solenoid operated valves (SOV). The SOVs were subjected to on-off switch cycles until failure or end-of-life (EOL), defined as the moment that the solenoid's magnetic force is insufficient to overcome the friction and move the plunger. This moment is observed both in the current signal, as the solenoid then behaves as a fixed nonlinear inductance, and in the thermal mass flow detecting leakage measured at the outlet ports and blow-off holes of the valves. The experimental dataset has been used before in (Tod et al., 2019; Mazaev, Ompusunggu, Tod, Crevecoeur, & Van Hoecke, 2020), where full details can be found.

In previous work, we have defined a number of features on the current signal and quantitatively assessed their feature performance for health monitoring quantitatively. For a detailed description of these features, we refer to (Ompusunggu & Hostens, 2021, 2023). For our purposes, it suffices to know that some features can be extracted from the current signal that contain information on the state of health of the SOV. Without loss of generality, we do not distinguish between direct measurement or derived features, we call them both *measurements*. Fig. 2 shows an important measurement *time-to-hit*, defined as the time between start of induced current in the solenoid at the beginning of the cycle and the plunger hitting the end of the shaft stopping its movement. In the induced increasing current signal, this stopping of the plunger is seen as a small dip in the first period. The time-to-hit increases when the SOV degrades, as it is related to the friction between plunger and shaft and therefore indicative of health. Fig. 3 shows the evolution of time-to-hit for 10 SOVs as a function of the number of past on-off cycles, together with the corresponding EOLs, except for two solenoids that did not fail before the end of the ALT. Note the strong increase of time-to-hit approaching the EOL.

2.2. Bearings

The SOVs were all tested under the same operating conditions. In order to illustrate the BN methodology for RUL prediction under *varying operating conditions*, we reused datasets of ALTs that we have conducted on bearings (Geurts, Eryilmaz, & Ooijevaar, 2023). These were generated using the Flanders Make Smart Maintenance living lab, an open test and development platform that aims to support the adoption

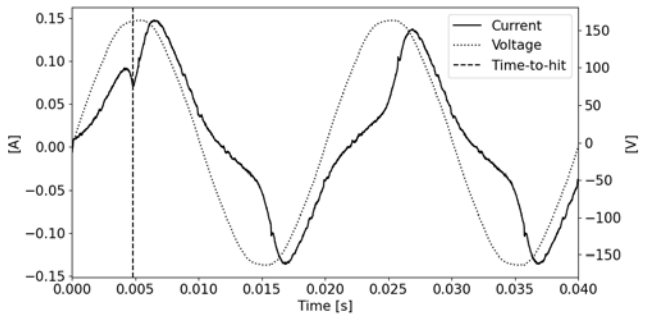

Figure 2. Definition of time-to-hit measurement in the SOV's alternating current signal.

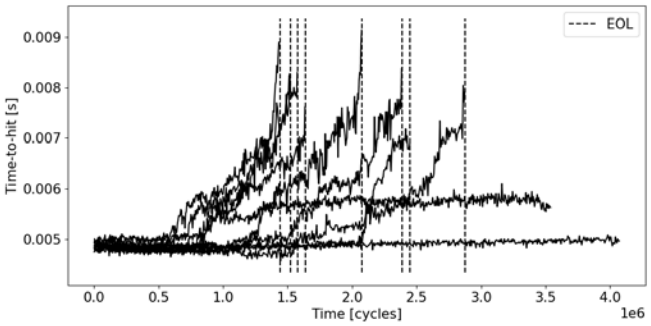

Figure 3. Evolution of time-to-hit for 10 SOVs. Two solenoids did not reach their EOL during the ALT.

of condition monitoring technologies in industry (Ooijevaar, Di, et al., 2019). Details of the setup and the tests can be found in the given references, we restrict ourselves here to the information required for a self-contained comprehension of this paper.

Before the start of each ALT, a small initial indentation was created in the bearing inner race in a repeatable manner. This serves as a local stress riser emulating a local plastic deformation caused by, for instance, a contamination particle. The EOL of a bearing is defined as the moment where the measured vibrations exceed a peak-to-peak acceleration of about 200 m/s^2. One set of bearings was subjected to stationary operating conditions, being a radial load of 9 kN and a rotary speed of 2000 rpm, another set of bearings to the same radial load but a varying speed going from 1000 to 2000 rpm in a cyclic saw-tooth pattern with a period of about 10 minutes, as shown in Fig. 4. Note how the acceleration depends on the speed, and how it increases exponentially with time near the EOL, similarly as the time-to-hit for the SOVs.

3. METHODOLOGY

3.1. Building the BN

The BN defines the joint distribution of all considered random variables X_i as a product of the individual density functions, conditional on their parent variables $\mathrm{pa}(i)$, i.e. the variables

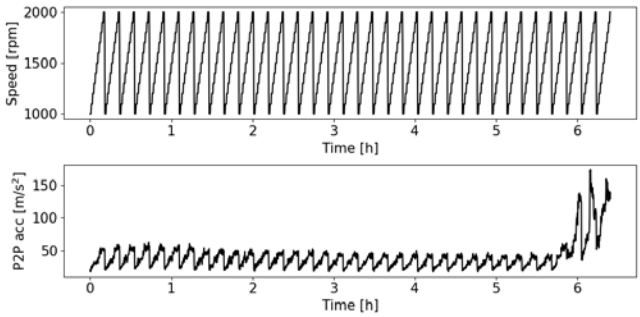

Figure 4. Speed and peak-to-peak acceleration of a bearing subjected to varying rotary speed.

that point to variable X_i in the graph representation:

$$p(X) = \prod_i p\left(X_i | X_{\mathrm{pa}(i)}\right). \quad (1)$$

We show how BNs naturally combine all available information for RUL prediction. The information we consider comprises:

- lifetime statistics,
- a degradation model,
- measurements revealing the underlying level of degradation.

A lot of research has been spent to each of these elements of information, either generic or specific to the considered asset. It is the sole purpose of this paper to show how these are *combined*, so we make a few simple assumptions, that sufficiently fit our example.

- In the following, we will refer to *time* not in a literal sense, but rather expressed in a unit that naturally relates to the usage of an asset. For solenoids, it is the number of on-off cycles; for bearings, it is the number of rotations. Similarly, lifetime and RUL are expressed in the same unit.
- For lifetime statistics, we assume a Weibull distribution, that corresponds to a failure rate that is proportional to a power of time (Jiang & Murthy, 2011). On top of that, in cases where the asset has not yet failed, we know that lifetime is greater than the current time.
- As a degradation model, we assume a hidden dimensionless degradation state, where the rate of degradation is proportional to the level of degradation itself. This simple first order dynamics boils down to an exponentially increasing degradation, or equivalently an exponentially decreasing health, which intuitively corresponds to the well-known P-F curve (Nowlan & Heap, 1978). The relation between health and measurements is a function that we will preferably describe with only a few parameters so as to keep complexity low, but the method allows any function fitting algorithm, including neural net-

works. Here we will adopt simple linear relations with normally distributed random noise, motivated by the exponential decay of health and the measurement evolution plots shown in Figs. 3-4.

These relations are captured in the generic BN structure of Fig. 5. Some of the variables are shown in rectangles, to indicate that they are deterministic, either always observed or a deterministic function of their parent variables. This simple model is captured in the following explicit relations:

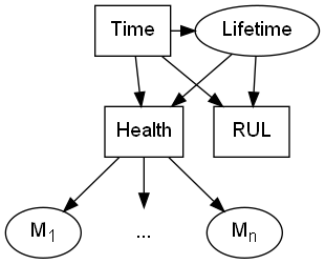

Figure 5. The generic BN structure for RUL prediction: time is given, and is a lower bound for the lifetime. Their difference is the RUL, and also defines the hidden health state. Measurements $M_1, \ldots, M_n$ are function of health.

$$\begin{aligned} L &\sim \text{Weibull}\,(k, \lambda)\,, \\ L &> T, \\ \text{RUL} &= L - T, \\ H &= 1 - \exp\left(\frac{T-L}{D}\right), \\ M_i &\sim \mathcal{N}\left(M_{i0}(1-H) + M_{i1}H, \sigma_i^2\right), \end{aligned} \tag{2}$$

where L denotes the lifetime, T time, and H health. The latter starts very close to 1 (at $T = 0$) and ends on 0 (at EOL, or $T = L$). This BN model leverages on expert knowledge captured in simple relations between the variables and is therefore capable of describing those relations using only a few parameters, as opposed to using e.g. neural network models that easily have hundreds of free parameters. The free parameters are in this case: the Weibull distribution shape k and scale λ, the degradation time D, which approximately corresponds to the time between onset of degradation and end-of-life, and for each measurement M_i the spread σ_i and the linear coefficients M_{i0}, M_{i1}, which are the mean measurement values at start and at EOL, respectively. One could wonder why health H is made a deterministic variable, and not a random variable. We motivate this by the fact that by defining lifetime L and the measurements M_i as random variables, all *real* stochasticity is already captured. Indeed, as H is never observed directly, it can be considered merely as an auxiliary variable linking the M_i with L and T. Its actual value is of no importance, unless it would have an impact on the (observed) performance, but here we only consider the EOL and the prediction thereof.

3.2. Training and prediction

The purpose of *training* the BN model is to fit the parameter values to the data from the ALTs. We can then use this model to *predict* RUL for new data of another asset. To this end, we have used PyMC, a probabilistic programming library for Python that allows users to build Bayesian models and fit them using *Markov chain Monte Carlo (MCMC)* methods (Patil, Huard, & Fonnesbeck, 2010). Essential to PyMC is that there is no distinction between parameters and variables, there are only (random) variables, including the parameters. This enables *Bayesian hierarchical modeling*, a type of Bayesian modeling where information is available on different levels (Allenby & Rossi, 2006). In our case, we assume a single set of parameters k, λ, M_{i0}, M_{i1}, D, σ_i for the entire population, but we have a different L for each asset, and H, RUL, M_i are different for each asset and each time T.

MCMC is used for both training and prediction, they only differ in which variables are observed and which not. This is graphically explained in Fig. 6, showing all variables including the parameters (but only one measurement, to not overload the picture), and marking their being observed as gray shading. In training, the parameters are unknown and are fitted to the data on lifetime and measurements. In prediction, the parameters are known, but the unknown lifetime distribution is to be inferred from the lifetime statistics and the measurements.

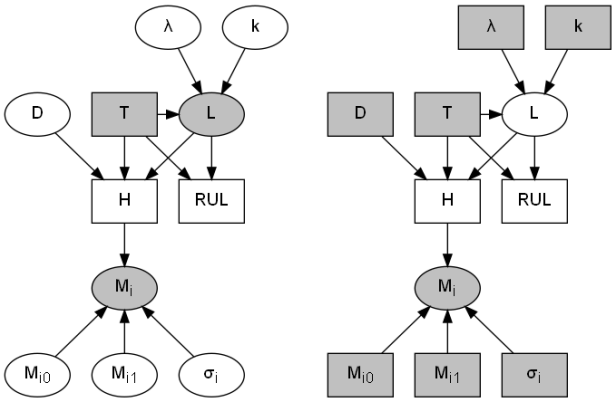

Figure 6. The BNs for training (left) and prediction (right). Gray shading represents known/observed variables, whereas white represents unknown/unobserved variables.

The MCMC algorithm updates the distributions of all unobserved random variables given their prior distributions and the data, through the likelihood of the data. The prior distributions, also called prior *beliefs*, quantify the uncertainty in the prior knowledge *before* data is acquired. It is based on previous data campaigns or *physical* and *statistical* knowledge of the asset's behavior and degradation. For instance, the shape parameter k is related to the trend of the failure rate, typically going up ($k > 1$) as the asset ages. If little is

known beforehand, prior beliefs should be chosen sufficiently wide, so-called *weakly informed priors*. The updating of prior beliefs into posterior distributions when new data comes in is the central paradigm of Bayesian statistics. Therefore, it is important to note that the BN for prediction in Fig. 6 is an oversimplification: the parameters do not become exactly known by the training, but if their posterior distributions become sufficiently narrow, their low remaining uncertainties can be ignored in their contribution to the total uncertainty of the RUL prediction.

Another important nuance to make about Fig. 6 is the fact that, as we saw in Section 2, some of the assets' EOL is never observed, simply because their ALT is stopped early. So not all L-nodes in the left graph (training) of Fig. 6 should be gray shaded (observed). Such *censoring* is quite common in statistical analysis of survival data in medicine (Kalbfleisch & Prentice, 2011). Because some of the lifetimes L are not observed, their values cannot be directly used to infer the Weibull parameters. This is exemplary for why the BN framework is powerful: although L is not observed, the uncertainty on its unknown value can nonetheless be significantly reduced through its relation with the measurements and the time during which it did not fail. Therefore this information still contributes to the fitting of the Weibull parameters. The BN truly leverages on all the available information combined.

3.3. Decision support for maintenance scheduling

We explain how the BN for prediction, shown in Fig. 6, is adjusted to provide decision support for maintenance scheduling. We only consider asset replacement as the maintenance action, but an analogous reasoning can be followed for other maintenance actions. The BN prediction yields a probability distribution of RUL. This is more useful than a single RUL expected value, because it allows to better balance the risk of unanticipated failure with the economic loss of early replacement. The BN allows the integration of a cost model and evaluate the prediction of cost given the replacement scheduling strategy. We illustrate this with a simple cost model. We assume the asset's cost C_A in the normal situation. This is for instance the sum of the costs of purchase and installation, the latter coinciding with the scheduled replacement of its used predecessor. If the asset fails before its scheduled replacement, there will be an extra *cost of failure* C_F. This cost is very dependent on the application: it can be very high for high impact failures, such as significant production loss or damage to other equipment, but it can also be low or even zero. In that case, the asset should only be replaced after EOL.

Another parameter we assume in this example is the *prediction horizon* T_{PH}, defined as the time required to schedule the replacement up front, for instance because it takes some time to send a maintenance engineer to the asset's remote location. If it is decided at time T to replace the asset, the actual replacement can take place at time $T+\Delta T$, where $\Delta T \geq T_{\mathrm{PH}}$. This is schematically depicted in Fig. 7.

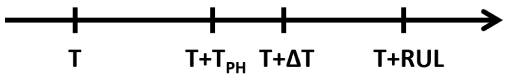

Figure 7. Replacement is scheduled at time T, and takes place at time $T+\Delta T$, which is $T+T_{\mathrm{PH}}$ at the earliest. $T+\Delta T$ should precede $T+\mathrm{RUL}$ to avoid the cost of failure.

Let $T+\Delta T$ be the asset's *replacement time* in the future, decided at the *scheduling time* T hence depending on the RUL prediction at time T. The resulting total cost depends on the actual RUL:

$$\begin{aligned} \text{total cost} &= C_A && \text{if RUL} \geq \Delta T, \text{ or} \\ &= C_A + C_F && \text{if RUL} < \Delta T. \end{aligned} \tag{3}$$

To balance the extra cost C_F with the cost of early replacement, where more assets are used in the long run, we have to evaluate the *cost per used time unit* C_T:

$$\begin{aligned} C_T &= \frac{C_A}{T+\Delta T} && \text{if RUL} \geq \Delta T, \text{ or} \\ &= \frac{C_A + C_F}{T+\mathrm{RUL}} && \text{if RUL} < \Delta T. \end{aligned} \tag{4}$$

Note that C_T is a deterministic function of other variables. We include it in the BN for prediction, shown in Fig. 8. Alongside the RUL prediction at scheduling time T, we can use this model to calculate the distribution of the cost $C_T(\Delta T)$ corresponding to the replacement time $T+\Delta T$, for multiple values of ΔT. Replacement should then be scheduled as soon as the

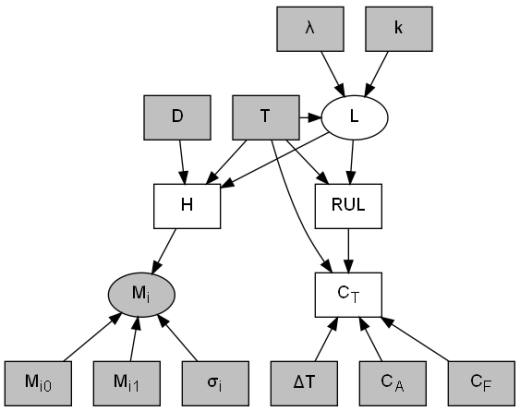

Figure 8. The BN for prediction, including the simple cost model.

expected value of this cost $E[C_T(\Delta T)]$ reaches a minimum for $\Delta T = T_{\mathrm{PH}}$, or if:

$$E[C_T(\Delta T)] > E[C_T(T_{\mathrm{PH}})], \quad \forall \Delta T : \Delta T > T_{\mathrm{PH}}. \tag{5}$$

3.4. Model uncertainty

As we mentioned in Section 3.2, the training of the BN will result in a posterior distribution of all non-observed random variables, including the model parameters. If these parameter posteriors are sufficiently narrow, we may consider the remaining uncertainty insignificant and select the means of the posteriors as fixed known parameters for the prediction BN, as was shown in Fig. 6. However, if training data is scarce, the remaining posterior uncertainty cannot be ignored and should be included in the prediction. This is achieved by making the parameter nodes in the prediction BN stochastic and unobserved, and using the posterior distribution after training as its prior. It is important to note that, in many cases, the parameter distributions will be mutually *dependent* after training. Therefore, one should use a single joint prior distribution for the parameters in the prediction BN.

MCMC does not output explicit posterior distributions, but a sample thereof, due to the way it works. To include it in the prediction, there are two options: either combine training and prediction in one MCMC run, or approximate the posterior parameter distribution. The former option is the most correct, since in this way we are combining all information at once, both of the past ALTs and the running one. However, this requires a lot of calculations and all data need to be kept, so this approach may become cumbersome. The latter option is most practical, since there is only one run of MCMC involving the training data, after which they are not longer needed. For approximating the posterior joint distribution of the parameters, in most cases a multivariate normal distribution is suited, motivated by the fact that, if the model is well designed, it is expected that the parameter estimates will converge. To this end, PyMC also supports *automatic differentiation variational inference (ADVI)* as an alternative to MCMC followed by the approximation of the posterior distribution from the sample. ADVI turns this around by up front assuming a parameterized approximation of the posterior distribution and reformulating its calculation as an optimization problem (Kucukelbir, Tran, Ranganath, Gelman, & Blei, 2017).

3.5. Varying operating conditions

In our original BN model of Section 3.1, we assumed the asset's degradation as the sole driver of further degradation. This works fine if other influences do not have a significant contribution to degradation. However, in most cases, the *operating conditions* (OC) do have a strong impact on degradation, and should be taken into account. Secondly, the OC also influence the measurements. This is clearly seen in Fig. 4 for the bearings. This influence further complicates the analysis, as the measurements serve as indicators for degradation, so we need to distinguish whether changes in the measurement are resulting either by changed OC, or by degrading health, or both.

Inquiring the effect of OC on degradation is particularly difficult, since the OC consist of multiple variables that often have a combined effect where one OC variable strengthens or weakens the effect of another. In such cases, on the one hand a detailed understanding is needed of how the asset's health evolves under given OC, in the form of engineering laws or physical models. On the other hand, a sufficient amount of ALT data is required to validate and quantify these models. However, ALT data are typically scarcely available because they are costly to generate. Again, maximally leveraging on all available knowledge and data is key. We show how the original BN for RUL prediction is adjusted such as to account for OC.

Let us first address the simpler case of *stationary* operating conditions. When the OC are stationary over the entire lifetime, even when they are different for different assets, training and using a BN for prediction of RUL is not a lot more complicated than before. Given sufficient ALT data for each OC, one can simply retrain another BN for each different OC. Of course it is more useful to leverage on knowledge of how OC affect lifetime, ideally in the form of a relation with the OC adding few free parameters, such as the empirical basic rating life model for bearings of (ISO281, 2007). Such knowledge is integrated in the BN by adding a relation from the OC to the lifetime and the measurements. The generic BN for RUL prediction, previously shown in Fig. 5, is then updated to the BN structure of Fig. 9.

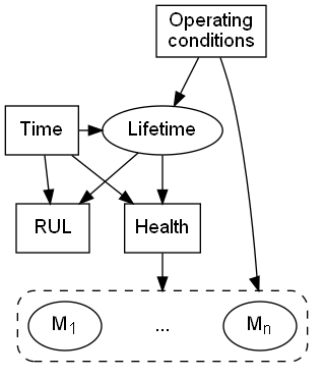

Figure 9. The generic BN structure for RUL prediction under stationary operating conditions.

For *varying* operating conditions, the relation between OC and lifetime is more complicated. One could interpret the relation between OC and lifetime in Fig. 9 as the *aggregated effect* of OC on lifetime, but as such the combined effect of the OC with health is overlooked. For instance, a higher load might have a larger damaging effect if the asset was already in a degraded state. Therefore, the OC effect should be aggregated in such a way that it takes that aspect into account, which it does not in the BN structure of Fig. 9.

We resolve this issue by assuming *nominal* parameters for a single nominal OC defined up front. We relate all other OC to this nominal OC, and express lifetime and RUL as their equivalent lifetime and RUL under the nominal OC. To deal with varying OC, we locally *compress* and *stretch* time into an equivalent time under the nominal OC. This idea is shown in the BN structure of Fig. 10. The variables Health, Lifetime and RUL are all expressed in the *Equivalent Time* corresponding to nominal OC. For the nominal OC, Equivalent Time and Time progress at the same rate. Note that Equivalent Time is defined as a stochastic variable (ellipse), because the relation between OC, Time and Equivalent Time might be uncertain. This BN structure also includes the immediate effect of OC on the measurements. The RUL that this model predicts is expressed as the equivalent RUL under nominal OC. Decision support should take the *expected future* OC into account for predicting the actual RUL. Note that such BN can also be used to recommend to change the future OC, if the application allows it, in order to delay potential failure.

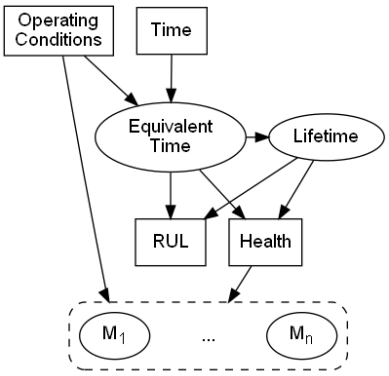

Figure 10. The generic BN structure for RUL prediction under varying operating conditions.

4. Application on case studies

In this section, we illustrate the methodology by the application on either SOVs or bearings in four case studies, corresponding to the topics explained in the previous section: (i) training and prediction, (ii) decision support for maintenance, (iii) model uncertainty, and (iv) varying operating conditions.

4.1. BNs for RUL prediction on SOV

We have trained the BN model of Fig. 6 on the ALT data of the 10 SOVs, whose time-to-hit measurement evolution was shown in Fig. 3, with 2 ALTs censored. For simplicity, we have only incorporated the time-to-hit measurement. Including other measurements would only reduce the prediction uncertainty, although not significantly since time-to-hit is the most informative on the hidden health. The BN automatically weighs the measurement contributions according to the amount of information they provide on the health. As such, it is an implicit form of *feature extraction*. We then used the fitted model parameters to predict the RUL of an SOV not used in the training, over its entire lifetime. The prediction yields a distribution of RUL, the evolution of which is shown in Fig. 11, compared to the RUL ground truth. Note the sud-

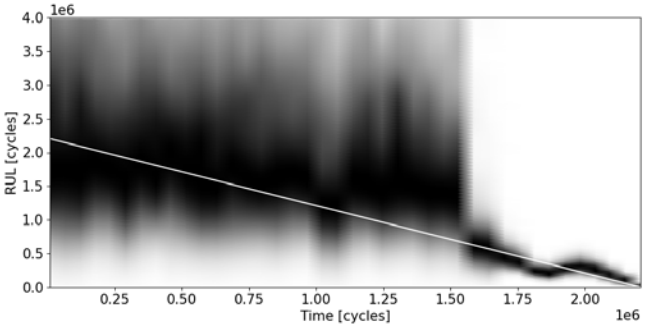

Figure 11. RUL prediction for one SOV (probability density in grayscale) compared to the ground truth RUL (white line).

den decrease of uncertainty around 1.5 million cycles. This decrease is due to the fact that at that point, the time-to-hit measurement starts increasing, thus providing crucial information on the imminent EOL. Before, the measurement reveals little on the SOV's health, so the prediction is mainly based on the Weibull statistics, truncated at the current cycle. This transition is naturally taken care of by the BN because it combines all information sources available and automatically weighs their uncertainties in the statistical posterior, as opposed to an explicit switching such as the one used in (Geurts et al., 2023).

The RUL prediction shown in Fig. 11 is based on the last measured time-to-hit at the present cycle. However, the time-to-hit measurement itself displays stochastic fluctuations, as can be clearly seen in Fig. 3. Therefore, it makes sense to include the *full history* of the measurement in the RUL prediction, so that this inherent stochasticity is filtered. Yet it is important to note that the fluctuations are not white noise, rather colored noise, which means the measurements are correlated over time. M_i should then no longer be defined as separate univariate normal random variables like in Eq. 2, but as a single multivariate normal random vector with the same mean and the measurement autocovariance as covariance. The resulting prediction ($5\% - 95\%$ quantiles near the EOL) is shown in Fig. 12, for both the last measurement only and the full history prediction, illustrating the advantage of the latter: it is more consistent and accurate compared to the true RUL.

4.2. BNs for maintenance decision support on SOV

For the SOV example of Fig. 11, we show a detail of the RUL prediction approaching EOL and the corresponding expected relative cost $E[C_T(T_{\mathrm{PH}})]/C_A$ in Fig. 13, for arbitrary cost model parameters $C_F/C_A = 10$ and $T_{\mathrm{PH}} = 2e4$. Note that

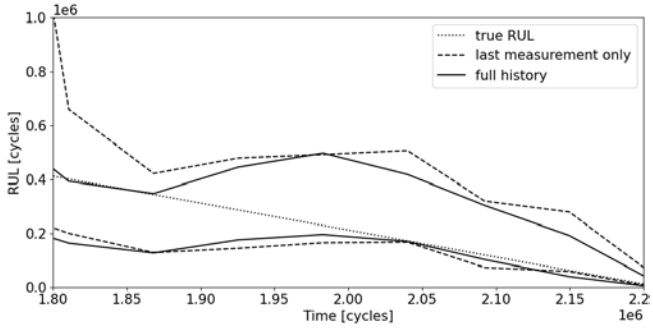

Figure 12. $5\%-95\%$ quantiles for RUL predictions from only the last measurement or from the full measurement history.

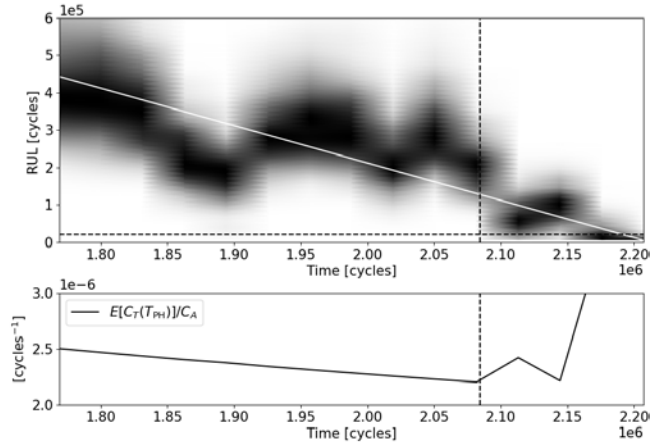

Figure 13. Top: RUL prediction. The dashed horizontal line marks the prediction horizon T_{PH}. Bottom: expected relative cost of replacement time $T + T_{\mathrm{PH}}$ at scheduling time T. The dashed vertical line marks the optimal scheduling time T^*.

at the optimal scheduling time T^*, the RUL prediction distribution still has the most part *above* the T_{PH} line. The optimal maintenance scheduling strategy therefore involves probing the *tail* of the RUL prediction distribution, which emphasizes the importance of correctly calculating this distribution.

4.3. Model uncertainty in BNs on SOV

We have redone the prediction of the SOV of Fig. 11, now using 40 SOVs in the training set instead of only 10. Both are compared in Fig. 14 through their $5\% - 95\%$ quantiles. In the RUL predictions, we have now included the posterior parameter uncertainty after training. Clearly, more training data results in a more accurate RUL prediction. It can be seen that this effect is most manifest in the healthy phase of the SOV, where the RUL prediction is mainly based on the EOL statistics and not on the measurement. This is to be expected from a statistical perspective. However, approaching the EOL, where the prediction accuracy is more important for optimal maintenance scheduling, both predictions become very close. This illustrates the power of BNs for RUL prediction, as in this case it suffices to have a training set of only 10 ALTs, two of which are censored, and a simple degradation and measurement model.

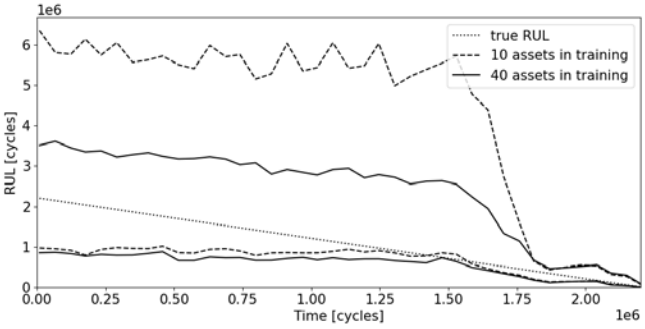

Figure 14. $5\%-95\%$ quantiles for RUL predictions including parameter uncertainty, where the BN parameters are trained either on 10, or on 40 SOVs.

4.4. BNs for varying OC on bearings

The bearing ALT dataset introduced in Section 2.2 is insufficiently rich to validate the proposed BN for RUL prediction under varying OC of Fig. 10. Indeed, because of the very uniform saw-tooth pattern of speed (Fig. 4) in the varying speed ALT, its long-term influence on degradation effectively corresponds to a stationary OC, albeit different from the stationary speed ALT. As a consequence, we have only two different long-term aggregated OC. We therefore use a combination of the BN structures of Figs. 9-10 for stationary OC and varying OC, respectively: we assume the long-term effect of OC on lifetime as equivalent to stationary, but the immediate effect of OC on the P2P measurement as varying. The resulting BN for training, now including the parameters,

is shown in Fig. 15. There are two extra variables SET and

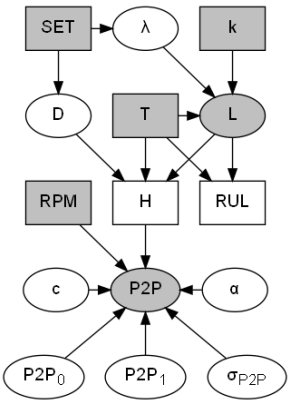

Figure 15. The BN for training of bearing RUL prediction, either under stationary or under varying RPM.

RPM, that relate to the aggregated effect of speed on lifetime and to the immediate effect of speed on the P2P acceleration measurement, respectively. The binary variable SET defines to which dataset the bearing belongs, either subjected to stationary speed ALT or to varying speed ALT. This variable essentially selects either one of two values for the parameters D and λ. The shape parameter k was fixed up front to a value of 1.3 building on historical knowledge on bearing fatigue lifetime statistics (NSWC, 2011). Extending Eq. 2 defining the relations between all variables, we define the distribution of the P2P measurement as:

$$\mathrm{P2P}_{\mathrm{nom}} \sim \mathcal{N}\left(\mathrm{P2P}_0(1-H)+\mathrm{P2P}_1 H, \sigma^2_{\mathrm{P2P}}\right), \quad (6)$$

$$\mathrm{P2P} = c\,\mathrm{P2P}_{\mathrm{nom}}\,\mathrm{RPM}^{\alpha}. \quad (7)$$

The expression in Eq. 7 with parameters c and α was established through a qualitative inspection of P2P data, both in healthy and degrading state as shown in Fig. 4, by comparing P2P values to the corresponding nominal P2P values around the nearest time where the speed is 2000 rpm. All 7 parameters of the BN model are simultaneously fitted to the training data.

We have trained this BN model on a set of 48 ALT, of which 7 were subjected to the varying speed profile. Bearings to validate the resulting RUL prediction were left out of the training data. As a benchmark, we also trained and validated the original model of Fig. 6 on the same data. An example of the resulting RUL prediction for both models on the same varying speed bearing is shown in Fig. 16. The RUL prediction with the original model is clearly disturbed by the varying conditions, emphasizing the need for including them. The same problem was manifest in the work of (Geurts et al., 2023).

A single asset's prediction may illustrate the added value, yet a proper comparison should be built on adequate RUL prediction performance metrics. A thorough overview and analysis of metrics is given in (Saxena, Celaya, Saha, Saha, & Goebel, 2010). To keep things simple, we have compared the benchmark model and the varying OC model by the log-likelihood evaluated at various relative locations in the lifetime and averaged over the varying speed bearings, as shown in Fig. 17. The log-likelihood is a straightforward generalization of mean squared error (MSE) that also covers the uncertainty of the prediction. The evaluation at multiple relative locations in the lifetime, similar to the alpha-lambda performance metric, addresses the application-specific prediction horizon as explained in Section 3.3.

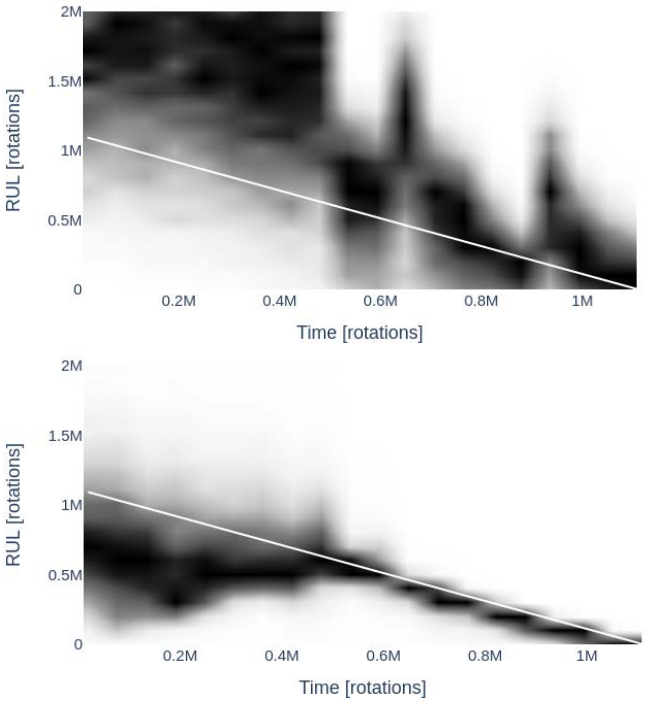

Figure 16. The RUL prediction for a varying speed bearing, both for the benchmark model (top) and the new model that includes the effect of varying OC (bottom), compared to the true RUL (white line).

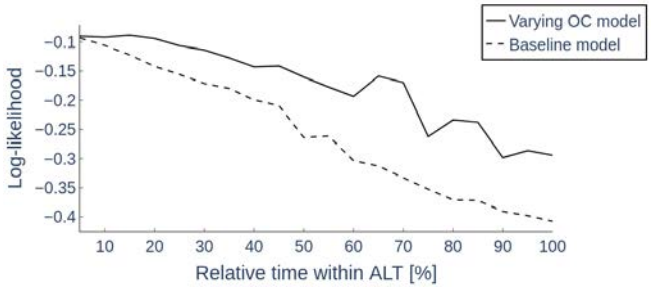

Figure 17. The average log-likelihood for the benchmark model and the new model, as function of relative time within the ALT.

5. CONCLUSION

We have shown a method for building, training and using Bayesian networks for RUL prediction. Next to the advantage of its comprehensibility, even when many factors contribute to the prediction, we have focused on the extension of RUL prediction with decision support for maintenance and the explicit inclusion of model uncertainty arising from the scarcity of training data. We have shown how the BN is adjusted to allow for RUL prediction under varying operating conditions.

This work is part of a larger study on the application of BNs for CBM and for maintaining quality in industry. We see the following open challenges and future research topics:

- Our current ALT datasets on SOVs and bearings do not allow for a proper validation of the generic method of Section 3.5. To this end, we are currently conducting a new ALT data campaign on SOVs under varying operation conditions.
- The inclusion of model uncertainty and its propagation to the RUL prediction is still lacking a quantified decision support for further data campaigns and design-of-experiments (DoE). We will investigate a practical method to assess the need for more training data and DoE, for instance through a criterion on the trend of a suitable performance metric such as the average leave-one-out log-probability.
- Investigate more complex degradation mechanisms, arising from multiple root causes that have different degradation dynamics.
- Instead of focusing on RUL which assumes the asset's quality as a binary variable and the EOL as a specific moment in time, we will shift towards the prognostics of a more nuanced application-oriented quality condition and corresponding decision support, such as condition-aware control.

ACKNOWLEDGMENT

This work has been carried out within the framework of Flanders Make's Strategic Basic Research project QUASIMO (Quality via a System Intelligence Methodology). Flanders Make is the Flemish strategic research centre for the manufacturing industry.

ABSTRACT

Floating Offshore Wind Turbines (FOWT) represent a promising solution to renewable energy challenges, yet effective maintenance remains critical for cost management. Traditional machine learning (ML) approaches for detecting FOWT damage often rely on extensive real-world data, which can be impractical and economically unfeasible. Alternatively, stochastic filtering-based time-domain approaches leverage physical understanding through dynamic models, typically finite element models. However, these methods are hindered by excessive simulation calls within the recursive filtering frameworks. This study proposes a novel filtering-based approach that replaces the computationally intensive process model with a Deep Neural Network (DNN) surrogate, addressing the aforementioned limitations. The proposed approach utilizes synthetic data generated from the high-fidelity calibrated OpenFAST model of FOWT dynamics to train a DNN toward learning the dynamic evolution of the FOWT conditioned on the current health state. By offering a computationally efficient representation of system dynamics conditioned on health state, this approach allows for real-time damage detection and interpretable information on damage severity within a stochastic inverse estimation framework, specifically employing Particle Filtering in this study. This approach contrasts with traditional black-box ML-based methods, which typically struggle to provide interpretable information on damage characteristics. Extensive numerical investigations on damaged FOWT mooring lines demonstrate this approach's practical applicability and superiority over traditional ML-based methods. Eventually, integrating explainable ML models within the filtering framework induces promptness in detection without sacrificing transparency.

1. INTRODUCTION

Research on Floating Offshore Wind Turbines (FOWTs) has advanced significantly, reflecting their growing adoption across industries. A key challenge is maintaining safety while minimizing maintenance costs, a critical issue that persists. Structural health monitoring (SHM), particularly data-driven methods, is valued for its noise robustness and cost-effectiveness, as demonstrated by (Azimi, Eslamlou, & Pekcan, 2020).

The complex inverse problems in SHM mandate linking measurements to causes or damages. Machine Learning (ML) approaches have showcased excellent reliability and predictability across applications, yet dependence on data alone raises concerns, especially in mooring line damage detection (Avci, Abdeljaber, & Kiranyaz, 2022). In ML-based system identification for FOWTs, strategies involve extracting damage-sensitive features (DSFs) using supervised or unsupervised learning. While unsupervised methods, such as novelty detection, are effective in damage detection, they face challenges in localization and quantification (Wang, Tian, Peng, & Luo, 2018). Supervised techniques, on the other hand, require large datasets and can function as classifiers or regressors, employing algorithms such as random forest, support vector machine (SVM), and multi-layer perceptron (MLP) (Regan, Beale, & Inalpolat, 2017).

In FOWTs, the selection of appropriate DSFs for mooring line damage detection holds significant importance. Super-

vised algorithms depend on the precise representation of damage scenarios through these selected DSFs. However, it's important to acknowledge that the resulting model is essentially a black box, lacking interpretability to extract additional information not included during training. Consequently, ML-based approaches relying solely on data may not comprehensively address mooring line damage detection, underscoring the necessity for a nuanced monitoring strategy (Malekloo, Ozer, AlHamaydeh, & Girolami, 2022).

1.1. Condition Monitoring of Mooring Lines

Mooring lines are vital components in ensuring the integrity of FOWTs, influencing the optimization of support structures (Altuzarra et al., 2022). Given their significance, monitoring the health of mooring lines is essential due to potential stability implications (Aqdam, Ettefagh, & Hassannejad, 2018). While deep learning (DL) algorithms show promise in detecting damages to wind systems (Choe, Kim, & Kim, 2021), it remains imperative to understand the behavior of coupled systems under extreme conditions (Li, Le, Ding, Zhang, & Zhang, 2019), necessitating the incorporation of physics-based or physics-guided support models. Despite the prevalence of model-based and fuzzy logic approaches for mooring damage diagnosis (Jamalkia, Ettefagh, & Mojtahedi, 2016) in current literature, research on ML and DL in this domain is limited. Vibration measurements facilitate efficient identification of structural damage, aiding in damage diagnosis across various domains, including FOWTs (Farrar, Doebling, & Nix, 2001). Recent studies (Gorostidi, Pardo, & Nava, 2023) highlight the advantages of ML over model-based methods in managing large data and promptness in detection.

Traditional ML models pose significant limitations for real-life SHM due to their lack of interpretability. These black-box models, while effective at processing large amounts of data, often fail to provide meaningful insights into the underlying dynamics of the monitored system. Alternatively, stochastic filtering-based approaches, although capable of incorporating physical understanding through complex models, suffer from the computational burden of these models, making them impractical for real-time applications. However, a compromise between interpretability and efficiency can be achieved by leveraging ML techniques to create a surrogate of the conceptual model. This approach, as proposed in this study, involves replacing the computationally intensive process model with a Deep Neural Networks (DNN) surrogate. By training the DNN with real (/synthetic) data sampled (/generated) from reality (/a high-fidelity dynamic model of the system), the proposed method offers both computational efficiency and interpretability. This surrogate model can then be seamlessly integrated into a stochastic filtering framework, providing real-time damage detection with required promptness while maintaining transparency and accuracy. Thus, the study bridges the gap between conventional ML-based approaches and complex stochastic filtering methods, offering a promising solution for effective SHM in practical applications.

2. METHODOLOGY

A process model plays a major role in filtering-based methods and is often built with a Finite Element (FE) modeling approach. These models, derived from physical systems, simulate and predict the system behavior under diverse operational conditions. Despite their widespread use in evaluating civil structure conditions and detecting damage, FE models face certain challenges, such as numerical convergence issues, memory demands, and complexities in parallelization. Surrogate models such as DNNs are known for their ability to identify complex patterns swiftly and accurately, particularly in one-step-ahead time series forecasting within a data-based time-series modeling framework, and hence are one of the best choices for replacing FE models.

DNN models are faster, more adaptable, and require comparatively less simulation effort than traditional FE models. DNNs also offer other computational advantages like scalability, capturing nonlinear data relationships efficiently, thereby enabling quick and accurate predictions without the need for iterative solutions. This streamlined approach accelerates development and reduces costs associated with model building and simulation.

Typical health assessment problems, addressed with conventional DNN models, require extensive datasets correlating response inputs with damage locations and severity labels to achieve comprehensive accuracy. To mitigate this issue, instead of correlating the response to its corresponding damage labels, the underlying dynamics are learned within a DNN framework utilizing a response time series of consecutive time steps as input-output pairs. The input is additionally augmented with the health states of the system to render the prediction conditional on the health state. Once trained, the unobserved health state can therefore be observed with the DNN network in terms of response. Filter-based estimation methods further leverage this mapping to inversely estimate the health state inferred from the measured response time history. However, before that, exploring the sensitivity of the prepared DNN models compared to traditional FEM-based models is essential to justifying their adoption over costlier FEM-based predictors.

The subsequent discussion focuses on a DNN model trained using simulations from an FEM-based model, synthesized from software like OpenFAST designed for FOWTs. Actual sampled responses will replace simulated ones for real-world implementation.

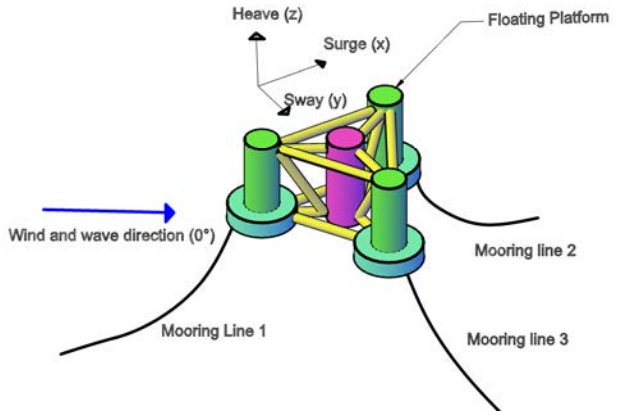

Figure 1. OC4 Semisubmersible floater along with catenary mooring system for NREL's 5MW wind turbine.

2.1. OpenFAST Model

Ensuring the DNN model undergoes thorough training necessitates a substantial volume of data. However, due to the limited prevalence and operational scope of FOWTs, obtaining a satisfactory quantity of authentic data is challenging. Consequently, we address this requirement by generating the requisite data through high-fidelity software capable of multi-physics simulation. In this investigation, we employ an NREL 5 MW Wind turbine model affixed to an OC4 semi-submersible model, as depicted in Figure 1. This configuration incorporates a catenary mooring system with three mooring lines fastened at 120° angles (Robertson et al., 2014); detailed mooring line specifications are provided in Table 1. The specifications for the 5 MW reference turbine are outlined in (Jonkman, Butterfield, Musial, & Scott, 2009). Additionally, data across varying sea states are simulated, characterized by wide-band operational scenarios involving a significant wave height (H_s) of 6 m and a Peak period (T_p) of 10 sec, assuming the turbine operates under a constant, steady wind speed of 8 m/s while in full operational mode.

Table 1. Mooring lines details

Diameter (m)	Mass density (kg m^{-1})	Axial stiffness (N)	Unstretched length (m)
0.0766	113.35	7.5903×10^8	835.35

In OpenFAST, various modules perform distinct functions. For instance, the HydroDyn module adopts a hybrid approach to handle hydrodynamic loads on the platform, merging diffraction theory with the Morison equation. The AeroDyn module uses blade element momentum (BEM) theory to manage aerodynamic loads. MoorDyn oversees loads related to mooring lines through the lumped mass method. ElastoDyn addresses structural and gravitational loads, while the InflowWind module supplies essential wind output. These modules are interconnected, collaborating to simulate the desired responses.

Table 2. Mooring Line's Damage (D) and Healthy (H) scenarios

Cases	Mooring Line's Damage Scenarios		
	Line 1 (k_1)	Line 2 (k_2)	Line 3 (k_3)
Case 1	H	H	H
Case 2	D	H	H
Case 3	H	D	H
Case 4	H	H	D
Case 5	D	D	H
Case 6	H	D	D
Case 7	D	H	D
Case 8	D	D	D

The DNN network underwent training to support the particle filter, capturing six distinct responses: the displacement and velocities of the floating platform in three directional axes. Response data was simulated over a duration of 3600 seconds, sampled at a frequency of 40 Hz. Variations in response resulting from alterations in the material properties of the mooring line were documented, leading to the simulation of different scenarios corresponding to various combinations of mooring line damage. Specifically, damages to the mooring lines were introduced as reductions in axial stiffness. For each scenario, 240 samples were simulated, resulting in a total of 1920 samples across 8 distinct cases as outlined in Table 2. Each case encompasses three discrete levels of damage for each mooring line, representing reductions of 10%, 15%, and 20% in axial stiffness (k_1, k_2, and k_3) of the mooring material.

2.2. Deep Neural Network (DNN)

The DNN model was subsequently developed to learn from data generated by OpenFAST. To predict the displacements and the velocities of a floating platform at the next ($k + 1^{th}$) sampling time step using the current time step (k^{th}) responses along with the health states as the input, the DNN utilizes a technique called back-propagation, wherein the prediction errors are propagated backward through the network, allowing the model to adjust its internal parameters, to improve future predictions. The architecture for the designed DNN model is provided in Table 3.

Table 3. Characteristics of the DNN model

DNN Architecture		
Layers	**Activation Function**	**Nodes**
Input Layer	-	9
Hidden Layer - 1	ReLU	128
Hidden Layer - 2	ReLU	64
Output Layer	Linear	6
Hyperparameters		
Optimizer		Adam
Epochs		1000
Learning Rate		10^{-6}

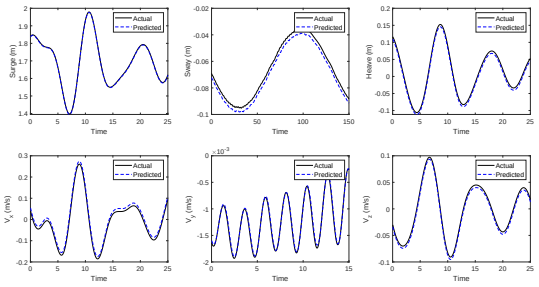

Figure 2. Actual and one-time step ahead predicted response comparison

The DNN architecture comprises an input, an output, and two hidden layers. The model is trained using 70% of the dataset allocated as training data. The remaining, 20% of data is used as a validation set to optimize hyper-parameters (activation function, learning rate, batch size) using RMSE and MAE metrics. Subsequently, testing is conducted using the remaining 10% of data. To ensure the required architecture for datasets, ReLU (Rectified Linear Unit) activation and linear activation functions are used in the hidden layers and output layer, respectively. The Adam optimizer, with a learning rate of 10^{-6} for 1000 epochs, was used for model optimization.

The model is tested on 10% of datasets. The model performed well in the provided regression task with good Root Mean Square Error (RMSE) and Mean Absolute Error (MAE) values, as shown in Table 4. Further, a comparison of one-time step-ahead predictions and actual simulated responses is shown in Figure 2.

Table 4. Trained DNN model's accuracy indices for testing data

	RMSE	**MAE**	**MBE**
Surge (m)	0.0014151	7.7249×10^{-5}	-9.0×10^{-5}
Sway (m)	0.0001885	9.1052×10^{-6}	9.0×10^{-5}
Heave (m)	0.0007831	2.5640×10^{-5}	-1.77×10^{-4}
V_x **(m/s)**	0.0022982	0.0015	-3.245×10^{-3}
V_y **(m/s)**	3.4311×10^{-5}	2.8587×10^{-5}	-1.8×10^{-5}
V_z **(m/s**	0.0006027	0.0003	9.8×10^{-5}

The performance of the DNN model, in predicting various responses, has been evaluated based on the provided accuracy indices. The RMSE values ranging from 3.4311×10^{-5} to 0.0022982 indicate relatively low prediction errors across different parameters, suggesting the model's capability to make accurate one-time step-ahead predictions. Likewise, the MAE values, ranging from 9.1052×10^{-6} to 0.0015, demonstrate the model's ability to predict parameter values with small deviations from the true values. Despite some biases observed in the Mean Bias Error (MBE) values, their magnitudes are relatively small, indicating an unbiased prediction by the ANN model. Overall, these accuracy indices suggest that the ANN model performs well in predicting the parameters of interest, making it useful for particle filters.

2.3. DNN-Particle filter

Particle filter, which typically approaches the Sequential Monte Carlo (SMC) method, is a powerful technique used for state estimation in nonlinear and non-Gaussian systems. The computational difficulties associated with scenarios where the state-space model is complex and the direct analytical solutions are intractable are handled effectively by PF-based algorithms.

The central idea behind a particle filter is that the posterior distribution ($p(x_{k-1}|R_{k-1})$) of the system state could be represented using a set of weighted samples, called particles $\{x_k^{(i)} : i = 1, 2, 3, \ldots, N\}$. These particles evolve according to the system dynamics and are updated based on their likelihood against measurements arriving sequentially in time. The filter approximates the posterior distribution by propagating particles through the system dynamics and adjusting their weights based on the likelihood of observed measurements.

The key steps in a particle filter algorithm include prediction, measurement update, and resampling. In the prediction step, particles are propagated forward in time according to the system dynamics, incorporating process noise, if present. In the measurement update step, particles are weighted based on their consistency with the observed measurements, calculated using the likelihood function. Upon receiving measurements, the probability of each sample from the previous time step is evaluated, and the normalized weight of each sample is determined using Eq. (1).

$$a_i = \frac{p(\Phi_k|\widetilde{x}_k^{(i)})}{\sum_{j=1}^{N} p(\Phi_k|\widetilde{x}_k^{(j)})} \tag{1}$$

Each sample $\widetilde{x}_k^{(i)} : i = 1, 2, 3, \ldots, N$ forms a discrete distribution with probability mass a_i associated with element i. Resampling is then performed to prevent particle degeneracy by replicating particles with higher weights and eliminating those with lower weights, redistributing the particle set to high-likelihood areas. The above process helps ensure a diverse representation of the posterior distribution. Resampling the discrete distribution N times creates new samples, weighted based on their likelihood against the observed data. Particle filters can handle nonlinear, non-Gaussian systems without linearization but may suffer in high-dimensional spaces due to the curse of dimensionality, requiring careful parameter tuning like the number of particles to balance efficiency and accuracy.

In essence, particle filters offer a flexible and effective framework for state estimation in nonlinear, non-Gaussian systems, serving as valuable tools in robotics, target tracking, and fi-

nancial modeling.

2.3.1. Parameter Estimation via PF

Within the PF framework, the adopted damage attributes, posed as parameters θ_k, are defined with a set of N_p independent parameter particles $\boldsymbol{\xi} = [\xi_{k-1}^1, \xi_{k-1}^2, \cdots, \xi_{k-1}^{N_p}]$ (?, ?). These particles, each representing a possible state of the system, are used to propagate system uncertainty over time through a process model. Subsequently, the propagated particles are evaluated against available measurements using the measurement model to compute their likelihood. This likelihood, when combined with the prior likelihood of particles, forms the posterior distribution. Finally, new particle samples are drawn from this posterior distribution to be utilized in the next iteration of the process.

The process model for this particle filter demonstrates the evolution of the parameter vector $\theta_k : \mathbb{R}^p$ to be estimated using a random walk model as follows:

$$\theta_{k+1} = \theta_k + u_k \tag{2}$$

θ_k signifies the health states, typically material properties, stiffness, or health indices, through which damage can be characterized. This model allows the parameter states to evolve in time to converge to their respective true values. Within the particle filtering framework, this uncertainty propagation is achieved by the time updating of several particles through the process model, along with the associated uncertainty u_k that has been modeled as a stationary white Gaussian noise (SWGN) of covariance Q_k.

Further, with each time step k, the evolution of the particle, ξ_{k-1}^j, is essentially represented by a random perturbation around its current position. A Gaussian blur ($\mathbb{N}(\delta\xi_k, \sigma_k^\xi)$) is additionally applied to ξ_{k-1}^j with a shift $\delta\xi_k = (1-\alpha)\bar{\xi}_{k-1}$ and a spread of σ_k^ξ [1]. The turbulence in the particle estimation is effectively managed through the implementation of hyperparameter α, which attempts to re-center the particles towards their mean ($\bar{\xi}_{k-1}$) as,

$$\xi_k^j = \alpha\xi_{k-1}^j + \mathcal{N}(\delta\xi_k, \sigma_k^\xi) \tag{3}$$

After propagation, each parameter particle undergoes observation against available measurements utilizing the DNN model. This model can map current responses and parameters to responses at the subsequent time step. The further mapping of the response at the next step to its corresponding available response is not explicitly elaborated here and is collectively incorporated within the measurement function $h(\bullet)$. The measurement model is defined as follows:

$$y_{k+1} = h_k(x_k, \theta_{k+1}, v_k) \tag{4}$$

In this context, h_k therefore utilizes the DNN surrogate of the FEM model trained with simulated synthetic response data. The DNN surrogate predicts the responses at the next time steps, some of which are observed as measurements y_{k+1}. v_k denotes measurement noise, modeled as another SWGN with covariance R_k. In the current FOWT monitoring scenario, the parameter vector encompasses the stiffness parameters of three mooring catenaries (k_1, k_2, and k_3).

Using this process and measurement model, the particle filter estimates the posterior of parameter particles, and the particle mean leads to the estimate of the particle filters. Due to space constraints, a detailed description of the particle filter is not provided here. Interested readers are encouraged to refer to the extensive literature available in this field.

2.3.2. Particle update and particle approximation

Next, the likelihood, $\mathcal{L}(\xi_k^j)$ for each j^{th} particle is computed using the corresponding innovation mean and covariance. These likelihoods are further convoluted with the prior weights $w(\xi_{k-1}^j)$ to estimate the corresponding posterior $w(\xi_k^j)$.

$$w(\xi_k^j) = \frac{w(\xi_{k-1}^j)\mathcal{L}(\xi_k^j)}{\sum_{j=1}^{N_p} w(\xi_{k-1}^j)\mathcal{L}(\xi_k^j)} \quad \text{with}$$
$$\mathcal{L}(\xi_k^j) = \left((2\pi)^n \sqrt{|\mathbf{R}_k|} \right)^{-1} e^{-0.5 i_k^{j\,T} \mathbf{S}_k^{-1} i_k^j} \tag{5}$$

With these updated weights, the particle approximations for the parameters are then estimated as:

$$\xi_{k|k} = \sum_{j=1}^{N_p} w(\xi_k^j)\xi_k^j \tag{6}$$

3. Results and Discussion

The integration of a DNN-based process model within a particle filtering environment underwent testing for two numerical case studies under two different operational conditions (refer Case 2 and Case 8). Under operating condition case 2, the numerical experiment additionally considers 10% damage in the first mooring line alone ($k_1 = 0.9k$), and no damage in other mooring lines, while under operating condition case 8, the numerical experiment assumes 20% damage in each of all the three mooring lines. To simulate real-world conditions, the observation vector was contaminated with 1% and 5% Gaussian noise. The objective was to assess the efficiency and robustness of the proposed detection approach in estimat-

[1] $A + B\mathbb{N}(\mu, \sigma)$ means $A + Bz$, where z follows $\mathbb{N}(\mu, \sigma)$

Algorithm 1 DNN-Particle Filter

Inputs:
N: Number of particles
$x(0)$: Initial state estimate
$p(x(0))$: Initial state probability distribution
$f(x_k, u_k)$: System dynamics function
$h_k(x_k, \theta_k)$: Measurement model function
$DNN(x_k, \theta_k)$: DNN surrogate model for measurement update STATE σ_ξ: Standard deviation for particle perturbation
α: Hyper-parameter for particle re-centering
Q_k: Process noise covariance
R_k: Measurement noise covariance
Outputs:
Estimated state posterior: $p(x_k|z_1 : k)$ (represented by particles)
Estimated parameter vector: θ_k
Initialization:
for $i = 1$ **to** N **do**
    Sample initial state: $x_0^{(i)} = \text{Sample\_From}(p(x(0)))$
    Initialize parameter particles:
    $\theta_0^{(i)} = \text{Random\_Vector}()$
    Initialize weights: $w_0^{(i)} = 1/N$
end for
Main Loop:
for $k = 1$ **to** T (number of time steps) **do**
    Prediction Step:
    for $i = 1$ **to** N **do**
        Propagate particle state: $x_k^{(i)} = f(x_{(k-1)}^{(i)}, u_k)$
        Perturb parameter particle:
        $\theta_k^{(i)} = \alpha\theta_{(k-1)}^{(i)} + \text{N}(0, \sigma_\xi)$
    end for
    Measurement Update Step:
    for $i = 1$ **to** N **do**
        Calculate innovation:
        $\text{innovation} = y_k - h_k(x_k^{(i)}, \theta_k^{(i)})$
        Calculate likelihood:
        $\mathcal{L}(\xi_k^j) = \left((2\pi)^n\sqrt{|\mathbf{R}_k|}\right)^{-1} \exp\left(-0.5(\boldsymbol{i}_k^j)^T\mathbf{S}_k^{-1}\boldsymbol{i}_k^j\right)$
        Update weight based on likelihood:
        $w_k^{(i)} = w_{(k-1)}^{(i)} \cdot \mathcal{L}(\xi_j^k)$
    end for
    Normalize weights: $w_i = \frac{w_i}{\sum_{j=1}^N w_j}$
    Resampling Step:
    Perform resampling to generate new particles and parameters based on weights
    Update particles and parameters based on resampling results
end for

ing the stiffness parameters (k_1, k_2, and k_3) of the mooring lines across varying noise levels.

Results indicate that, regardless of the noise level, the integrated model effectively estimated the states and stiffness parameters with sufficient accuracy. Figures 3, 4, 5, and 6 demonstrate the proposed framework's parameter estimation capabilities even in the presence of noise. However, an increase in noise led to decreased accuracy in parameter estimation. Higher noise levels introduced greater ambiguity into the observation vector, resulting in increased inaccuracy in the estimation process. The accuracy of the estimated parameters is quantified in terms of RMSE, with lower RMSE values indicating better accuracy.

Although all 8 scenarios in Table 2 were studied with the proposed estimation framework, only the results corresponding to Case 2 and Case 8 are presented in the paper for the numerical demonstration due to technical limitations.

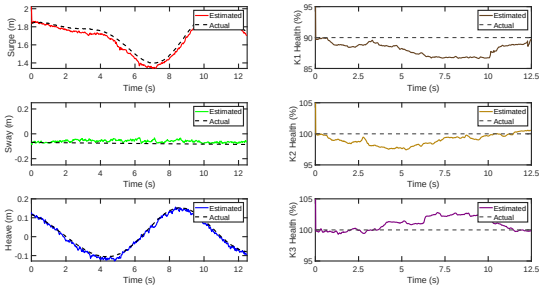

Figure 3. Actual and estimated states (left) and stiffness (right) parameters for Case 2 with 1% noise.

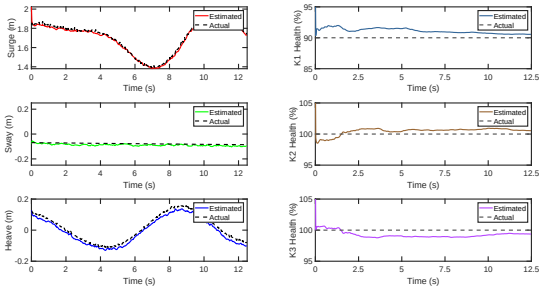

Figure 4. Actual and estimated states (left) and stiffness (right) parameters for Case 2 with 5% noise.

4. Conclusion

The initial findings suggest that the DNN-particle filter holds promise as a means to enhance the reliability and efficiency of mooring line monitoring by integrating an ML-based predictor model instead of a high-fidelity FEM model. By leveraging synthetic data generated from a calibrated OpenFAST model of FOWT dynamics, the DNN-particle filter offers a

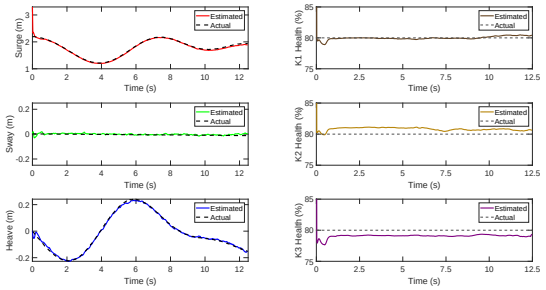

Figure 5. Actual and estimated states (left) and stiffness (right) parameters for Case 8 with 1% noise.

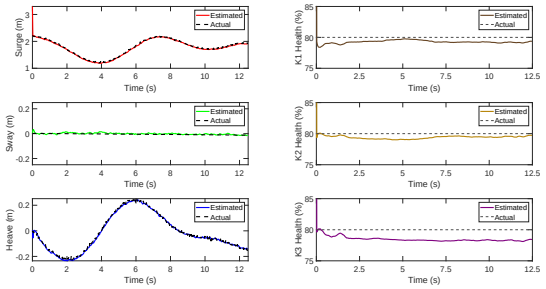

Figure 6. Actual and estimated states (left) and stiffness (right) parameters for Case 8 with 5% noise.

computationally efficient representation of system dynamics, enabling real-time damage detection and interpretable information on damage severity within a stochastic inverse estimation framework. This contrasts with traditional black-box ML-based methods, which often struggle to provide interpretable information on damage characteristics.

The DNN-particle filter's data processing capabilities maximize resource allocation by focusing efforts on critical areas identified by the model. By doing so, it enhances the promptness of the detection algorithm without sacrificing accuracy and transparency. This development has the potential to usher offshore operations into a new era of durability and resilience by ensuring the integrity of mooring lines and streamlining operating procedures. Ultimately, it has the potential to enhance the safety and longevity of offshore operations by effectively managing damage and noise.

ABSTRACT

The world is experimenting a decarbonization process, mainly through lithium-ion-based solutions. Nonetheless, catastrophic events have negatively affected the social acceptance of lithium-ion-based solutions. One of the most interesting projects regarding catastrophic event prevention is the internal short-circuit detection. This paper proposes to detect it using different machine-learning algorithms such as random forest and combination of random forest with neural network-based algorithms through time-instant classification and historical feature classification. The hyper-parameters have been optimized through grid-search. The selected algorithms have been trained thanks to synthetically generated data using a first-order electrical equivalent circuit model. The performance of the generated models has been verified and compared thanks to testing and validation data sets taken from the synthetically generated data. Afterward, the most accurate internal short circuit detection algorithm was selected and validated through laboratory-level data. The selected cell in this study is SLPB526495HE, a pouch cell of 3.7Ah. The generated data are time series of voltage and current, which are the variables that will be available in a real application. The results demonstrate an accuracy above 90% in detecting an internal short circuit in the most interesting cases. The validation with laboratory data has shown that an accuracy of 90% can be achieved. This paper provides learned lessons on the process of developing the internal short circuit detection machine-learning model, highlighting the potential they possess to detect accurately internal short circuits.

1. INTRODUCTION

Lithium-ion batteries have been acclaimed for their high energy density, low self-discharge rates, and environmental compatibility since a decade ago (Diouf & Pode, 2015). This battery technology has emerged as a key component in global decarbonization strategies, finding extensive application in diverse energy storage systems such as electric vehicles and smart grids (Zubi et al., 2018). Despite their notable advantages, safety concerns, particularly those stemming from internal short circuits (ISC) leading to thermal runaway, remain a primary impediment to their broader adoption(Zhan et al., 2023). Such incidents can result in battery fires or even explosions, leading to grave consequences. Thermal runaway is often initiated by ISC events (Ren et al., 2021), and the detection of such events poses significant challenges, especially during their incipient stages.

ISC faults often begin with mild severity, starting with high resistance values, which decrease as the fault progresses. In this process, the voltage, current, and State of Charge (SoC) of normal batteries and those with varying ISC resistance values exhibit similar characteristics during charging and discharging processes. This similarity significantly complicates the diagnosis of early-stage ISC faults, leading to researchers to apply data-driven algorithms (Zhang et al., 2021). The application of data-driven or machine learning (ML) algorithms in ISC fault detection can be categorized further into two main types: unsupervised and supervised learning.

Unsupervised learning methods train fault detection models using data generated during the charging and discharging processes of normal batteries. These methods identify potential anomalies by defining deviation measures between normal and abnormal data, deciphering the standard patterns within the data, and employing specific decision rules. Typical algorithms include Support Vector Machine (SVM) (Chatterjee et al., 2023), Relevance Vector Machine (RVM) (Xie et al., 2020), Kernel Principal Component Analysis (KPCA) (Schmid & Endisch, 2022), and Isolated Forest (Cheng et al., 2023), which have demonstrated effective anomaly detection capabilities in various scenarios. Nonetheless, unsupervised learning algorithms have their limitations. Particularly when the abnormal data closely resemble the normal data with no significant distributional

differences, as it is our case. These methods may struggle to distinguish between them accurately. This is why, it is challenging for unsupervised learning algorithms to detect these subtle anomalies.

Supervised learning methods utilize pre-labeled datasets for training, differentiating like this battery performance data under normal operations and abnormal conditions in the training process. Through training, these models are adept at distinguishing between normal battery behavior and potential fault signals. Typical algorithms include Random Forest (RF) (naha et al., 2020), Convolutional Neural Network (CNN) (Yang et al., 2022) and Long Short-Term Memory (LSTM) (Wang et al., 2023). Nonetheless, it is not clear which should be the one to be applied. In light of this, our research aims to explore and apply various supervised learning algorithms to help researchers find the most suitable algorithms for ISC detection.

This paper proposes the development and comparison of ISC detection supervised learning algorithms, enhancing the detection capabilities at early stages of ISC. This study seeks to provide an ISC detection algorithm selection background to fellow researchers and boost the reliability and safety of lithium-ion batteries in operational contexts.

This paper is structured as follows. The data generation is detailed in section 2. The ISC detection methods are described in section 3. The hyperparameter tuning process undergone in this paper is placed in section 4. The results are shown in section 5. The discussion is done in section 6 and the conclusions are drawn in section 7.

2. DATA GENERATION

The selected battery is SLPB526495HE. The synthetically generated data has been generated with a first-order equivalent electric model. The experimental data has been generated in laboratory testing facilities. During the training and testing phases, only virtual datasets were utilized to develop the models. In the validation phase, experimental datasets were additionally incorporated. This approach was adopted to evaluate the performance of the models trained on virtual datasets in real-world scenarios.

This study focuses on charging data. In practical scenarios, battery discharging conditions are highly complex, whereas the charging scenarios are relatively monotonous. Therefore, we chose charging data to train the model for detecting ISC anomalies during the charging phase.

The operational conditions of the generated data are the same for the synthetically generated one and the one generated through laboratory tests: an ambient temperature of 25°C and a charge process at constant charge mode from 1% SoC to the maximum voltage value.

The extracted feature data during this process included the battery voltage and the battery's current voltage increment relative to its voltage before charging an amount equivalent to 1% of its nominal capacity, denominated as voltage difference, see Eq. (1).

$$V_{diff\_k} = V_k - V_{k-1\%c} \quad (1)$$

2.1. Virtual dataset

The virtual data set used for model training and testing was generated by a first-order electric equivalent circuit model (Arrinda, Oyarbide, Macicior, Muxika, et al., 2021) for the SLPB526495HE battery, as shown in Figure 1.

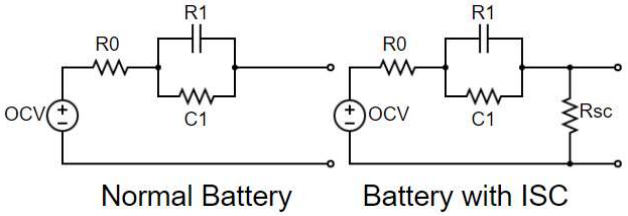

Figure 1: Equivalent electric circuit models.

The parameters of the model were obtained by conducting specific modeling tests on the SLPB526495HE battery, see Figure 2.

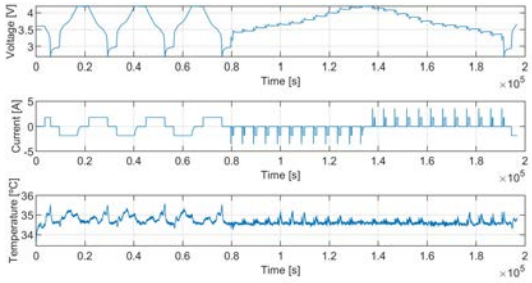

Figure 2: Modeling tests. A capacity and pulse based impedance characterization and OCV characterization test is performed at controlled ambient temperature.

The built model was run to obtain data from a normal battery and a battery with different level of ISC faults (a total of 21 stages): 5Ω, 50Ω, 100Ω, 150Ω, 200Ω, 250Ω, 300Ω, 350Ω, 400Ω, 450Ω, 500Ω, 550Ω, 600Ω, 650Ω, 700Ω, 750Ω, 800Ω, 850Ω, 900Ω, 950Ω and 1kΩ.

2.2. Experimental dataset

The experimental Data Set used for the model validation was generated in the laboratory by cycling the cell with constant current charging tests from 1% SOC to maximum voltage value, see Figure 3. The reference test has been tested only with the cell. The ISC has been emulated by connecting an external bleed resistor of 10 Ω and performing the charge.

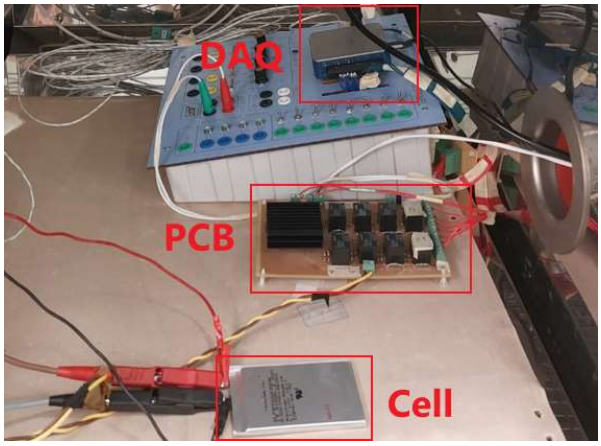

Figure 3: Experimental setup. Within a controlled temperature chamber, a battery cell is interfaced with a Printed Circuit Board (PCB), which incorporates various resistors to simulate an Internal Short Circuit (ISC) phenomenon. This setup is further connected to a Data Acquisition System (DAQ) for comprehensive data collection and monitoring.

3. DETECTION METHODS

This paper presents and compares various ISC detection solutions based on different ML models. These solutions can be divided into two main categories according to the data types they utilize: the Instantaneous Feature-based Method and the Historical Feature-based Method.

3.1. Instantaneous Feature-based Method

As illustrated in Figure 4, the ISC detection solutions under the Instantaneous Feature-based Method determine whether the battery is in a normal state or experiencing an ISC anomaly by analyzing the feature data at every single moment and treating it as a binary classification task at every moment. The ISC detection solutions proposed in this paper that are under the Instantaneous Feature-based Method category are the RF solution and the RF combined with Multilayer Perceptron (RF+MLP) solution.

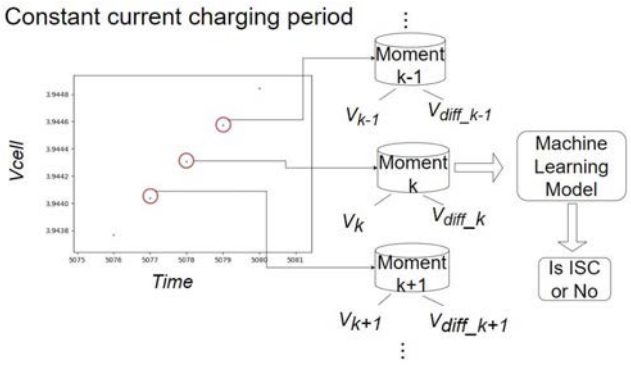

Figure 4: Instant-based methods' main concept diagram. Instant-based methods treat each moment k as an independent data point, characterized by two features: the cell voltage at time k (Vk) and the voltage difference (Vdiff_k) at time k. A machine learning model is then employed to classify each time point as either a normal or an ISC label.

3.1.1. Data treatment

A dataset for the charging process on a battery without an ISC was gathered with no ISC labels. A dataset of battery charging data that reflects the 21 stages of ISC fault conditions has been generated with ISC anomaly labels. The dataset with ISC anomaly labels has a significantly higher volume of data compared to the one with no ISC labels. To address this issue, a down-sampling method was adopted to balance the label distribution in the training dataset.

The specific down-sampling process involves randomly selecting data from the dataset with ISC anomaly labels. The total number of data points is the same in both data sets, 4000. The data with ISC anomaly labels is evenly taken from all the simulated cases. This method ensures the consistency of the total volume of ISC anomaly data with normal data and guarantees a balanced sampling quantity of different stages of ISC anomaly data generated from different short-circuit resistance values.

The final step in data handling involves splitting the dataset obtained through down-sampling into a training set and a test set based on an 80% to 20% ratio. This approach allows the model to train on a substantial portion of the data while retaining a separate subset for evaluation, ensuring that the model's performance can be accurately assessed.

3.1.2. Random Forest (RF)

The RF classifier, as a widely used ML model for classification tasks, leverages ensemble learning techniques to enhance the accuracy and stability of predictions. This model employs bootstrapping to draw multiple subsets of samples with replacements from the original training dataset and randomly selects subsets of features during the construction of each decision tree. In classification tasks, RF makes the final decision by aggregating the predictions from all its decision trees, adopting the class supported by the majority of the trees as the prediction outcome.

3.1.3. Randon Forest with Multilayer Perceptron (RF+MLP)

The RF+MLP combines the RF and MLP to detect the presence of ISC phenomena in batteries. The main workflow consists of training first a RF classifier to be used to predict the data. Then, the prediction results from each decision tree within the RF classifier are used as new input features of the MLP. This approach aims to leverage the MLP to learn the relationships between decision trees, thereby enhancing the

model's ability to distinguish between data with ISC and data without ISC.

3.2. Historical Feature-based Method

The historical feature-based method for detecting ISC events utilizes a sliding window technique. Starting from the (n+1)th time point, it combines the feature data of that moment with the feature data from the preceding n moments to construct a time series window. The window then slides forward, step by step, continuing this process to generate a series of time series window data, see Figure 5. Subsequently, deep learning models specifically designed for time series classification are applied to distinguish between ISC event data and no ISC data.

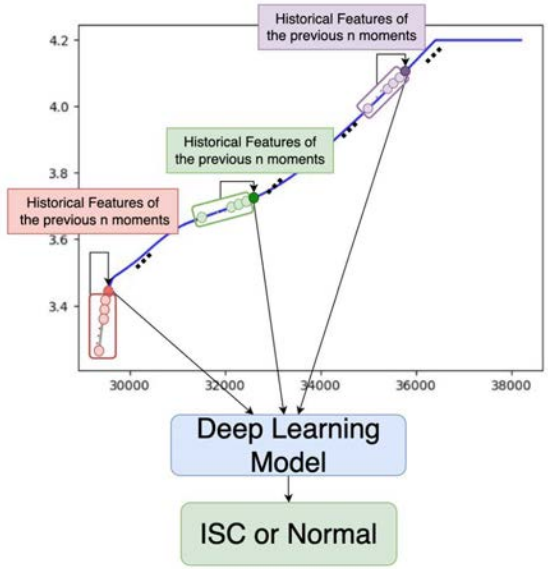

Figure 5: Historical feature-based methods' main concept diagram.

3.2.1. Data treatment

A series of data preprocessing steps are necessary. Initially, the sliding window technique is applied to transform the charging data of batteries without ISC and the charging data of batteries with ISC anomaly using different short-circuit resistance values. Starting from the (n+1)th moment, the feature data of each moment and its preceding n moments are combined to form individual 3x(n+1) dimensional time series windows. Here, 3 represents the number of features:

- The battery voltage at each moment.
- The voltage difference or the voltage increment of the battery at each moment relative to its voltage before charging an amount equivalent to 1% of its nominal capacity.
- The probability that the current moment might correspond to ISC data as determined by the Random Forest classifier analyzing the current battery voltage at each moment and the voltage difference.

Subsequently, down-sampling of ISC time series window data is performed as in the data treatment performed for the instant-based methods to balance the data label distribution and prevent data bias issues during the training process.

Unlike the RF algorithm, neural network models typically require data normalization prior to training. This normalization accelerates model convergence, prevents issues with vanishing or exploding gradients, and enhances the model's generalization capability to new data. Common data normalization methods include the min-max normalization and the Z-score normalization (Patro & sahu, 2015).

The min-max normalization method adjusts the scale of the data so that all features have values ranging between 0 and 1. Specifically, for each feature, this is achieved by subtracting the minimum value of that feature from each value, then dividing by the difference between the maximum and minimum values of that feature, Eq. (2).

$$x_{norm} = \frac{x - x_{min}}{x_{max} - x_{min}} \tag{2}$$

The Z-score normalization, also known as standard score normalization, normalizes the data by subtracting the mean of each feature from its values and then dividing by its standard deviation, resulting in a dataset with a mean of 0 and a standard deviation of 1, Eq. (3).

$$x_{norm} = \frac{x - \mu}{\sigma} \tag{3}$$

Beyond the normalization methods, the choice of normalization strategy is crucial and can be based on one of the considered normalization processes: normalization-by-moment, normalization-by-feature, and normalization-by-window.

The normalization-by-moment strategy involves normalizing the values of all features at each specific moment. It treats each point in time independently, adjusting the features across all samples at that particular moment to conform to the chosen normalization scale. This approach is useful when the relative magnitudes of features at each moment are important for the model to recognize patterns over time.

The normalization-by-feature strategy operates on each feature across all moments. It normalizes the values of a single feature over the entire dataset, ensuring that the feature's values are on the same scale across all time points. This is particularly beneficial when you want the model to understand the behavior of each feature independently across time, emphasizing the feature's overall distribution without the influence of varying scales.

The normalization-by-window approach treats all the data within a sliding window as a whole for normalization purposes. Each window is normalized independently, meaning that the scale of the features is adjusted within the context of that window. This strategy is useful when the relationship between features within each window is critical to identifying patterns, and it aims to preserve the internal dynamics of each time window.

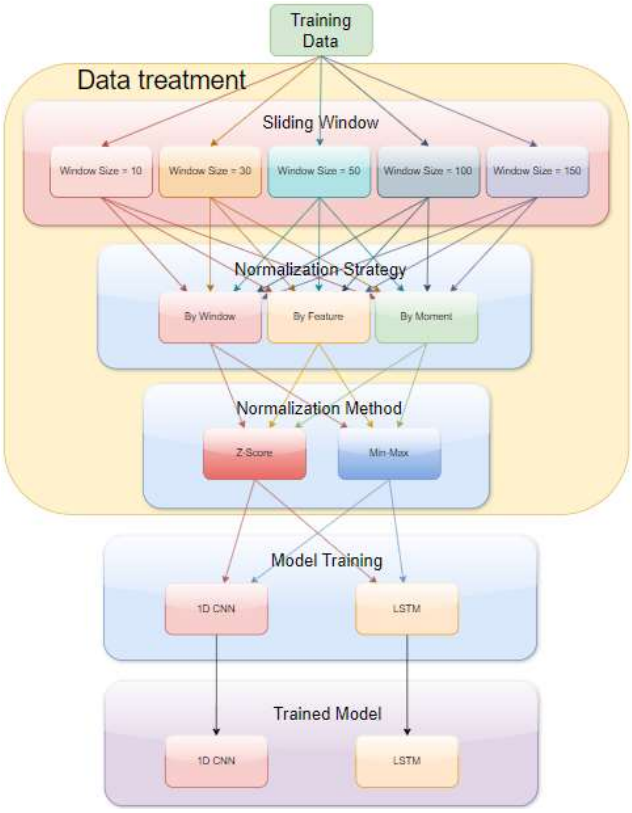

Figure 6: Data treatment processing selection diagram.

As a result, six distinct data preprocessing schemes have been developed based on the aforementioned. To identify the most suitable data processing approach for various models and to find the optimal sliding window size, an experimental workflow was designed as follows (Figure 6):

- Experiment with window sizes equals to 10, 30, 50, 100, 150 are evaluated.
- The six different data preprocessing schemes are applied to each window size experiment, resulting in 30 different data processing configurations.
- Train 1D CNN and LSTM networks using the processed data.
- Evaluate the performance of these models through cross-validation to determine the most suitable data processing method and window size for each model type.

3.2.2. Random Forest with Convolutional Neural Network (RF+CNN)

1D CNN algorithms are frequently employed for processing sequential data, such as time series data. A 1D CNN processes input data through a series of specific layers to extract useful features for classification or other tasks. The fundamental architecture of a simple 1D CNN consists of an input layer, convolutional layer, activation function, pooling layer, fully connected layer, and output layer. In the context of time series classification tasks, the input layer initially receives the raw data. This is followed by the convolutional layer, where multiple kernels slide across all features of the data to perform convolution operations and extract features, which are subsequently subjected to an activation function. The pooling layer then reduces the dimensionality of the feature maps, decreasing the volume of data that needs to be processed. Finally, the fully connected layer and the output layer classify the previously extracted features, producing the final outcome.

3.2.3. Random Forest with Long short-term memory (RF+LSTM)

LSTM networks are a specialized type of Recurrent Neural Networks (RNNs) particularly suited for classifying, processing, and predicting based on time series data. LSTMs are adept at addressing issues of vanishing or exploding gradients, which are common with traditional RNNs. The basic structure of an LSTM includes an input layer, LSTM layer, hidden layers, and an output layer. Within the LSTM layer, each LSTM unit contains several key components: Cell State, Input Gate, Forget Gate, Output Gate, and Hidden State. When LSTMs are employed for time series data classification tasks, data is initially decomposed into individual time steps through the Input Layer and then fed into the LSTM layer. This layer captures long-term and short-term relationships within the time series data by maintaining, ignoring, or updating information through an internal state and three gate structures. The output from the LSTM layer is then passed to one or more Hidden Layers for further feature extraction, with the final classification result being produced by the output layer.

4. HYPERPARAMETER TUNING

Hyperparameter tuning plays a crucial role in the training of ML and deep learning models, as the choice of hyperparameters directly affects the performance, learning capability, and generalization ability of the model. During the training of various models mentioned before, such as RF, MLP, 1D CNNs, and LSTMs, experimenting with multiple combinations of hyperparameters is an effective method to find the relatively optimal hyperparameter settings.

4.1. RF Classifier Hyperparameter Tuning

The use of the grid search through "GridSearchCV" tool from the Scikit-learn python's library is proposed to systematically explore and optimize the hyperparameter settings of the RF classifier (Arrinda, Oyarbide, Macicior, & Muxika, 2021). Initially, we defined a search space containing various combinations of hyperparameters, including the number of decision trees, the maximum depth of the trees, the minimum number of samples required to split an internal node, the minimum number of samples required at a leaf node, and whether bootstrap sampling is used.

"GridSearchCV" tested each of the 2,400 different hyperparameter combinations defined in our search space and employed cross-validation to comprehensively assess the performance of each combination. The training dataset was divided into five subsets, with one subset being used as the validation set to evaluate the model and the remaining four subsets for training. The performance of each combination was assessed based on the average results of these five validations.

The optimal combination of hyperparameters for the model was finally identified by analyzing and comparing. After determining the best hyperparameters, these parameters were used with the full training dataset to conduct the final training of the random forest classifier, ensuring the model achieved optimal predictive performance.

4.2. Neural Networks Hyperparameter Tuning

The grid search method used for identifying the optimal hyperparameters of the RF Classifier was considered unsuitable for neural networks due to time cost concerns. Hence, the "Keras Tuner" Python's library is proposed to perform hyperparameter optimization through random search of neural network based models. Similar to "GridSearchCV", before starting the random search, a search space for each model is defined. However, the distinct feature of the random search method provided by "Keras Tuner" is that it does not attempt every possible combination of hyperparameters. Instead, it randomly selects n combinations of hyperparameters from the defined search space to experiment with. A key advantage of this approach is its ability to significantly reduce the search time while still maintaining the possibility of discovering well-performing hyperparameter sets.

5. RESULTS

The most suitable data processing approach and the most optimal hyperparameters for each model are shown in Figure 7. Each trained model has been validated both by virtual datasets and experimental datasets.

Figure 7 The most suitable data processing approach and the most optimal hyperparameters for each model.

5.1. Validation with virtual dataset

The virtual dataset comprises one charging data set generated by a normal battery electric equivalent circuit model and other two charging data sets generated respectively by ISC battery electric equivalent circuit models, characterized by short-circuit resistances of 10Ω and 510Ω, respectively.

The validation results of models of the instantaneous feature-based method are shown in Figure 8, whereas the results for models utilizing historical feature-based methods are illustrated in Figure 9. These figures illustrate the temporal variation of cell voltage (Vcell) during the constant current charging process of normal batteries and batteries experiencing ISC faults with short circuit resistances of 10 ohms and 510 ohms. Furthermore, the figures depict the fault detection outcomes at each time point during the charging process, as predicted by the RF model and the RF model integrated with MLP. The prediction outcomes are marked in blue and red, indicating correct predictions and incorrect predictions, respectively.

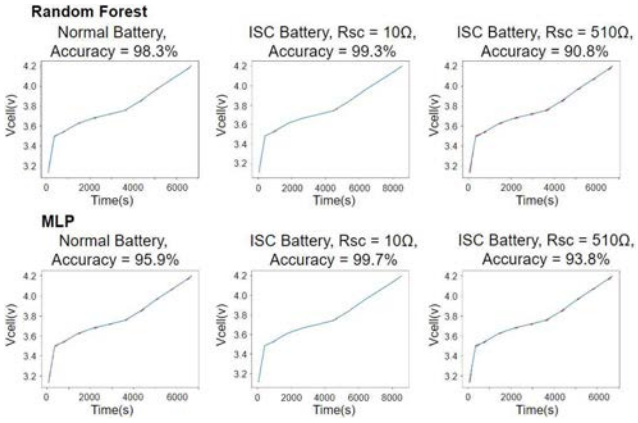

Figure 8: Validation Results of models of Instantaneous Feature-based method with virtual dataset. The blue line is the Vcell vs time, and the red points represent the moments where the prediction is wrong.

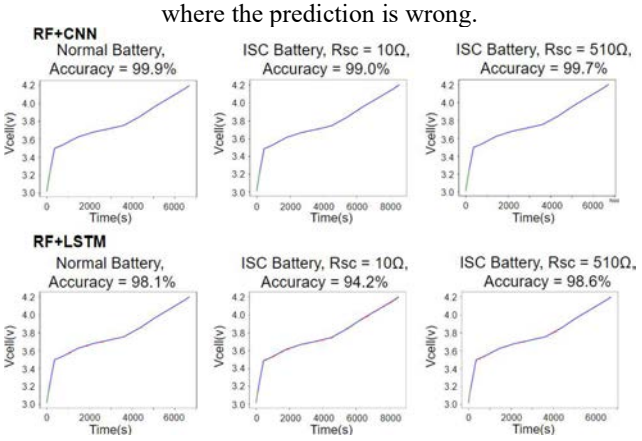

Figure 9: Validation Results of models of Historical Feature-based Methods with virtual dataset. The green part represents the moments when the charging amount is still less than 1% nominal capacity.

5.2. Validation with experimental dataset

The experimental dataset consists of two datasets. One of them is the charging dataset of a real battery without any fault. The other one is the charging dataset from the same battery connected with a 10Ω short-circuit resistance emulating an ISC condition.

The battery model used to generate the virtual data assumed a state of health (SoH) of 100%, whereas the battery utilized for the experimental dataset did not have the exact same SoH. Hence, Eq. (4) should be employed for calculating the voltage difference of the experimental dataset.

$$V_{diff\_\exp\_k} = (V_k - V_{k-1\%c}) \cdot SoH_{exp} \qquad (4)$$

Figure 10 and Figure 11 illustrate the validation results of Instantaneous Feature-based method models and Historical Feature-based method models respectively. These figures also use red and blue markers to denote the accuracy of predictions in relation to the actual conditions, where red indicates a mismatch between predicted and actual label, and blue signifies correct predictions.

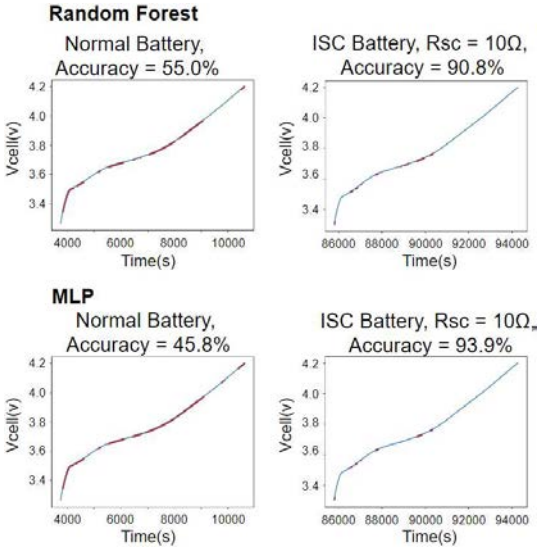

Figure 10: Validation Results of models of Instantaneous Feature-based method with experimental dataset.

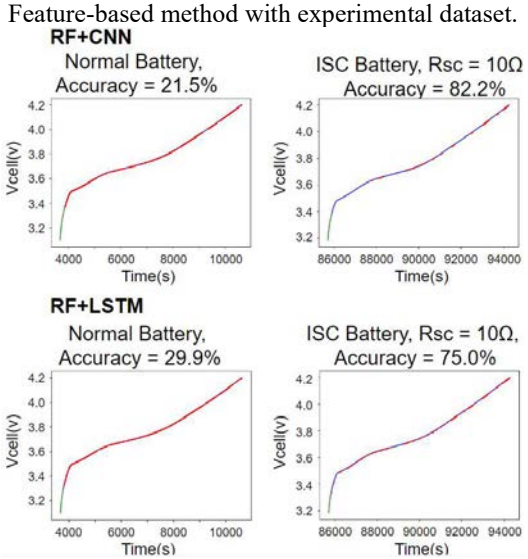

Figure 11: Validation Results of models of Historical Feature-based Methods with virtual dataset.

6. DISCUSSION

This study introduced four innovative methods for detecting ISC faults, all of which demonstrated a prediction accuracy above 90% (and 8 of 12 close to 99%) during the validation process with virtual data, including the identification of normal data and ISC data with 10Ω and 510Ω short-circuit resistances. The validation results are presented in Table1.

Table 1. Validation Accuracy of models on Different Validation Dataset.

Dataset	RF	RF+MLP	RF+CNN	RF+LSTM
Normal (Virtual)	98.3%	95.9%	99.9%	98.1%
Normal (Experimental)	55.0%	45.8%	21.5%	29.9%
10 Ω (Virtual)	99.3%	99.7%	99.0%	94.2%
10 Ω (Experimental)	90.8%	93.9%	82.2%	75.0%
510 Ω (Virtual)	90.8%	93.8%	99.7%	98.6%

The RF method, being the earliest and simplest instantaneous feature-based method, shows excellent performance in distinguishing between ISC and normal data within the virtual dataset. It achieved an accuracy of 98.3% for normal data and 99.3% for severe ISC detection (lower short-circuit resistance values), though its accuracy slightly decreased to 90.8% for early-stage ISC detection (higher short-circuit resistance values). To enhance the model's accuracy in predicting high resistance value ISC conditions, three other detection methods based on model stacking were proposed, using RF as the base model whose output serves as additional input features for other models.

The combination of RF with MLP slightly improved the accuracy for high resistance value ISC conditions to 93.8%, at the cost of reduced accuracy for normal battery data predictions, which fell to 95.9%. This is a consequence of the weight distribution of RF's estimators provided by the MLP.

The combination of RF with CNN performed best in virtual data validation. It achieved a 1.6% increase in accuracy for normal data predictions, reaching 99.9%. Moreover, this method improved the detection accuracy for 510Ω short-circuit resistance ISC from 90.8% to 99.7%. Nonetheless, its accuracy for detecting lower resistance ISC slightly fell by 0.3% to 99.0% compared to using RF alone.

The combination of RF with LSTM networks increased the prediction accuracy for high resistance ISC detection to 98.6% while maintaining the accuracy for normal data predictions at 98.1%. Nevertheless, lower resistance ISC detection slightly decreased to 94.2%.

The validation process with experimental data has shown a decrease in accuracy. All models experienced a significant performance decline in the validation with the experimental dataset, especially in predicting normal data. The instantaneous feature-based methods outperformed the historical feature-based methods overall in the experimental dataset. RF and RF+MLP maintained over 90% accuracy in predicting low resistance ISC conditions, but their accuracy in predicting normal data dropped to 55% and 45.8%, respectively. The HFM-based methods had less than 30% accuracy in predicting normal data, and their detection accuracy for ISC faults did not reach 80%.

This performance drop could be attributed to overfitting on virtual normal data, as the virtual normal battery could generate only a single set of normal battery charging data, and to discrepancies between data generated by equivalent circuit models and real data, preventing the RF model from accurately learning subtle changes in real conditions. The performance of model stacking methods was impacted by the base model RF's performance; if RF could not provide accurate predictions, the overall performance of the stacked models was negatively affected.

In real applications, as the performance gap between electric equivalent circuit model and actual battery increases, and therefore, the negative effect of stacked models will be amplified, making the RF model a preferred choice for ISC detection algorithms in the absence of real data. Nonetheless, if the performance gap could be resolved, or if real-life data could be used to further train the stacked models, models like RF+CNN could achieve significantly higher accuracy levels in early-stage ISC detection compared to the RF model alone.

7. CONCLUSION

This paper developed four methods for detecting ISC faults. Data is obtained from simulations and experiments at lab level. The ISC fault detection methods are trained using the virtual data. The normalization method, normalization strategy, are performed by using an exhaustive method and hyperparameter tuning is done by grid-search and random-search. After the training and hyperparameter tuning, these methods have been evaluated respectively by conducting validations and performance comparisons with both the virtual and experimental datasets.

The validation with virtual data shows that the historical feature-based method combining RF and CNN demonstrated superior performance. However, the limitations of virtual data became apparent during the validation with experimental data. The base model, the RF model, fails to achieve satisfactory prediction results on the experimental dataset. It suffers a drop of accuracy from 98.3% to 55% in describing data without ISC. This limitation further impacted the overall performance of the RF+CNN methods in the experimental data validation, having higher accuracy drops than the ones observed in RF.

To address this issue in future research, one of the potential approaches could be integrating digital twin and cloud computing technologies. Digital twins can facilitate the collection of extensive real-world data to refine the model, while cloud computing, combined with the gathered real-world data, can enable continuous learning for the model.

This method ensures the model's adaptability to real-world data. Moreover, as a battery's SoH gradually declines, affecting its charging data throughout its use, continuous learning can also allow the model to adjust to these changes. This synergy of multiple technologies considerably augments the flexibility and universality of ISC detection systems, equipping them to accommodate a wider array of scenarios and conditions.

BIOGRAPHIES

Zihong Zhang received the B.S. degree in electrical engineering and automatization in 2019 at Shanghai Institute of Technology, Shanghai, China. He obtained M.S. in computational methods in sciences at University of Navarra, Pamplona, Navarra, Spain in 2021. In 2023, he completed the second M.S. in Artificial Intelligence at Tecnun, University of Navarra, Donostia, Gipuzkoa, Spain. His main responsibility in CIDETEC concentrates on development machine learning and deep learning models for applications in fault diagnosis, predictive maintenance, digital twins for lithium-ion batteries.

Mikel Arrinda received the B.S. degree in industrial electronic engineering in 2012 at MU, Mondragon, Basque Country, Spain. In 2013 completed his studies with a M.S. in integration of renewable energy sources into the electricity grid at EHU, Bilbao, Basque Country, Spain. In 2020, he obtained his Phd degree in apply engineering at CIDETEC institute for Energy Storage. His research interest is focused on lithium-ion batteries in terms of electric-thermal-aging modeling, SoX algorithms, thermal control strategies, digital twin applications, AI implementation and safety measures.

Jon Perez received the B.S. degree in electrical engineering in 2020 at Tecnun University of Navarre, Donostia – San Sebastian, Basque Country, Spain. In 2022, he received the M.Sc degree in Energy and Power Electronics from Mondragon University, Mondragon, Basque Country, Spain. From 2022 onwards, he is pursuing a PhD degree in applied engineering at CIDETEC institute for Energy Storage. His research interests are focused on lithium-ion batteries aging detection, SoX algorithms and early detection of Thermal Runaway and other failures.

Continuous Test-time Domain Adaptation for Efficient Fault Detection under Evolving Operating Conditions

ABSTRACT

Fault detection is crucial in industrial systems to prevent failures and optimize performance by distinguishing abnormal from normal operating conditions. Data-driven methods have been gaining popularity for fault detection tasks as the amount of condition monitoring data from complex industrial systems increases. Despite these advances, early fault detection remains a challenge under real-world scenarios. The high variability of operating conditions and environments makes it difficult to collect comprehensive training datasets that can represent all possible operating conditions, especially in the early stages of system operation. Furthermore, these variations often evolve over time, potentially leading to entirely new data distributions in the future that were previously unseen. These challenges prevent direct knowledge transfer across different units and over time, leading to the distribution gap between training and testing data and inducing performance degradation of those methods in real-world scenarios. To overcome this, our work introduces a novel approach for continuous test-time domain adaptation. This enables early-stage robust anomaly detection by addressing domain shifts and limited data representativeness issues. We propose a Test-time domain Adaptation Anomaly Detection (TAAD) framework that separates input variables into system parameters and measurements, employing two domain adaptation modules to independently adapt to each input category. This method allows for effective adaptation to evolving operating conditions and is particularly beneficial in systems with scarce data. Our approach, tested on a real-world pump monitoring dataset, shows significant improvements over existing domain adaptation methods in fault detection, demonstrating enhanced accuracy and reliability.

1. INTRODUCTION

Fault detection aims to identify evolving faults or degradation in complex industrial systems, aiming to prevent system failures or malfunctions. Early and robust fault detection is essential for optimizing equipment performance and minimizing maintenance and unavailability costs. Recently, data-driven methods have been widely applied to fault detection facilitated by the growing availability of system condition monitoring data (Fink et al., 2020). However, these methods often assume the availability of abundant, representative training datasets to learn a data distribution that is applicable across all relevant operating and environmental conditions. Such representative training datasets are frequently not available due to the high diversity of systems and the wide range of operating conditions. This issue is particularly acute for newly installed or refurbished units with limited observation periods. A potential solution to this problem is to transfer knowledge and operational experience from fleet units with extensive and relevant data to those lacking representative training data. This approach leverages the rich experience and datasets of 'experienced' units to enhance the learning and performance of less experienced ones, aiming to bridge the gap in data availability and representativeness across the fleet. However, such knowledge transfer might lead to insufficient performance, as data-driven methods typically assume

identical and independent distributions (i.i.d) between training and testing data, which does not hold true in real-world industrial complex systems with varying operating conditions and dynamic environments. This leads to significant discrepancies in data distribution between fleet units. Consequently, a model trained on one unit may perform poorly when applied to another, evidenced by a high rate of false alarms, preventing them from benefiting from the existing fleet knowledge.

A substantial amount of research has been performed to address such a challenge by applying domain adaptation (DA) approaches (Yan et al., 2024), which aim to bridge the domain shift between a labeled source and a related unlabeled target domain. However, The scarcity of faulty data in industrial systems introduces specific challenges for DA in fault detection because industrial applications typically lack labeled source data for supervised learning. Furthermore, these methods usually assume discrete source and target domains. However, the operating conditions of complex systems evolve over time, leading to continuous domain shifts within the same unit. Therefore, domain adaptation should not only occur between units but also be continuously applied within a unit, rather than assuming a single, discrete target domain, to ensure robust fault detection.

In this work, we propose a novel approach for fleet-wide continual test-time domain adaptation, aiming to achieve robust anomaly detection across different units of a fleet over time. Our proposed fault detection framework, based on signal reconstruction, integrates a domain adaptive module specifically designed to address the dynamic and evolving environments of complex industrial systems. This approach aims to enhance robustness and adaptability in fault detection within these challenging contexts. To prevent overfitting to the faulty data distribution during adaptation, we categorize the input variables into two groups: control parameters and sensor measurements. We then integrate two domain adaptive modules to adapt to the data distribution of each category separately. This strategy enables us to distinguish between normal variations inherent within the systems and abnormal changes in operating status, thereby improving the accuracy of our anomaly detection framework. By integrating adaptation into the basic fault detection pipeline, TAAD facilitates the transfer of operational experience between different units of a fleet, thereby benefiting from the collective knowledge of the fleet. TAAD has been evaluated on a real-world pump monitoring dataset, and the results demonstrate notable improvements compared to other domain adaptation methods. Our proposed framework is transferable to other industrial applications and enables more timely and robust fault detection in complex industrial systems.

2. Related Work

2.1. Fault Detection in Prognostics and Health Management

Prognostics and Health Management (PHM) seeks to enhance equipment performance and minimize costs by enabling precise detection, diagnosis, and prediction of the remaining useful lifetime as accurately as possible. It integrates the detection of an incipient fault (fault detection), its isolation, the identification of its origin, and the specific fault type (fault diagnostics), along with the prediction of the remaining useful life (Fink et al., 2020). Fault detection aims to identify faulty system conditions based on current operating conditions and gathered condition monitoring data. The complexity of real-world industrial systems poses specific challenges for achieving accurate and robust fault detection. First, faulty data is scarce in real industrial systems. Failures in critical systems, such as power or railway systems, are infrequent. Furthermore, it often takes a considerable amount of time for a system to degrade to the point of failure or the end of life. As a result, faults are often never or seldom encountered during limited time periods and are therefore absent in training datasets.

Consequently, one of the main research directions in fault detection has focused on unsupervised learning, which can be categorized into three main directions(Ruff et al., 2021). Probabilistic models aim to approximate the normal data probability distribution. The estimated distribution mapping function can then be used as an anomaly score. Different deep statistical models have been applied for probability-based anomaly detection, such as energy-based models (EBMs) (Zhai, Cheng, Lu, & Zhang, 2016). One-class classification models directly learn a discriminative decision boundary that corresponds to a desired density level of normal samples, instead of estimating the full density (Ruff et al., 2021). This approach aims to learn a compact boundary that encloses the normal data distribution (J. Wang, Qiu, Liu, Yu, & Zhao, 2018; Z. Zhang & Deng, 2021). Reconstruction-based methods learn a model, such as autoencoders (AEs), are optimized to reconstruct the normal data samples well and detect via reconstruction error (Lai et al., 2023; Hu, Zhao, & Peng, 2022). These models are expected to fit the data distribution under healthy conditions and then raise an alarm for predictions with large deviations when the test data distribution is significantly different from the learned distribution. Thus, the reconstruction error serves as an anomaly score for detecting faults.

Other studies have focused on semi-supervised learning, where it is presumed that a limited number of faulty data samples are accessible for training (Ramírez-Sanz, Maestro-Prieto, Arnaiz-González, & Bustillo, 2023).

2.2. Fleet Approaches for Fault Detection

Unsupervised fault detection, as discussed in section 2.1, relies on the assumption that all possible normal conditions of the system can be learned from a sufficiently large and representative training dataset. However, collecting a dataset representative enough for new systems or refurbished units to cover all possible normal operating conditions within a short time period is unlikely. While extending the observation period can facilitate the collection of more comprehensive data, it also hinders early monitoring of the system. In such cases, transferring operational experience from other similar units with longer and more representative data can significantly enhance robust detection at an early stage. These units can be grouped into a fleet, where each unit shares similar characteristics (Leone, Cristaldi, & Turrin, 2017). A good example would be a fleet of gas turbines or cars produced by the same manufacturer, albeit with different system configurations, operating under varying conditions in different parts of the world (Fink et al., 2020).

The direct transfer of fleet knowledge assumes identical and independent distributions (i.i.d) between training and testing units. However, this assumption often does not hold for complex industrial systems, which are characterized by varying operating conditions and changing environments. This discrepancy poses a significant challenge in transferring a developed model across different units within the fleet. Traditional methods focus on identifying units that are similar enough to form sub-fleets (Leone, Cristaldi, & Turrin, 2016; Liu, Tan, Zhen, Yin, & Cai, 2018; Michau, Palmé, & Fink, 2018; Michau & Fink, 2019). Such methods depend on the entire fleet sharing sufficient similarity and fail when units under homogeneous conditions do not exist or cannot be identified. Recently, domain adaptation has been used to transfer knowledge between units or between different operating conditions within the same unit (Yan et al., 2024), a topic discussed in section 2.3.

2.3. Domain Adaptation Applied to Fault Detection

A substantial amount of research in the field of PHM has focused on domain adaptation, a subtopic of transfer learning, including discrepancy-based methods (J. Zhang et al., 2022; Qian, Wang, Zhang, & Qin, 2023) and adversarial-based methods (Michau & Fink, 2021; Qian, Qin, Luo, Wang, & Wu, 2023; Nejjar, Geissmann, Zhao, Taal, & Fink, 2024). These DA methods aim to align the data distribution between the source and target domains, assuming that the target samples available are abundant enough to represent target data distribution. However, this assumption does not hold true for newly installed systems with limited data samples collected, which prevents prompt system monitoring as discussed above (Michau & Fink, 2021). Furthermore, these methods typically assume one or more discrete, static target domains and attempt to adapt to them. However, operating conditions often evolve continuously over time, potentially leading to unseen distribution shifts in the future. Therefore, it is necessary to continuously adapt to domain shifts on the fly, rather than assuming a single discrete target domain (Q. Wang, Fink, Van Gool, & Dai, 2022).

Test-time adaptation (TTA) aims to adapt a source-pretrained model to a target domain without using any source data. The model is dynamically updated on the fly, based on the current data batch, without exposure to the entire target data set. Representative methods utilize batch normalization, estimating and normalizing mean and variance on each batch to update the model (D. Wang, Shelhamer, Liu, Olshausen, & Darrell, 2021; Liang, Hu, & Feng, 2020). Thus, TTA can be applied to adapt batch data online, accommodating continuous domain shifts for fault diagnosis (Q. Wang, Michau, & Fink, 2019). Although this branch of methods can be directly adapted for the fault diagnostic task, it is not suitable for unsupervised fault detection. In scenarios of unsupervised fault detection, where detection is based on deviation from the norm, applying TTA to the current batch of data with unknown labels may cause the model to unintentionally fit potentially faulty data within this batch. Consequently, the anomalies might not be recognized as out-of-distribution, leading to a reduced ability of the model to identify faults based on prediction errors.

To conclude, robust fault detection in PHM at the early stage encounters the challenge of data scarcity. Fleet approaches help units that are newly taken into operation benefit from fleet knowledge, while their transferability is constrained by the high variability of system operating conditions within the fleet. Current DA methods applied for fault detection cannot simultaneously address all of the challenges we discussed above. They either fail to adapt to continuous domain shifts or are incompatible with the limited data and label availability elaborated above.

3. METHODOLOGY

3.1. Problem Definition

The primary motivation of this research is to transfer knowledge from one system, which has abundant monitoring data, to other systems or fleets operating under varying conditions. Often, these systems and fleets are newly taken into operation, for which only a limited amount of observations can be collected for training. Their data distribution can evolve continuously due to changes in operating conditions and environmental factors. The objective is to adapt the prediction model trained on the original system, enabling it to make accurate predictions for new systems and fleets, even when only a few training samples are available. Given:

- abundant healthy training data from the source system:

$X_s = [x_1^s, \cdots, x_n^s]$, where s denotes the source domain and n denotes the number of data samples from the source domain, and

- limited observed normal data from the target domain: $X_t = [x_1^t, \cdots, x_m^t]$, where t denotes the target domain and m denotes the number of available data samples from the target domain,

the goal here is to achieve robust fault detection in the target domain t.

The proposed method takes into account limited data availability and varying operating conditions, specifically addressing scenarios where: 1) no anomalies are available for training; 2) only limited target data is available for adaptation; and 3) continuous changes in operating conditions occur during test time.

3.2. Reconstruction-based Anomaly Detection Framework

We develop a reconstruction-based anomaly detection pipeline, which achieves robust fault detection by continuously adapting to novel operating conditions, as depicted in Figure 1. This approach utilizes an autoencoder (AE), denoted as f_θ, trained exclusively on normal source data samples, X_s, for the purpose of signal reconstruction. The goal of f_θ is to accurately model the normal data distribution of X_s with accurate predicted signal value $\hat{X_s}$. The training objective is to minimize the mean-squared error (MSE) between the original data samples X_s, and their reconstructed counterparts $\hat{X_s}$:

$$loss_{MSE} = \frac{1}{n}\sum_{1}^{n}\left(X_s - \hat{X_s}\right)^2 \tag{1}$$

where n denotes the number of training samples. Thus, on the healthy source dataset, we expect a small residual value $\hat{r_s} = \hat{X_s} - X_s$. During testing, data samples generating large residuals are considered out-of-distribution and subsequently labeled as anomalies.

The autoencoder architecture consists of two parts: an encoder f_e and a decoder f_d. f_e comprises three fully-connected layers each followed by a batch normalization layer and a ReLU activation function, which consecutively map the original signal input to feature dimensions of 50, 50, and 10. f_d follows a similar architecture but without batch normalization layers, decoding the latent representation from 10 to 50, 50, and then back to the original signal dimension.

3.3. Anomaly Score and Anomaly Detection

During test time, we compute the fault label $y \in [0, 1]$ based on the reconstruction result. 0 denotes a healthy sample while 1 indicates a faulty sample. Given the i_{th} data sample $X_i = [x_i^1, ...x_i^k]$, we compute its relative residual:

$$r_i = \frac{|\hat{X_i} - X_i|}{\bar{X}_{t\_training}} \tag{2}$$

given its predicted reconstruction result $\hat{X_i}$. k indicates the input dimension. $\bar{X}_{t\_training}$ represents the mean value of target data samples for training (including validation data), which helps scale the residual values. The anomaly score s_i is calculated by integrating the scaled residual values across all sensors:

$$s_i = \frac{1}{k}\sum_{j=1}^{k} r_i^j + max\sum_{j=1}^{k} r_i^j \tag{3}$$

To avoid false detection by outliers with extremely large residuals, the computed anomaly score is smoothed within a certain window length l:

$$s_{i\_smooth} = min\sum_{q=0}^{l-1} s_{i+q} \tag{4}$$

Anomalies are then detected based on s_{i_smooth}, using a threshold determined via statistical analysis of the healthy validation set. We identify the data sample X_i as an anomaly if:

$$s_{i\_smooth} > \alpha * \bar{r}_{t\_training} \tag{5}$$

where α is set empirically with a trade-off between the reduction of false alarms and sensitivity to faults.

In this case study, potential faults are reported and examined daily. Thus, the evaluation of abnormal conditions is conducted on a daily basis, where we compute the number of cumulative abnormal data samples of the day.

3.4. System Variables

Directly applying domain adaptation to the current anomaly detection framework can potentially cause the model to fit unknown abnormal samples in the target domain's current batch during test time, thus impairing the model's ability to detect those faults. To distinguish between data distribution shifts due to changing operating conditions and occurrences of abnormal operating status, we split the input parameters into two groups: $X = [x, w]$. w denotes control variables, indicating variables that control system conditions. These variables are set by the operators or by the control system to optimize the performance under specified conditions. x represents sensor measurements, which are sensor signals monitoring system components and reflecting real-time system states. Here, we assume that changes in the distribution of control variables do not necessarily indicate an abnormal status but rather distinct operating conditions to which we should adapt.

3.5. Test-time Domain Adaptation Anomaly Detection

Figure 2 illustrates our proposed cross-domain, reconstruction-based anomaly detection framework TAAD, inspired by recent advancements in test-time domain adaptation. This framework enables us to achieve robust anomaly detection across different domains through online adaptation. Based on the pretrained reconstruction framework introduced in 3.2, we integrate an adaptive module, h_ϕ, for test-time domain adaptation to bridge the domain gap between the source and target domains. The decision to incorporate a separate adaptive module, h_ϕ, rather than embedding adaptive layers directly into the reconstruction model, stems from limitations observed in unsupervised anomaly detection. TTA methods, such as AdaBN, adapt to each batch during test time, inevitably fitting the distribution of abnormal data points. This impairs the model's ability to distinguish between normal and abnormal samples. Instead, our adaptive module takes the predicted value and original controlled system variables as inputs. By excluding monitoring data signals from adaptation, this approach prevents overfitting to the potentially faulty data distribution, thereby preserving the model's capability to accurately distinguish anomalies.

The adaptive module is a simple network composed of two fully connected layers that map the group of control variables from its original feature dimension to 10, and then back to its original dimension; the first is followed by a batch normalization layer and ReLU activation, while the second is followed by ReLU activation only. This adaptive module exclusively processes the control variables w as its input. During the adaptation phase, the pre-trained autoencoder f_θ is frozen, and the adaptive module h_ϕ is trained on a few target data samples to predict Δx, aimed at compensating for the large prediction errors due to the domain gap between source and target data. To address continuous domain shifts during test time, an AdaBN layer is incorporated into the adaptive module. This layer updates its mean and variance based on batch statistics during test time. The predicted δx is then added to the original prediction made by f_θ to compensate for inaccurate predictions caused by operating condition domain shift.

4. Case Study on Real-world Pump Dataset

4.1. Industrial Pump Dataset

In this case study, we aim to achieve early and robust fault detection while reducing false alarms under normal operating conditions. We evaluate our proposed method on a case study of a real industrial dataset, highlighting its effectiveness in achieving early fault detection and minimizing false positive alarm rates. The experiments are conducted on a real-world pump dataset, which comprises condition monitoring data collected from users with installations of various types of pumps in different locations. As a result, these data represent real-world, noisy data distributions and encompass a wide range of diverse domains, including operating conditions, environments, and pump types. In this dataset, we apply the proposed methodology to obtain robust adaptation across pumps, stations, and different pump types.

The selected dataset has two installation stations, with four Heat Transfer Fluid pumps installed at each, and the pumps are equipped with dual seals of two different types. Several seal failures were recorded for seven out of eight pumps during the data collection period. This dataset is marked by continuous changes in operating conditions as the controlled parameters are adapted by the operators regularly. We chose five pumps from this dataset with enough recorded data samples for validation for the case study, as summarized in Table 1. To comply with data policy requirements, we use virtual dates (year.month.day) to represent timelines. Fault durations reported by on-site operators may lack precision due to delayed inspections. Additionally, faults often occur significantly earlier than actual failures, and systems do not immediately return to normal conditions after maintenance of those failures. Given these factors, we consider data samples within a two-month window of any reported faults as uncertain regarding their health status. Therefore, we exclude them from both training data and the subsequent evaluation of false alarms.

We categorize the input variables according to the sub-components associated with the pumps of this dataset. The studied pumps are composed of four main parts: pump bearings, pump driver axial bearings, motor bearings, and seals. Since only seal faults are reported in this dataset, we specifically focus on performance and seal-related variables, while disregarding other

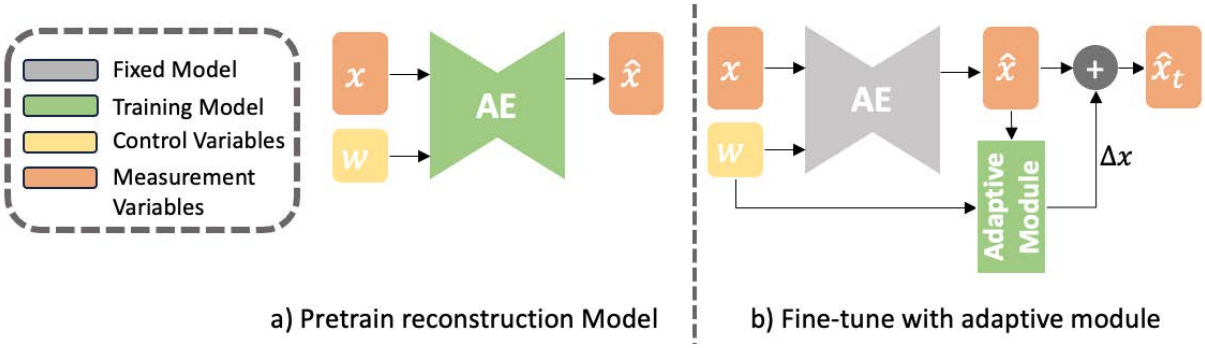

Figure 2. Test-time domain Adaptation Anomaly Detection (TAAD). a) We first pretrain the reconstruction-based anomaly detection model on the source dataset; b) For domain adaptative prediction, we add domain adaptive module and train it on the target training data.

parameter groups. The used parameters are displayed in table 2. Sensor monitoring data are available for both the drive end (DE) side and non-drive end (NDE) side of the pumps, reflecting the state of the dual seal on either side and its primary and secondary components. We exclude pump seal level variables due to their frequent manual adjustments, which do not accurately reflect the operating status of the pump seal. Instead, we focus on variables within the pump performance group, which represent the general operating condition of the current pump. In all our experiments, we designate the seal DE and NDE variables as x and the pump performance group variables as w inputs, as introduced in Section 3.4.

Group	Description	Variable
Pump DE Seal	Dual Seal Parameters	pump DE seal pressure

Table 2. Groups of input variables of the industrial pump dataset

4.2. Details on Data Selection and Implementation

Robust fault detection is critical for newly established industrial systems, posing a challenge due to the brief operational history of such pumps. Our goal is to enable early fault detection capabilities with minimal data. To address this, we adopt a strategy where a source model is pretrained on a well-established pump with abundant data samples, then adapted to target pumps with limited operational data. This approach aims to achieve robust fault detection on target pumps despite the limited available data for these new installations.

We select pump B-C as our source domain, ensuring that abundant normal data samples are available for training. We train the source model on this pump using data samples from a 12-months period and validate it with an additional 12 months of healthy data. The remaining pumps are treated as target domains, each with limited training samples. For each pump, we use three months of normal data samples for training and one month for validation. The training and testing data for the target domains are summarized in Table 3. Due to sensor failures, some data samples lack measurements related to seal components. Considering that only four parameters are available for each seal, with each being crucial and independent of the other parameters, we exclude any data samples with missing measurements. We use the Min-Max Scaler to scale the signals to a range between 0 and 1.

During test time, we combine the 3-month training and 1-month validation data in the target domain to compute the threshold $\bar{r}_{t\_training}$ for anomaly detection. We set $\alpha = 1.5$ for domain adaptation within the same installation station and $\alpha = 2.0$ for adaptation across stations, as the domain gap is comparatively larger.

4.3. Evaluation Metrics for Robust and Early Detection

Given the real-world nature of our dataset, which features imbalanced data, limited collected samples, and uncertain labels for validation, traditional evaluation metrics such as F1 score

and accuracy may not be applicable. To align with needs and interests in real industrial application scenarios, we evaluate TAAD from two perspectives: 1) minimizing false alarms on normal data samples caused by domain shift and 2) achieving early detection of significant system faults.

Unsupervised fault detection relies on the assumption that the model learns the healthy data distribution and identifies deviating distributions as faults. As the operating conditions of complex industrial systems vary, novel operating conditions that have not been seen by the model are often identified as faults. Such false positive (FP) predictions need to be avoided. To assess the effectiveness of TAAD in reducing false alarms due to domain shift, we test TAAD on data collected under unseen healthy conditions with only positive samples. Thus, any reported faults are FP. We identify periods of known normal operations and evaluate the prediction results for these periods, excluding data samples from two months before and after any reported fault to avoid periods of potential pre-fault conditions. The evaluation periods vary for each pump due to data sample availability limitations, as detailed in Table 3. We determine the count of FP, which indicates inaccurately predicted faults, and compute the false positive rate: $\frac{FP}{FP+TP}$ (TP indicates true positives). The lower the rate, the better our adaption to novel operating conditions and our ability to avoid false alarms.

Faulty conditions vary in severity levels. The system or a specific component can continue to operate despite the occurrence of faults, gradually degrading until a complete failure. This gradual degradation can lead to more severe faults, ultimately stopping operation and potentially leading to secondary damages. Therefore, our goal is to achieve early detection before the faults are observed and recorded. For early detection of system faults, we summarize all reported faults for each pump in Table 3. We conduct an evaluation starting 14 days before the recorded fault date to determine the earliest point of detection achievable by TAAD. This evaluation, performed daily as stated in section 3.3, focuses on the first predicted abnormal day. This value indicates how early we can detect potential faults in the system and preemptively address them. Additionally, we report the number of days detected as anomalies within this 14-day window to assess detection robustness. A higher count of abnormal days following the initial fault observation indicates better robust detection capability in consistently issuing alarms, enhancing certainty to involve on-site inspection and minimizing missed faults.

5. Experimental Results Pump Case Study

Experiments on fault detection in this pump system, which includes two installation stations, involve two distinct case studies: intra-station transfer, where the domain gap is relatively smaller, and inter-station transfer, which has a larger domain gap. The proposed method is compared with AdaBN and MMD, as well as with the baseline model without adaptation on the target data. Performances are reported based on the evaluation metrics introduced in section ref. General experiment results are summarized in Table 4.

5.1. Case 1: Transfer within Station

In the first case study, we evaluate the adaptation performance of our TAAD applied to two pumps characterized by a relatively small domain gap. These two pumps are installed at the same station as pump B-C, on which we train the source model.

Pump B-D: Two seal leakages were observed after the training time period of this target pump. We visualize this case in Figure 3 for a better understanding. The yellow vertical lines mark the recorded first occurrence data of the faults. We scatter the predicted faults of each method on a daily basis. In the case of the earlier secondary seal leakage, occurring 4 months after the adaptation, all methods managed to detect it, however, TAAD not only detected it but also did so earlier and the detection is more robust with more true positives. Regarding the later primary seal leakage, which occurred 1 year 7 months after adaptation, all other methods failed to trigger any alarms as the operating condition evolved. In contrast, TAAD successfully detected the reported fault 9 days in advance, registering 8 abnormal days, thus demonstrating its superior adaptability to long-term changes in operating conditions. As AdaBN does not consider source data and thus tends to overfit current batch statistics, it fails to detect any fault. Furthermore, compared to MMD, TAAD effectively reduced false alarms, highlighting the robustness of our proposed approach, which benefits from avoiding overfitting to unstable and unrepresentative measurement variables during adaptation.

Pump B-B: A leakage in the secondary seal is reported 5 months after the training period for adaptation. Given the proximity of the event and the small domain gap, all methods were capable of predicting the fault 14 days in advance. In this scenario, TAAD significantly reduced the false alarm rate from 0.15 to 0.02 by adapting to changing operating conditions. Even when compared to MMD – which benefits from access to the source domain's training data for direct data distribution alignment – TAAD demonstrated superior adaptation capabilities by avoiding overfitting to the system's atypical operating status.

5.2. Case 2: Transfer across Stations

This case study involves transferring a model pre-trained on pump B-C from station B to station A, anticipating a significantly larger domain gap due to variations in environments and operational regimes across the stations.

Pump A-A: Two seal leakage faults were reported succes-

target domain	training time period on target domain	normal test time period	fault type	faulty time period
B-B	00.01.01-05.01	00.05.01-06.01	secondary seal replacement	00.10.07-10.14
B-D	00.01.01-04.01	00.11.01-01.01.01	secondary seal leakage	00.08.07-08.22
			primary seal leakage	01.11.12-11.13

			secondary seal leakage	01.12.26

Table 3. Experimental settings on pump dataset. We report the training time period for domain adaptation for each pump and the normal test time period with no observed faults in between for evaluating the false alarm rate. We report the fault type and the observed faulty time period of each occurrence of fault to evaluate the detection days in advance and the number of detected abnormal days within 14 days prior to the first reported date of the fault. The dates are represented by virtual dates with the same duration and intervals as in the real dataset due to the data privacy policy.

target domain	num of normal samples	false alarm rate ↓				fault type	detection days in advance ↑				num of detected abnormal days within 14 days ↑			
		baseline	AdaBN	MMD	TAAD		baseline	AdaBN	MMD	TAAD	baseline	AdaBN	MMD	TAAD
B-B	1903	0.15	0.03	0.05	**0.02**	secondary seal replacement	**14**	**14**	**14**	**14**	**12**	**12**	**12**	**12**
B-D	2275	**0**	**0**	0.01	**0**	secondary seal leakage	2	0	2	**4**	1	0	1	**3**

						primary seal leakage	0	0	0	**1**	0	0	0	**1**
A-C	2135	**0**	**0**	0	0.07	primary seal leakage	0	0	0	**1**	0	0	0	**2**
						secondary seal leakage	0	0	0	**14**	0	0	0	**6**

Table 4. Experimental results on pump dataset. We compare our method with the baseline model w/o domain adaptation, AdaBN, and MMD, and report the false alarm rate and detection days in advance on 4 pumps across two stations. The best results are in bold.

sively 3 months after the training time period for adaptation on this target pump. For the first secondary seal leakage fault, TAAD achieved the earliest detection with the highest number of days detected as anomalies within this 14-day window before the recorded fault and only 1% false alarms during the normal operating period. Detecting the subsequent primary seal leakage proved much more difficult, as it occurred shortly after the maintenance of the previous fault and operated under unstable and significantly different operating conditions. Here, while all the compared methods failed to detect the fault, our proposed method managed to raise an alarm on the last day before the fault was reported.

Pump A-C: Two seal leakage faults were recorded. The other methods failed to detect either fault, whereas TAAD successfully reported both. However, in this challenging scenario, TAAD increased the false alarm rate by 7% due to the less accurate adaptation.

Generally, experimental results confirm that detecting faults is more challenging than in intra-station cases. Nonetheless, TAAD successfully detects faults under these challenging scenarios, outperforming other methods.

5.3. Discussion

We demonstrate the effectiveness of TAAD to achieve early and robust fault detections in the above two case studies. First, TAAD significantly reduces the false alarm rate under easy-to-detect scenarios compared to other methods, as proved in case 1 on pump B-B, when the target pump is installed within the same station with a smaller domain gap and the fault happens shortly after the adaptation training. Second, TAAD remains effective and robust long after the initial adaptation phase, as shown in the inboard seal leakage of pump B-D and the outboard seal leakage of pump A-C. Those cases demonstrate the ability of the proposed method to adapt to dynamic evolving operating conditions Third, TAAD achieves robust detection under significant domain shifts across different installation stations compared to other methods which fail to detect before the occurrence of faults, as shown in the experiments on pumps A-A and A-C.

In general, our TAAD achieves overall better performance than the other methods achieving earlier detections, and providing more continuous and robust detection within the time window before fault occurrences, all while maintaining a low false alarm rate.

6. Conclusions

In this paper, we propose an effective continuous test-time domain adaptation approach TAAD for efficient and robust anomaly detection under evolving operating conditions. This approach does not require labeled faulty data and needs only a minimal amount of normal data samples for adaptation. Such requirements align well with the practical needs of real-world

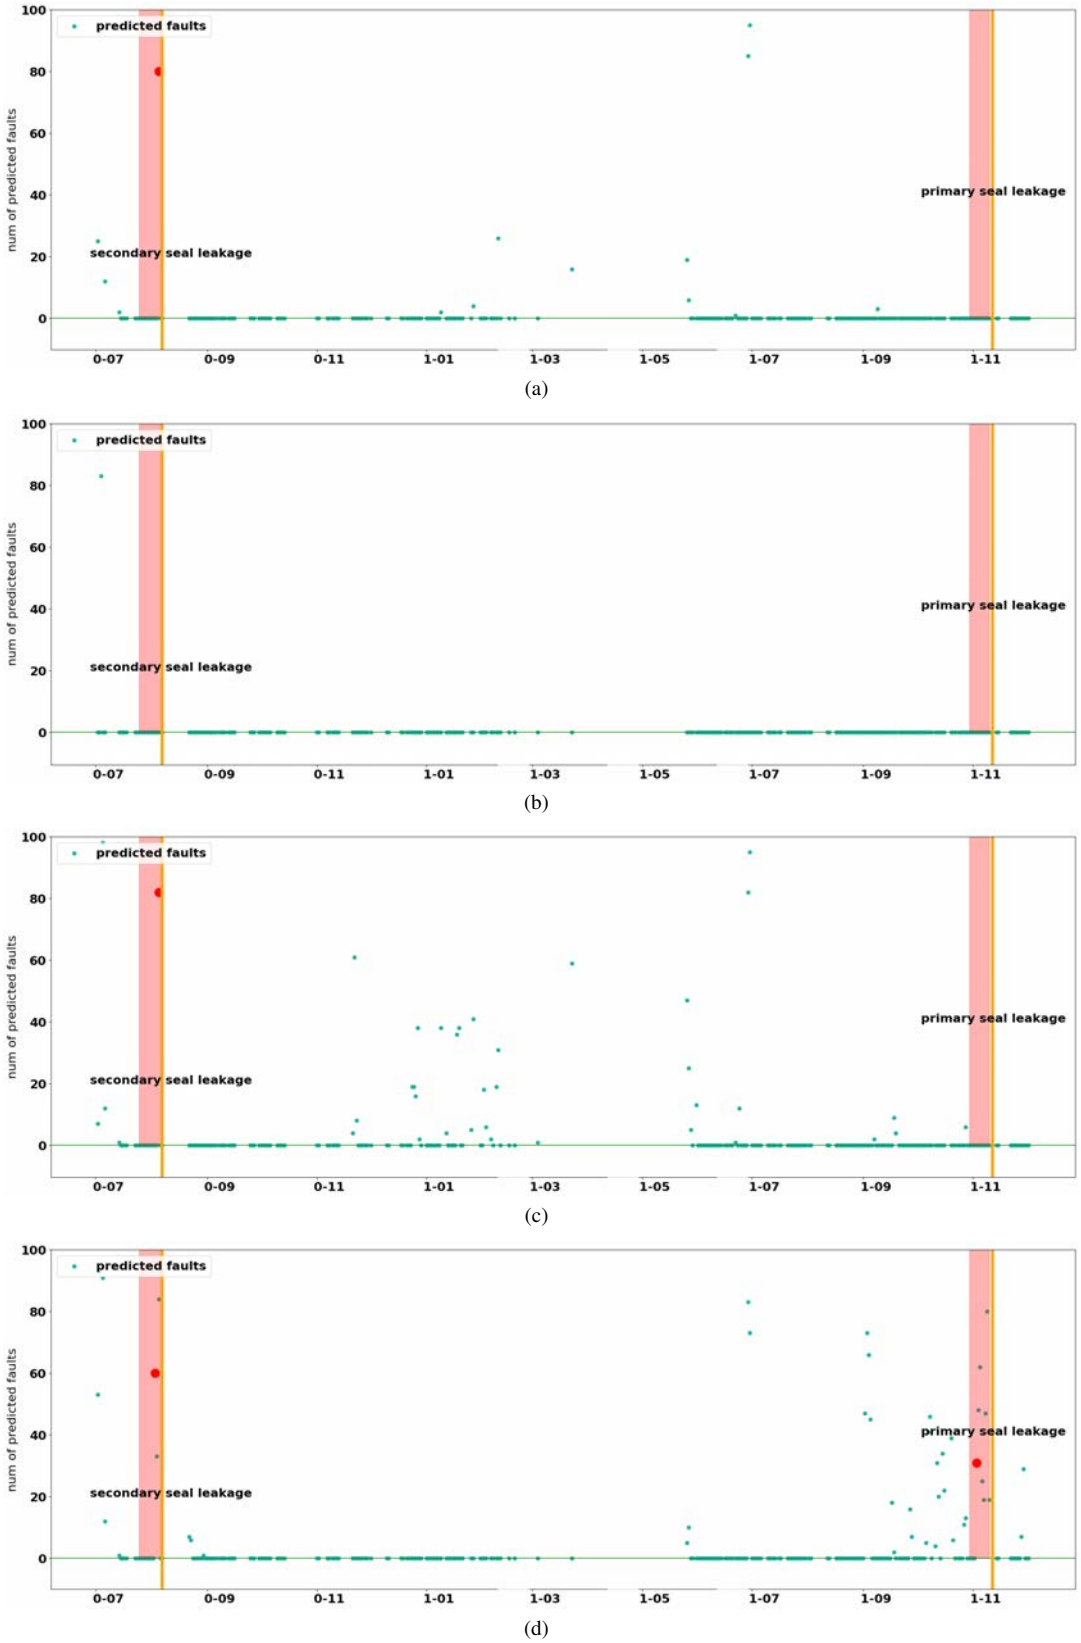

Figure 3. Comparison of performance of (a) baseline (b) AdaBN (c) MMD (d) TAAD for fault detection on Pump B-D. The number of predicted faults per day is plotted. The yellow lines mark the starting date of the reported faults. Red regions mark the 14-day time window before the occurrence of reported faults, and the red dots within this region mark the first detected abnormal day within this period.

industrial systems. We compared our method with two other representative domain adaptation methods. The experimental results demonstrate TAAD's effectiveness in achieving early fault detection under significant domain shifts, both across different stations and over time, while maintaining a low false alarm rate.

Despite its satisfying performance, we see potential improvements in the current method. First, our adaptive module continuously adapts to the current batch without considering the size of the domain gap. We hypothesize that the performance could be enhanced by re-training this module once a significant domain shift is detected. Second, the thresholding parameter α is currently determined empirically. An automatic adjustment of this parameter, taking into account both distribution shifts and operational requirements, could optimize the trade-off between minimizing false alarms and attaining prompt fault detection.

ABSTRACT

The complexity of modern electro-mechanical systems require the development of sophisticated diagnostic methods like anomaly detection capable of detecting deviations. Conventional anomaly detection approaches like signal processing and statistical modelling often struggle to effectively handle the intricacies of complex systems, particularly when dealing with multi-variate signals. In contrast, neural network-based anomaly detection methods, especially Auto-Encoders, have emerged as a compelling alternative, demonstrating remarkable performance. However, Auto-Encoders exhibit inherent opaqueness in their decision-making processes, hindering their practical implementation at scale. Addressing this opacity is essential for enhancing the interpretability and trustworthiness of anomaly detection models. In this work, we address this challenge by employing a feature selector to select features and counterfactual explanations to give a context to the model output. We tested this approach on the SKAB benchmark dataset and an industrial time-series dataset. The gradient based counterfactual explanation approach was evaluated via validity, sparsity and distance measures. Our experimental findings illustrate that our proposed counterfactual approach can offer meaningful and valuable insights into the model decision-making process, by explaining fewer signals compared to conventional approaches. These insights enhance the trustworthiness and interpretability of anomaly detection models.

1. INTRODUCTION

Modern electrical and mechanical systems are increasingly equipped with more sensors, enabling the development of new anomaly detection methods to identify and alert on deviations indicating failures or malfunctioning. Traditionally, these anomaly detection systems were meticulously designed for specific machines and specific components. However, this requires deep domain knowledge and understanding of the systems.

Recent data-driven approaches offer a compelling alternative. They leverage generalizable algorithms that can learn from data, eliminating the need for expert-crafted rules for each specific scenario. This reduces the efforts required for building an anomaly detector. Neural networks, in particular, have shown remarkable effectiveness in anomaly detection for various applications (Schmidl, Wenig, & Papenbrock, 2022).

Detecting anomalies in a system using sensor data is a task within the field of multivariate time-series analysis. Current trends of neural-network based time-series anomaly detection methods fall under two main categories, i.e., forecast and reconstruction (Schmidl et al., 2022). The forecasting methods are state-based models, they learn the inherent mechanism for forecasting the future states. When the observations and model forecast deviate by a certain threshold an alarm is raised. On the other hand, the reconstruction-based methods learn to compress the normal data (fault free) to a lower dimensional latent space. This lower dimensional latent space is transformed back to the original space. Any data with the reconstruction error higher than a given threshold is considered anomalous.

In real settings just raising anomaly alert is not enough to act upon it. A context is required, such as to know why the model

is flagging an anomaly and which sensor data is behaving anomalous. Neural networks are inherently black-box models and neural-network-based anomaly detection does not naturally provide its internal decision-making process. Significant progress has been done within the field of explainability in this direction (Molnar, 2020). The explainability methods can provide global or local explanations. The global explanations aim to distill the model in an easily understandable logic form (i.e., to explain the model mechanism). Whereas the local explanations aim to explain the prediction of each input sample, e.g., Saliency map and counterfactuals.

Counterfactual explanation is a promising tool that provides context to the anomalies found by neural-network-based models. This explanation method is especially interesting for diagnostic applications, as their explanation focuses on answering the question: 'why is sample A classified as an anomaly and not normal?'. The usual approach for building counterfactual explanations is to start from an anomalous sample and optimise it via a cost function, towards a counterfactual sample which would be classified as normal by the same model that classified it as anomalous. To our knowledge, there is very limited amount of work focused on explaining time series anomaly detection (Haldar, John, & Saha, 2021; Sulem et al., 2022). From the perspective of component diagnostics and maintenance, the existing approaches have a crucial limitation: they often modify all features within a time series to explain the anomaly. The freedom of adjusting just any signal of the anomalous sample in the optimisation process to change the classification averages out valuable information and spreads it over many signals. This loss of information makes it more difficult to interpret the generated counterfactual and makes it less useful for root-cause analysis and diagnostics.

For gaining valuable insights into the anomalies, it is crucial to know the specific features responsible for the anomaly *and* the reason behind the model's classification. As discussed in the previous paragraph, conventional counterfactual explanations solely address the reason behind the anomalies. In this work, we propose an explanation method that identifies the relevant features *and* simultaneously explains the reason behind the anomaly detection for time series reconstruction-based models.

Our approach was tested on the SKAB benchmark data (Katser & Kozitsin, 2020) and on a real-world industrial time-series data using Auto-Encoder based anomaly detection. The results show that counterfactual explanations, using the proposed approach, provide insightful explanations about the nature of the anomalies such as correlation loss and data drift.

2. Related Work

Counterfactual explanation approaches in general have different focuses, including generating valid, sparse, actionable, and causal explanations (Verma, Dickerson, & Hines, 2020). Few address the problem of explaining time-series or anomaly detection. Haldar et al. (2021) investigate the challenge of generating robust counterfactuals for anomaly detection. They define robust counterfactuals as counterfactual samples that don't flip back to the original class in the vicinity of a certain distance. They solve this by adding a constraint in the cost function used for counterfactual optimisation. Sulem et al. (2022) build upon the previous work DiCE (Mothilal, Sharma, & Tan, 2020) for generating diverse counterfactual bounds for time-series anomaly detection. They promote diversity on the generated counterfactual to address the problems of classical counterfactual explanation methods, i.e., generating only one of many possible solutions. Here, their focus was to provide explanation bounds through diverse explanations.

Other research, such as that by Li, Zhu, and Van Leeuwen (2023) and Antwarg, Miller, Shapira, and Rokach (2021), utilise feature importance, a different class of explanations, for Auto-Encoder based anomaly detection. In contrast to ours, their studies do not target time-series data. Antwarg et al. (2021) use a Shapley-values-based approach (feature importance) for Auto-Encoders to explain the impact of a certain feature on other features reconstruction. (Chakraborttii & Litz, 2020) use feature level thresholds for explanations and use feature selection to raise alarms individually. However, they do not explain the reason behind the model prediction.

To our knowledge, previous work has focused on providing either the relevant features or the reason behind anomaly detection. Whereas our approach provides both; the relevant features responsible for the anomaly and the reason why the model classified it as an anomaly. These two factors play a vital role in planing a meaningful action for diagnostics, such as troubleshooting and maintenance scheduling.

3. Preliminaries

3.1. Auto-Encoder (AE)

Auto-Encoders (AE) are unsupervised modeling approaches. An AE model reduces the input, i.e., high dimensional data $x \in \mathbb{R}^n$ into a low dimensional latent representation (encoding) $z \in \mathbb{R}^k$, where $k < n$, using an encoder $E(x, w_e)$. This encoder is followed by a decoder $D(z, w_d)$ which reconstructs the input (decoding) $\hat{x} \in \mathbb{R}^n$ from the latent representation. The encoder and decoder are neural networks with parameters w_e and w_d, respectively. The training process optimises the parameters of the encoding and decoding functions to provide a reconstruction $\hat{x}$ as close as possible to the input x. Some common loss functions utilised are mean square error (MSE), mean absolute error (MAE), and Huber loss.

To extend the AE approach to time-series data we use convo-

lution-based architectures for the encoder and the decoder. We pre-process the data into time-windows. A time-window of length l is represented as $X = (x_t, ..., x_{t+l}) \in \mathbb{R}^{n \times l}$, where $x_t \in \mathbb{R}^n$ are the signal values at time t.

3.2. Gradient based Counterfactual Explainer

In this section, we outline the fundamental principles of gradient based counterfactual explanation techniques. Counterfactual explanations are generated by gradient optimisation on the objective function posed by Wachter, Mittelstadt, and Russell (2017). The objective function $l(x')$ written in general form is given by

$$l(x') = cost(x', model(x')) + (\lambda * d(x, x')) \,, \quad (1)$$

where x is the sample, x' is the generated counterfactual, λ is the weighted factor and the function $d(.,.)$ is a distance measure. This objective function contains two parts, the first part optimises to flip the class (from anomalous to non-anomalous) of the provided anomalous sample and the second minimizes the change between the explanation and the provided sample. Other custom parts can be added depending on the use-case.

In addition to requiring an objective function, this approach also requires the model to be differentiable to be able to use a gradient-based optimisation for counterfactual generation. A simple gradient descent optimisation is given by

$$x'_i = x'_{i-1} - \eta . \nabla l(x'_{i-1}) \,, \quad (2)$$

where i is the optimisation iteration number, η is the step length and x'_{i-1} is the sample form the previous iteration.

4. METHOD

Our approach has three different modules; illustrated in figure 1: 1) Anomaly detector, 2) Feature selector, and 3) Counterfactual explainer. The anomaly detector detects the anomalies. If the provided sample is anomalous, the feature selector provides a list of relevant features to be explained. The counterfactual explainer builds an explanation on the relevant signals that the feature selector selects.

The anomaly detector (module 1) uses an AE, with an encoder *E* and a decoder *D*. The encoder *E* consists of 1D-convolution layers followed by fully connected layers, whereas the decoder *D* uses a mirrored architecture starting with fully connected layers and then 1-D transpose convolution layers. The resulting outputs from the decoder have the same dimension as the inputs. The AE is trained to minimize the reconstruction loss using Huber loss given by

$$L(Y) = \frac{1}{M} \sum_{ij} \begin{cases} 0.5 \cdot y_{ij}/\beta, & \text{for } \sqrt{y_{ij}} < \beta \\ \sqrt{y_{ij}} - 0.5 \cdot \beta, & \text{otherwise} \end{cases} \,, \quad (3)$$

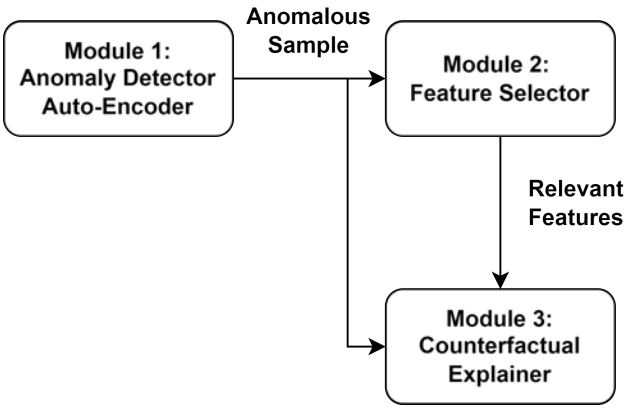

Figure 1. Our proposed methods has 3 modules, 1) Anomaly detector, 2) Feature selector, and 3) Counterfactual explainer. The samples that are classified anomalous by the anomaly detector (module 1) are explained though the feature selector (module 2) and the counterfactual explainer (module 3). The explainer (module 3) uses the selected features from the feature selector and the input sample.

where $Y = (X - \hat{X})^2_\circ \in \mathbb{R}^{n \times l}$, the $\circ$ denotes element wise operation, M is the number of elements of the matrix Y, X is the input to AE and $\hat{X}$ is the reconstruction from AE. Once the AE is trained, the anomaly score (AS) for the validation set is calculated using

$$AS(X, \hat{X}) = MSE(X, \hat{X}) + MAE(X, \hat{X}) \,, \quad (4)$$

where $\left\{X, \hat{X}\right\} \in \mathbb{R}^{n \times l}$ and $MSE(\cdot, \cdot)$ is the mean square error and $MAE(\cdot, \cdot)$ is the mean absolute error of all elements of the matrices. The mean squared error (MSE) element emphasizes larger errors (greater than one) more heavily than the mean absolute error (MAE). Conversely, MAE penalizes smaller errors (below one) more severely. This combination of properties contributes to the effectiveness of the AS. Scores above a threshold are considered anomalous, where the threshold is defined as $\theta_{th} = \mu_{scr} + (k * \sigma_{scr})$ and μ_{scr} is the mean anomaly score on the validation set, σ_{scr} is the standard deviation of anomaly scores on the validation set and k a parameter.

Explanations are provided by the next two modules only when a given sample is classified as anomalous, i.e., when the AS is above the defined θ_{th}. The feature selector (module 2) selects features relevant to the anomaly. It processes the anomalous time window and identifies the features as having either a high or low impact on the anomaly. High-impact features are defined as the ones that are over $m \times percentile(ASW, 90)$ for more than 90% for the window duration, where we choose $m = 0.75$ and ASW is the anomaly score for each feature and time point in the window and is given by

$$ASW(X, \hat{X}) = (X - \hat{X})^2_\circ + |X - \hat{X}|_\circ \,, \quad (5)$$

where $\left\{X, \hat{X}\right\} \in \mathbb{R}^{n \times l}$ and the $\circ$ denotes element wise operation. The key difference between equation (4) and equation (5) lies in the averaging of the error term. ASW in Equation (5) does not average the error, retaining the time and feature dimension assists feature selector to select the right features where anomalies are observed.

The counterfactual explainer (module 3) takes in an anomalous time-window and the features selected by the feature selector. The counterfactual generator uses a modified gradient based explanation (see section 3.2). The difference is that the counterfactual explanation is generated only for the selected features by module 2. This is done by setting the gradients of non-selected features to zero and using the same equation (2) for optimisation, where the $cost$ term is given by the AS in equation (4) and the $model$ given by the anomaly detection AE model.

4.1. Evaluation Metrics

4.1.1. Anomaly Detection Evaluation

As a sanity check, the developed anomaly detection is evaluated with three different metrics; F1-score, False Positive Rate (FPR) and Recall. Equations for these evaluation measures are provided by

$$\text{F1-score} = \frac{TP}{TP + (0.5 * (FP + FN))}\,, \tag{6}$$

$$\text{FPR} = \frac{FP}{FP + TN}\,, \tag{7}$$

$$\text{Recall} = \frac{TP}{TP + FN}\,, \tag{8}$$

where, TP, FP, TN, and FN refer to true positive, false positive, true negative, and false negative, respectively.

4.1.2. Explainability Evaluation

The developed explainability approach is evaluated with measures: *validity, sparsity, and distance*. *Validity* checks if the generated counterfactual is valid, i.e., if the produced counterfactual is classified as normal. *Sparsity* measures the proportion of features changed in order to generate the counterfactual. Finally, the *distance* provides the mean absolute error distance between the sample and counterfactual.

$$\textit{validity}(x') = \frac{1}{N}\sum_{i=1}^{N} \chi\left(AS(x'_i, AE(x'_i)) < \theta_{th}\right)\,, \tag{9}$$

$$ind(x, x') = \chi(\frac{1}{l}(\sum_{j=1}^{l} |x_{ijk} - x'_{ijk}|) > \epsilon)\,,$$

$$sparsity(x, x') = \frac{1}{N}\sum_{i=1}^{N}\left(\frac{1}{n}\sum_{k=1}^{n} ind(x_{ijk}, x'_{ijk})\right)\,, \tag{10}$$

$$d(x, x') = \frac{1}{N}\sum_{i=1}^{N}\left(\frac{1}{l \cdot n}\sum_{j,k} |(x_{ijk} - x'_{ijk})|\right)\,, \tag{11}$$

where $\{x, x'\} \in \mathbb{R}^{N \times n \times l}$

- N: the number of samples,
- l: the sequence length, i.e., the number of time steps per sequence,
- n: the number of features,
- x: sample to be explained,
- x': the counterfactual explanation,
- θ_{th} the threshold used for anomaly detector,
- ϵ: limit defining significant change.
- $\chi(c)$: the indicator function, returning 1 when its argument condition c is true, and 0 otherwise.
- $AE(c)$: is the Auto-Encoder model.

The significant change ϵ in sparsity allows some wiggle room. Typically, this parameter is defined based on the context and the application. In this study ϵ is set to 0.005, i.e., any change above is counted to be a significant.

5. Experimental Setting

5.1. SKAB dataset

(Katser & Kozitsin, 2020) designed a benchmark dataset for time-series anomaly detection. This data is collected from a test-rig consisting of a water tank, valves, and a pump. In this setup, the pump is specifically crafted to extract water from the tank and subsequently circulate it back into the same tank. This setup is equipped with numerous sensors like accelerometer on the pump, pressure sensor after the pump, thermocouple in water, current, and voltage, in total of 8 signals. The collected data is organised in four parts 'no faults', 'valve 1', 'valve 2', and 'others'. 'No fault' has data from normal operation. Data in 'valve 1' and 'valve 2' has data where the corresponding valves were closed for partial duration. The 'others' comprises data from multiple anomaly categories including rotor imbalance, cavitation, and fluid leaks. Each file in 'valve 1', 'valve 2' and 'others' is part normal and part anomalous. It is crucial to note that no two anomaly types co-occur at the same time. The data utilization from different parts of the dataset is summarised in the table 1. The files

$1-4$ are omitted as the data is marked to be simulated and has different characteristics than the other files. After pre-processing into windows, the size of train, validation and test set is 18584, 4658 and 10426 samples. Out of 10426 test samples 3876 are anomalies.

Dataset	Used as	Files
Anomaly-free	80% Train, 20% Valid	All
Valve 1	80% Train, 20% Valid	Only normal behaviour
Valve 2	80% Train, 20% Valid	Only normal behaviour
Others	Test	5-14

Table 1. Table summarizing utilization of SKAB dataset used in our experiments.

5.2. Real-world industrial Data

A commercial, real-world industrial data was collected from a field truck. This data consists of recordings from sensors during normal and anomalous behaviour. Similar to SKAB data, this industrial data encompasses two anomaly types, with no instances of simultaneous occurrences. Two different anomalies were considered: "correlation loss" and "change in relation". A set of 11 relevant sensor signals were utilised for the experiment. The training and validation processes were conducted using two separate dataset containing only normal data (i.e., no-fault data). The test set involved one no-fault scenario and two anomalous runs, where the anomalies were of a different nature. After pre-processing into windows the number of samples in train, validation and test set is 3231, 1074 and 4355 samples. Out of 4355 test samples 1396 were anomalies.

5.3. Model and Explainer Setup

To pre-process the data, we have used min-max normalisation. This involves using the minimum and maximum values from the train-set to normalise the train, validation, and test sets. The time-series sensor signals were pre-processed into smaller chunks using a sliding window technique, with a window length *l* of 64 over *n* signals, *n* being 8 and 11 for SKAB and real-world data respectively.

Experiments on the SKAB dataset employed a random seed of 125. The AE model consists of: i) Encoder with 2 layers of 1D convolution with 64 and 32 filters, kernel size of 5 and stride of 2, followed by a fully connected layer of 8 units; ii) Decoder consists of a mirrored architecture to the above, starting with a dense layer of size 128 followed by 2 layers of 1D transpose convolution with 32 and 8 filters, kernel size of 5 and stride of 2. The model was trained for 150 epochs with a batch size of 64, using Adam optimiser with a learning rate of $\lambda = 0.001$, parameters $\beta 1 = 0.9$, and $\beta 2 = 0.999$, we set $k = 8$ for calculating θ_{th}.

Experiments on the industrial employed uses a random seed of 42. The AE model consists of: i) Encoder with 2 layers of 1D convolution with 32 and 64 filters, padding 1, kernel size of 5 and stride of 1, followed by 4 fully connected layers with 64, 32, 16, and 8 units; ii) Decoder consists of the mirrored architecture, starting with 2 dense layers of size 16 and 32, followed by 2 layers of 1D transpose convolution with 64 and 32 filters, kernel size of 5 and stride of 1. The model was trained for 100 epochs with a batch size of 32, using Adam optimiser (AMSGrad variant) with a learning rate of $\lambda = 0.001$, parameters $\beta 1 = 0.9$, and $\beta 2 = 0.999$, we set $k = 10$ for calculating θ_{th}.

Experiments on both dataset used gradient descent optimisation for 75k iterations, with a learning rate of 0.01 for generating explanations in the the counterfactual explainer (module 3).

6. Results and Discussion

This section is organized into two parts, first evaluation of the anomaly detection and second the results from the counterfactual explanations.

6.1. Results from Anomaly detection

Two AE models were trained, one for each dataset (SKAB and industrial). The anomaly detection threshold was calculated on the validation set, as described in Section 4. The trained models were then evaluated on their respective test sets. The performance of the anomaly detector is summarized in Table 2.

The SKAB dataset results show satisfactory performance with F1-score and Recall around 0.7, along with a False Positive Rate (FPR) of 0.24. The industrial dataset exhibits exceptional performance, achieving F1-score and Recall close to 0.9, with a perfect zero FPR. Anomaly detection confusion matrix for both datasets can be found in Appendix A1.

Table 2. Evaluating anomaly detection models on SKAB and industrial dataset.

Dataset	**F1-score**	**Recall**	**FPR**
SKAB	0.68	0.72	0.24
Industrial data	0.94	0.88	0

6.2. Results from counterfactual Explanation

To demonstrate the effectiveness of our method in explaining time-series anomalies, we compare it with two other approaches:

- **Reconstruction**: This method directly uses the AE reconstruction as the explanation for an anomaly. This is based on the assumption that the reconstructions are projected onto the normal space, hence, a plausible counterfactual explanation.

- **Counterfactual Explainer** (Without Feature Selection): This approach utilizes a counterfactual explainer (module 3) to generate explanations directly for all features, similar to gradient-based counterfactual explanations with $\lambda = 1$ in equation (1). This essentially explains every feature without any selection.
- **Our Proposed Approach** (With Feature Selection): This combines a feature selector (module 2) and a counterfactual explainer (module 3). The feature selector identifies the most relevant features, and the counterfactual explainer then focuses its explanation on these selected features only, with $\lambda = 0$ in equation (1).

We evaluate the explanations generated by these three approaches using three metrics: validity, sparsity, and distance. These metrics are explained in detail in section 4.1.2. The results of this comparison are presented in Table 3.

Table 3. Compilation of evaluation measures from SKAB and industrial dataset. The arrow direction indicates if higher or lower values that makes the approach better.

Dataset	Method	Validity ↑	Sparsity ↓	distance ↓
SKAB	Reconstruction	1.0	1.0	0.246
SKAB	Counterfactual	0.72	1.0	0.214
SKAB	**Ours**	0.67	0.16	0.150
Industrial data	Reconstruction	1.0	1.0	0.140
Industrial data	Counterfactual	0.93	0.99	0.200
Industrial data	**Ours**	0.99	0.17	0.156

Table 3 shows that our approach has reasonably good validity and distance values compared to the other two simpler methods, but with a much better sparsity values than the other methods. Note that the reconstruction method will always have the highest possible validity value due to its nature that the reconstructions are in the same manifold as training data. So this method scores best in this validity measure on both datasets. The counterfactual explainer (without feature selection) has higher validity measure than our proposed method on the SKAB data. The counterfactual explainer (without feature selection) has an advantage of being able to vary all features to provide explanations. This does not necessary mean that the explanation will be more meaningful as by adjusting all features simultaneously the information (the reasons) about the raised anomaly gets diluted. Additionally, altering all signals by the counterfactual explainer (without feature selection) results in a the sparsity scores much worse than our method (with feature selection). Scores form our approach are consistently good in all three measures. To look further into the meaningfulness of the given explanations we illustrate some scenarios in section 6.2.1.

We leverage UMAP embedding (a dimension reduction technique) to achieve two objectives: visualize the relationship between the generated counterfactuals and the test data, and evaluate the *validity* of the explanations independent of the model used for counterfactual generation. In Figure 2 we visualize the UMAP embedding trained on the test-set data from the industrial dataset. Green points represent the non-faulty data (based on ground truth), red points represent the anomalies (based on ground truth), and yellow points represent the projected counterfactuals (generated form our approach). As evident from the Figure 2 the majority of counterfactuals projected on top of the green normal data embeddings, indicating that they represent valid non-faulty behaviors. Only a few, 12 out of 1350 explanation are non-valid (which is reflected in the *validity* measure). These non-valid samples are projected onto the same space as the red faulty data embedding. The lack of valid explanations can be due to parameter selection, optimisation budgets and quality of the feature selection. The validity in confusion-matrix form for the SKAB test data is given in Table 6 in Appendix A2, the validity confusion-matrix form for real-world industrial test data is given in Table 7 in Appendix A2.

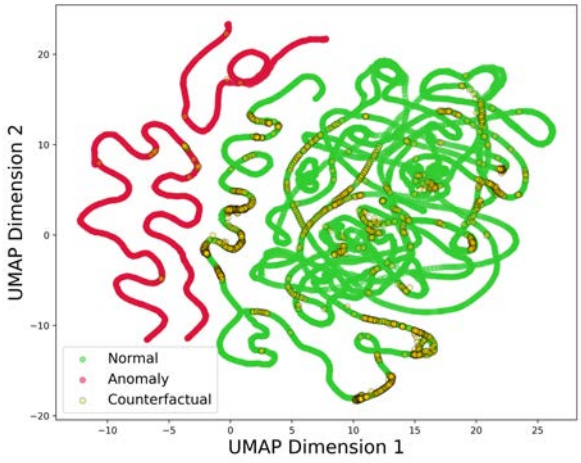

Figure 2. Industrial data: UMAP embedding learnt on no-fault and anomalous data from the test set. Later the generated counterfactual is projected into the same embedding.

6.2.1. Plots showing insights on the explanations

In this section, we show two different explanation scenarios, one from the industrial and the other from the SKAB dataset. Scenario 1 is from the industrial dataset and is illustrated in the Figure 3. The time-window plotted in Figure 3 was classified as anomalous and signal 7 was selected as high impact feature. In Figure 3 we show the input signal 7 and signal 8 in blue and the counterfactual explanation in orange (see Figure 6 in the Appendix A3 for comparison with reconstruction and counterfactual signals). The root cause of this anomaly is a loss of correlation in signal 7. In normal (no-fault) data signal 7 and signal 8 are correlated with a median correlation coefficient of 0.99 and our explanation restored the correlation between the signals on the anomalous data (of this type)

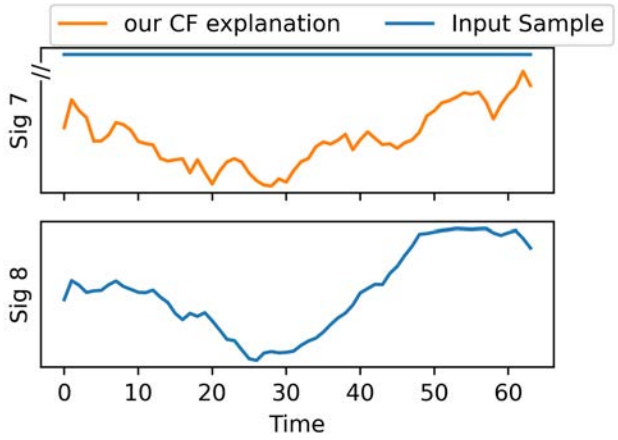

Figure 3. Plot of counterfactual explanation generated by our approach for industrial dataset. This plotted sample was of correlation loss anomaly. Signal 7 and signal 8 in blue show the input and signal 7 in orange shows the explanation.

to a median correlation coefficient of 0.93.

Figure 4 shows the second scenario from SKAB data. Here the selected anomalous window belongs to the rotor imbalance anomaly. This window was classified as anomaly and our feature selector selected Acc1RMS and Acc2RMS signals which belong to the accelerometer sensors as high impact features. The explanation from our approach indicates that the vibrations observed by the accelerometer should be lower to be classified as normal (see the Figure 5 in Appendix A3 to see the comparison with CF and reconstruction signals).

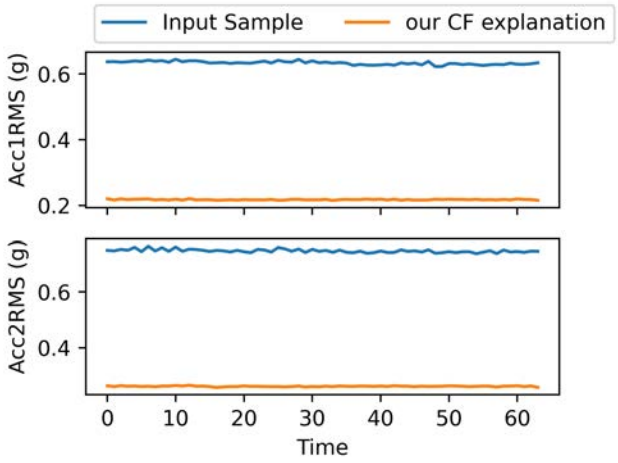

Figure 4. Plot showing the counterfactual explanations provided by our approach and the anomalous samples. Only the high impact features that were explained are plotted.

In Scenario 1, the explanation hints that the the correlation between signal 7 and signal 8 is broken by the flat line and is confirmed by the correlation analysis. Combining this explanation with the domain expertise, it is easy to conclude that the sensor for signal 7 is broken. In Scenario 2 from the explanation we know that we have too high vibrations that often are originated by rotor imbalance. The explanations provided by our approach are meaningful in the context of system functionality and provides insights about the nature of the anomaly when compared to other approaches. This is due to it's capacity to select features for explanation. The comparison between different approaches can be seen in the detail in the Figure 5 and Figure 6 provided in Appendix A3.

7. Conclusion

In summary, our work proposes a method for explaining AE-based anomaly detection for time-series data, based on relevant feature selection and counterfactual explanations. This approach can answer on which features the anomaly is located together with why the sample was classified as an anomaly. We find that these explanations have consistently good scores in all three measures, *validity*, *sparsity* and *distance*, which translates into useful and actionable insights from a diagnostic perspective. We give two examples, one from a benchmark dataset and one from an industrial dataset, on how the proposed method can help to diagnose the classified anomalies from the AE anomaly detection model. This contribution serves as a diagnostic tool, enhancing our understanding and analysis of anomalous events. Note that the quality of explanation depends on the performance of the selected anomaly detection model, parameter selection and the quality of feature selection.

Future work can focus on different optimisations for the explanation, improve the quality of the feature selector and understand the model relation with the explainer.

		Prediction outcome		
		Valid	**Not Valid**	**Total**
Model Prediction	**True Positives**	1338	12	1350
	False Positives	0	0	0
	Total	1338	12	1350

A3. Plot comparing different approaches

A sample from rotor-imbalance anomaly is plotted along with different explanations in the Figure 6. The plotted sample is the same as in the Figure 4. In figure 6, explanations from different methods are compared. It can be seen that other approaches explains by changing all the features where as the explanation from our approach changes only *ACC1RMS* and *ACC2RMS* signals. In similar way , for the sample plotted in the Figure 3, in Figure 5, we compare our approach with other type of explanations.

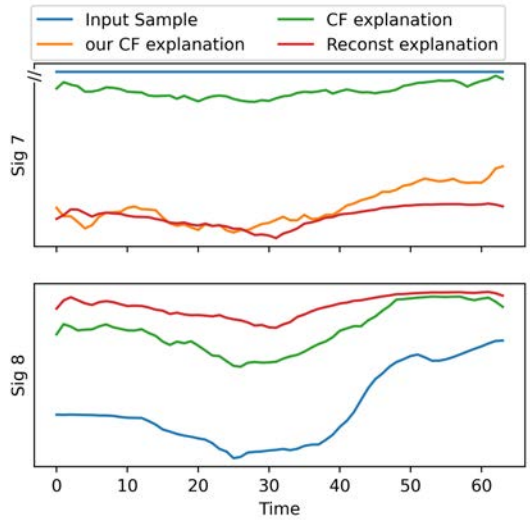

Figure 5. Plot showing the explanations provided by reconstruction, counterfactual(CF) based (i.e., without feature selector) and our approach (i.e., with feature selector). Additionally the input sample is plotted.

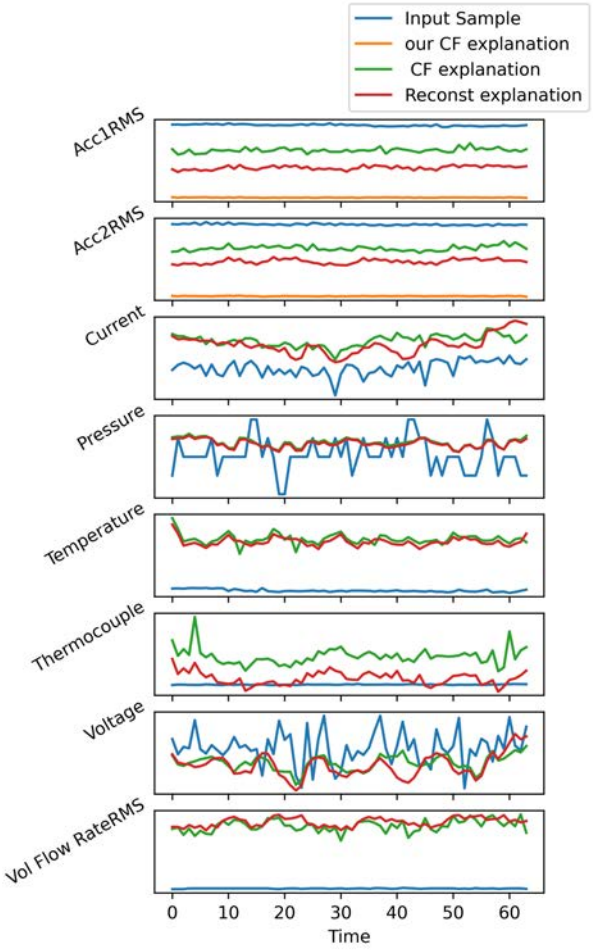

Figure 6. Plot showing the explanations provided by reconstruction, counterfactual(CF) based (i.e., without feature selector) and our approach (i.e., with feature selector). Additionally the input sample is plotted.

Damage Detection using Machine Learning for PHM in Gearbox Applications

ABSTRACT

Early damage detection in gearbox applications enables the implementation of Prognostics and Health Management (PHM). On the one hand, the earliest possible damage detection provides a precise in-sight into the state of health of a gearbox. In addition, early damage detection offers the possibility to slow down the damage progress and extend the remaining useful life (RUL) by intervening in the operating state at an early damage stage. The main contribution of this work is that existing Machine Learning tools are applied to the challenge of very early damage detection in gearboxes. Thus, the need for complex physically based data evaluation is avoided. The aim of this investigation is a comparison of two different machine learning approaches. To investigate the detection possibilities test bench experiments were conducted with a single stage spur gearbox. For a comprehensive investigation, i.e. to detect damage under different operating conditions, the test runs are carried out at different damage sizes, speeds and torques. Based on the recorded vibration data, the damage detection is examined. Two machine learning approaches of anomaly detection are considered: An encoding approach and a loss approach. The same sparse autoencoder is developed for both approaches Both machine learning approaches are able to detect even the smallest damage of about 0.5 % in most operating states. The loss approach allows the different damage stages to be recognized much more clearly than the encoding approach. The comparison of the different approaches provides valuable insights for the further development of robust damage detection algorithms.

1. INTRODUCTION

In many mobile and stationary applications, gearboxes are essential for adjusting speed and torque. The greater the power that needs to be transmitted, the larger and more expensive the corresponding gear units are. In gearboxes one of the most common types of damage on a tooth flank is pitting. As soon as a pitting exceeds a size of 4 % in relation to the size of the tooth flank, the gear is considered as failed according to the 2016 International Organization for Standardization [ISO] report. Damaged tooth flanks are one of the leading reasons of downtime and each failure can be associated with high repair costs and time-consuming repair work. This particularly applies to large gearboxes and applications in remote locations, such as offshore wind power drives. For this reason, gearboxes in critical industrial applications are often equipped with condition monitoring systems (CMS) based on vibration sensors. They continuously monitor the current state of health of the gearbox. If the CMS detects damage, depending on the damage extent, a complete shutdown or a load reduction can be initiated. Expensive subsequent damage can be prevented and, in case of a reduced load, the remaining useful life (RUL) of the gearbox can be extended until it is repaired or replaced. However, the CMS's are only developing their full potential if damage can be detected at a very early stage.

The earliest possible damage detection in gearboxes enables comprehensive Prognostics and Health Management (PHM) to be implemented in gearbox applications. According to Goebel, Celaya, Sankararaman, Roychoudhury, Daigle and Abhinav (2017), a PHM approach consists of the 5 sub-areas of the system: data, diagnosis, prognosis, optimization and the system itself. The earliest possible damage detection affects all of these areas.

First of all, the health of a system, which according to the 2017 Institute of Electrical and Electronics Engineers [IEEE] committee standards include all information regarding the functionality of a system, can be diagnosed much more precisely using the data of the system. The time gained by early damage detection can be used to acquire more data for a possible RUL prediction. Finally, health management of the system can be realized. Health management describes the control of damage according to the aim of the PHM solution

(Bertsche & Dazer, 2023). A potential goal is the optimal utilization of the RUL without unexpected failure until scheduled maintenance. For instance, this can be achieved by avoiding particularly damaging operating points. Another option is to implement an adaptive operating strategy that enables the extension of the RUL without any loss of performance (Gretzinger, Lucan, Stoll & Bertsche, 2020). Due to the application of the operating strategy, the load on the predamaged tooth is significantly reduced. This results in a slowdown of the damage progress. The other teeth on the circumference of the gear, which can still withstand the designated load, are being slightly overloaded. Thus, the load reduction is compensated without any overall power reduction. Control of the plant is carried out by a corresponding optimization algorithm.

Overall, comprehensive PHM in gearbox applications offers numerous benefits. However, damage detection at a very early stage is a prerequisite. The aim of this study is to investigate the earliest possible damage detection in gearboxes with the help of machine learning. Experiments were conducted on a test gearbox, vibration data was recorded and evaluated using an Autoencoder (AE).

2. Experiments and Machine Learning Approaches

Following, the test bench experiments for the earliest possible damage detection are described first. Subsequently, the developed autoencoder is presented. Finally, the two machine learning approaches (encoding and loss), which are based on the developed autoencoder, are discussed in more detail.

2.1. Test Bench Experiments

The test gearbox is designed as a single stage spur gear unit. Figure 1 illustrates the design of the test gearbox. The gear ratio is $i = 25/36 = 0.69$. More information on the test gears in (Binanzer, Merkle, Dazer & Nicola, 2023).

The test bench is set up as an inline concept (2 motor concept). The electric drive motor loads the transmission input side and the second electric motor loads the transmission output side. Torque measuring shafts and incremental encoders for speed and angular position measurement are mounted between the electric motors and the test gearbox. Further information on the test bench setup can be found in (Binanzer et al., 2023). The mounted test gearbox on the test bench is shown in figure 2.

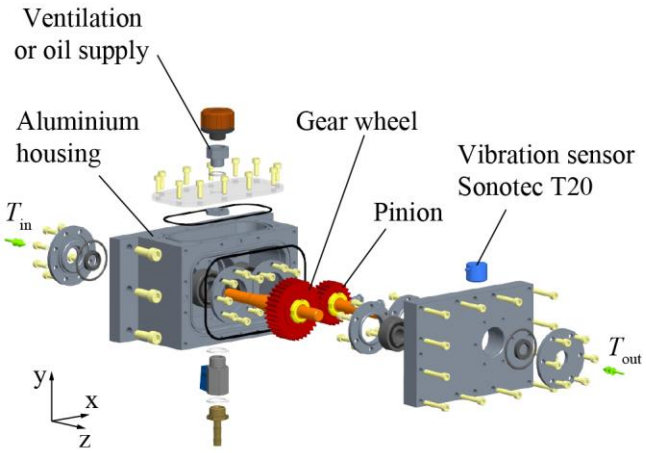

Figure 1. Design of the test gearbox.

For lubricating the tooth contact, FVA reference oil no. 3 (see the 1985 Research Association for Drive Technology [FVA] report) is used. This is a mineral oil without additives with a viscosity corresponding to ISO 3448 (see the report (ISO, 2010)). To ensure constant test conditions, the oil is preconditioned in an external fluid tempering device to 29.54 °C. A gear pump supplies the oil to the tooth contact. A Pt100 temperature sensor in the oil supply measures the oil temperature during the test runs.

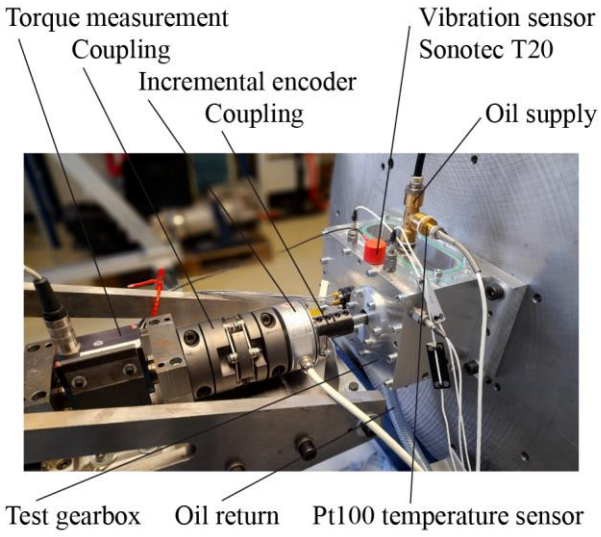

Figure 2. Test gearbox mounted.

The test gearbox is equipped with a Sonotec T20 sensor. This ultrasonic accelerometer is located between the bearings and measures in the y-direction. The maximum measuring frequency of the Sonotec T20 sensor is 100 kHz. However, the sampling rate of the Sonotec T20 sensor is limited to 96 kHz due to the maximum sampling rate of the data acquisition system that is used (PAK MK2). Thus, according to the Nyquist-

Shannon sampling theorem, maximum frequencies of 48 kHz can be measured with the system.

Since the earliest possible damage detection using machine learning algorithms is to be investigated as part of this work, damage well below the 4 % criterion is examined. Artificially generated pitting serves as representative gear damage. Following a test series without damage, a total of three damage sizes are tested - small (S), medium (M) and large (L). The tests without damage serve as a reference and thus as a training data set for the machine learning algorithms. The pitting damage is applied using a numerically controlled milling machine. This ensures that the pitting can be easily and reproducibly manufactured on the tooth flanks. A suitable radius milling cutter with a head diameter of 2 mm is used. Due to the higher number of load cycles, pitting damage usually occurs on the pinion. Consequently, the artificial damage is applied on the pinion. The gear wheel remains undamaged. The pitting is located in the center of a tooth flank below the pitch circle. Figure 3 shows the pinion with the manufactured pitting damage.

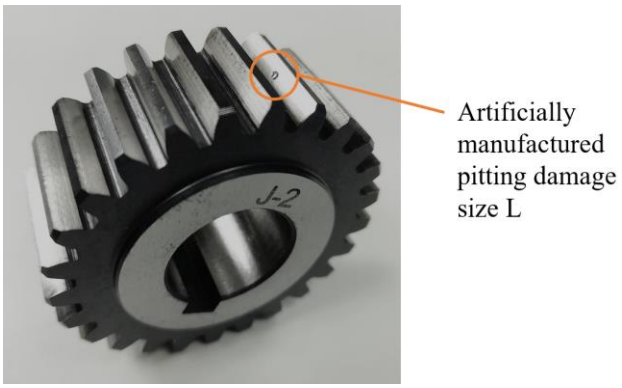

Figure 3. Pinion of second gear pair with manufactured pitting damage size L (1.72 %).

For a comprehensive investigation, i.e. to detect damage under different operating conditions, the test runs are carried out not only at different damage sizes, but also at different speeds and torques. In each of the four test series (no damage, S, M, L), six operating conditions are tested. These six operating states result from a combination of two speed levels (72 rpm, 636 rpm) and three torque levels (18 Nm, 24 Nm, 30 Nm). Within a test series, the six operating states are varied randomly in their sequence. The measurement duration for each test run is 100 s. Between the test series, the damage on the pinion is then artificially applied and milled larger. In this way, increasing damage on the pinion can be tested and the different damage sizes can be directly compared with each other. In order to achieve a more meaningful result, the tests are carried out with a total of three pairs of gears. The pinion and gear are always tested in the same pairs. This ensures that the algorithms do not detect any anomalies caused by manufacturing tolerances or material deviations of different pinion - gear combinations. The only difference between the test series of a gear pair is the increasing damage on the pinion. The surface area of each pitting is measured after the milling process using a digital microscope (see table 1).

Table 1. Pitting surface areas.

Gear pair	Pitting level	Pitting surface in mm^2	Relative surface area in %
1	S	0.48	0.61
1	M	0.97	1.23
1	L	1.40	1.77
2	S	0.40	0.51
2	M	0.92	1.16
2	L	1.36	1.72
3	S	0.62	0.78
3	M	1.01	1.28
3	L	1.40	1.77

2.2. Autoencoder

A test run duration of 100 s and a sample rate of 96 kHz result in 9,600,000 data points per test (acceleration over time). These data points are then converted into the frequency spectrum. For this purpose, Fast Fourier Transforms (FFT) of 10,000 data points each are performed, thus 960 FFT's per test. Each FFT results in 5,001 frequency points. The two rotational speeds of the tests result in the following: At a speed of 72 rpm, approximately 11.6 FFTs are conducted for each revolution of the pinion. At a speed of 636 rpm, approximately 1.3 FFTs are generated for each revolution of the pinion.

The AE developed in this study emerged from literature research and empirical hyperparameter tuning. It is a multilayer AE, which consists of three joined AEs, each with a hidden layer, see figure 4. The number of units in layer l is defined as s_l. The input of the first AE used in this study contains $s_1 = 5{,}001$ units corresponding to the number of frequency points per FFT. Accordingly, layer 3 and 5 have $s_3 = s_5 = 5{,}001$ units. The first hidden layer (layer 2) has $s_2 = 560$ units, the second hidden layer (layer 4) has $s_4 = 200$ units. Finally, the third hidden layer (layer 6) learns a compressed representation of the frequency spectrum with $s_6 = 50$ features. The output after the last decoding process again has $s_7 = 5{,}001$ frequency points. The aim of the AE is to ensure that the output $\hat{x}$ is the most accurate possible reproduction of the input x. For this purpose, the AE has to learn a function $h_{W,b}(x)$ with the parameters W and b, for which the following is valid:

$$h_{W,b}(x) \approx x \qquad (1)$$

Since the AE in this paper has a total of 7 layers, layer 1 corresponds to the input and layer 7 to the output:

$$x = x^{(1)} \tag{2}$$

$$\hat{x} = h_{W,b}(x) = x^{(7)} \tag{3}$$

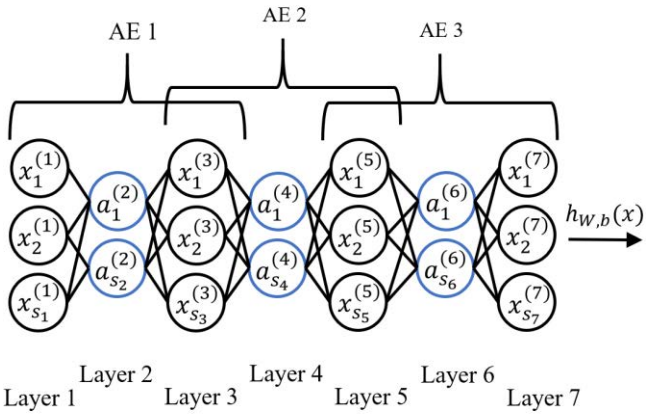

Figure 4. Structure of the Autoencoder.

For parameter W, the notation $W_{i,j}^{(l)}$ is used and this is associated with the weighting of the connection between unit j in layer l and unit i in layer $l+1$ (Ng, 2011). Parameter $b_i^{(l)}$ is the bias associated with unit i in layer $l+1$ (Ng, 2011). Eq. (4) and (5) are valid to the layers of the AE. For this, $a_{s_l}^{(l)}$ corresponds to the output of the hidden unit s_l in layer $l = 2, 4, 6$ and $x_{s_l}^{(l)}$ corresponds to the output of unit s_l in layer $l = 3, 5, 7$.

$$a_{s_l}^{(l)} = f\left(\sum_{i=1}^{s_l-1} W_{s_l,i}^{(l-1)} x_i^{(l-1)} + b_{s_l}^{(l-1)}\right) \tag{4}$$

$$x_{s_l}^{(l)} = f\left(\sum_{i=1}^{s_l-1} W_{s_l,i}^{(l-1)} a_i^{(l-1)} + b_{s_l}^{(l-1)}\right) \tag{5}$$

The function $f(z)$ with $f: \mathbb{R} \to \mathbb{R}$ is called activation function. The sigmoid function (Eq. (6)) is chosen as the activation function in this study. This function can assume values between 0 and 1, see figure 5.

$$f(z) = \frac{1}{1 + exp(-z)} \tag{6}$$

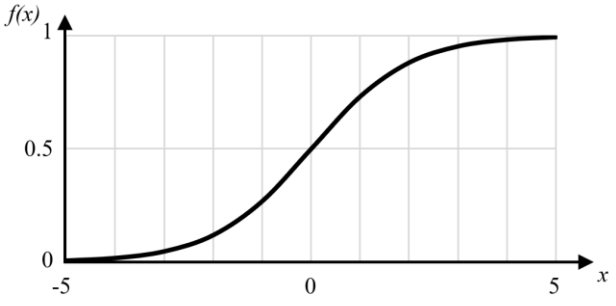

Figure 5. Sigmoid function.

The AE requires training with a training data set with m training examples. The data from the tests without damage serves as the training data set. Thus, the training data set consists of 960 FFTs each ($m = 960$). If training data set number m is used as input, then $x^{(l),(m)}$ results in layer l. The three AEs are trained one after the other. The corresponding loss function $J_{AE}(W, b)$ with $AE = 1, 2, 3$ is defined for training the AE for both approaches (encoding and loss) and consists of three terms:

$$\begin{aligned} &J_{AE}(W, b) \\ &= \left[\frac{1}{m}\sum_{i=1}^{m}\left(\left\|x^{(l+2),(i)} - x^{(l),(i)}\right\|^2\right)\right] \\ &+ \lambda \sum_{l}^{l+1}\sum_{i=1}^{s_l}\sum_{j=1}^{s_{l+1}}\left(W_{ji}^{(l)}\right)^2 \\ &+ \beta \sum_{j=1}^{s_l} KL(\rho \| \hat{\rho}_j) \end{aligned} \tag{7}$$

$$with$$

$$l = 1\ for\ AE = 1;$$

$$l = 3\ for\ AE = 2;$$

$$l = 5\ for\ AE = 3$$

The first term of the loss function is the average sum-of-squares error term (Ng, 2011). It describes the deviation of $\hat{x}$ from x and can therefore also be described as a reconstruction error. The second term is the regularization term, also known as the weight decay term, which tends to reduce the size of the weights W and helps to prevent overfitting (Ng, 2011). It therefore ensures that the network does not simply memorize the data, but learns the underlying structure. The weight decay parameter λ determines the relative importance of the second term. $\lambda = 0.001$ is selected.

Additionally, a sparsity constraint is imposed on the hidden units of layer 2, 4 and 6. Therefore a sparse AE is obtained and the third term of the loss function is the sparsity penalty term. With $\beta = 1$, the weighting of the term corresponds to a single weighting compared to the first term. A sparsity constraint permits the AE to learn the underlying structure in the data even with a large number of hidden units. For this

purpose, the average activation of unit j in the hidden layer l is calculated:

$$\hat{\rho}_j = \frac{1}{m}\sum_{i=1}^{m}\left[a_j^{(l)}\left(x^{(i)}\right)\right] \quad (8)$$

This average activation of the neuron should match the selected sparsity constraint ρ:

$$\hat{\rho}_j = \rho = 0.3 \quad (9)$$

The sparsity penalty term penalized if $\hat{\rho}_j$ deviates significantly from ρ. The penalty term is based on the Kullback-Leibler (KL) divergence:

$$\sum_{j=1}^{s_l} KL\left(\rho \| \hat{\rho}_j\right) = \sum_{j=1}^{s_l} \rho \, log\frac{\rho}{\hat{\rho}_j} + (1-\rho)\, log\frac{1-\rho}{1-\hat{\rho}_j} \quad (10)$$

The aim of training the AE is to minimize the function $J(W,b)$ as much as possible. $J(W,b)$ becomes as small as possible when an optimal combination of the parameters W and b is found. First, these parameters are randomly initialized, then backpropagation is applied. During backpropagation, the connections of the AE's units are either strengthened or weakened via the weightings to further minimize the loss between input and output. Each AE is trained for 100 iterations.

2.3. First evaluation approach: Encoding

After training the AE on the basis of the vibration data of a test without damage, the trained AE is used to evaluate all data of an individual operating condition of this gear pair. For this purpose, the recorded vibration data of the test without damage and the three tests with damage sizes S, M and L are appended to each other and an FFT is generated from 10,000 data points each. This results in a total of 3,840 FFTs. These are each encoded to 50 features using the trained AE. A Principal Component Analysis (PCA) is then used to determine a one-dimensional real number from these 50 features. According to the number of FFTs, 3,840 real numbers are obtained. The first 960 one-dimensional representations of the frequency spectrum are those of the test without damage. The data points are normalized between 1 and 2.

The data points of the test without damage are transformed using a Box Cox transformation. The aim is to modify the data in such a way that it is closer to a normal distribution. This provides a standardized baseline for the comparison with the untransformed data from the tests with damage. For the comparison, the arithmetic mean μ and the standard deviation σ are determined from the transformed data without damage. Three intervals are defined based on the standard deviation:

$$1^{st}\text{ interval: } \mu \pm \sigma \quad (11)$$

$$2^{nd}\text{ interval: } \mu \pm 2\sigma \quad (12)$$

$$3^{rd}\text{ interval: } \mu \pm 3\sigma \quad (13)$$

In case of an optimal normal distribution, 68.27 % of the data are in the first interval, 95.45 % in the second interval and 99.73 % in the third interval, see figure 6.

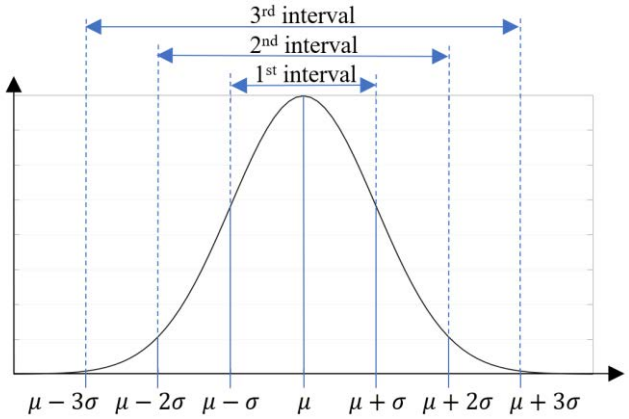

Figure 6. Normal distribution.

Based on the determined intervals, it is calculated how many of the 960 data points each of the tests with damage size S, M and L are outside the intervals. Since the limits of the intervals are further apart as the interval increases, the proportion of data points of the tests with damage that are outside the limits decreases. The first interval will therefore always show a greater deviation between tests without and with damage than intervals 2 and 3.

However, the different machine learning approaches (encoding and loss) can be compared with each other on the basis of the interval method, as it is used in both approaches. If a deviation between the test without and with damage can still be detected with the second or third interval in one approach, the damage is more clearly detectable and the approach is therefore more suitable. The approaches can therefore also be compared in terms of how much the detectability decreases with increasing interval. The less influence the used interval of an approach has on the detectability, the more suitable the approach is.

In the context of this paper, no fixed threshold for the data proportion outside the limits is to be defined with which damage can be detected. Instead, the two approaches (encoding and loss) are to be evaluated and compared with each other based on the predefined intervals.

2.4. Second evaluation approach: Loss

In the second evaluation approach, the AE is also trained on the basis of the vibration data from a test without damage. All vibration data from the test without damage and the three damage variables S, M and L of the individual operating state

are then appended to each other. After 3840 FFTs have been generated from 10,000 data points each, these are encoded and decoded using the trained AE. The FFTs produced by the AE are then compared to the original FFTs by calculating the mean squared error (first term of the loss function, see Eq. 7). The loss approach, such as the encoding approach, provides 960 real numbers per test without damage, damage size S, M and L. Based on this, a Box Cox transformation can be performed again on the data without damage and the three intervals can be determined (see Eq. (11), (12) and (13)). Subsequently, the proportion of data points outside the intervals is calculated for each of the tests with damage.

3. RESULTS

The results of the encoding and the loss approach are presented below.

3.1. Encoding approach

Figures 7 to 12 show the results of the encoding approach of the first gear pair for each operating condition. The lower and upper limits of the first interval are determined on the data without damage (see Eq. (11)). The upper and lower limits are marked with a red line. All blue data points are within this interval, all orange ones outside. For the damage sizes S, M and L, the proportion of data points inside and outside the interval is calculated.

For all operating conditions, it can be seen that the plotted data points per damage size scatter significantly. Overall, this applies even more to the higher speed level of 636 rpm than to the lower speed level of 72 rpm. The most difficult pitting to detect using the encoding approach for the first gear pair is pitting M at 72 rpm and 24 Nm (see figure 8). Here, only 20.2 % of the data points lie outside the first interval. The difference is therefore not as significant as with the other pitting sizes or operating conditions, for which at least 33.5 % of the data points always lie outside the interval.

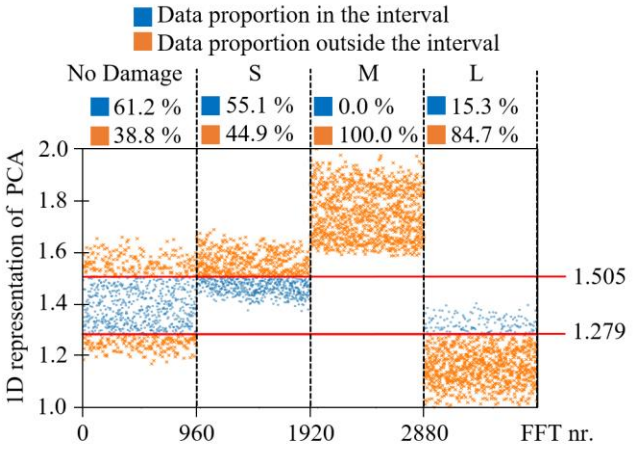

Figure 7. Encoding approach, 1st gear pair, 72 rpm, 18 Nm, 1st interval.

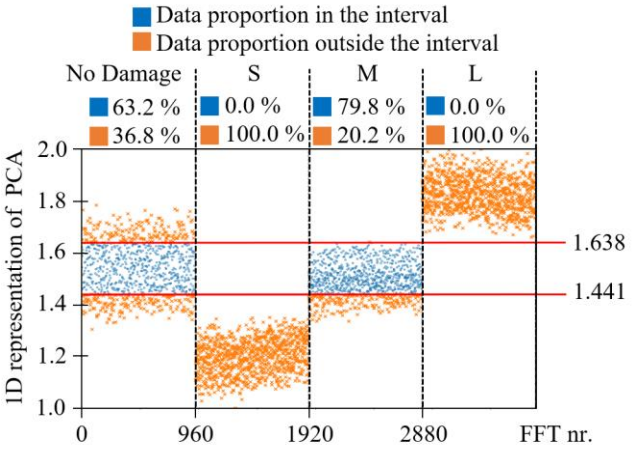

Figure 8. Encoding approach, 1st gear pair, 72 rpm, 24 Nm, 1st interval.

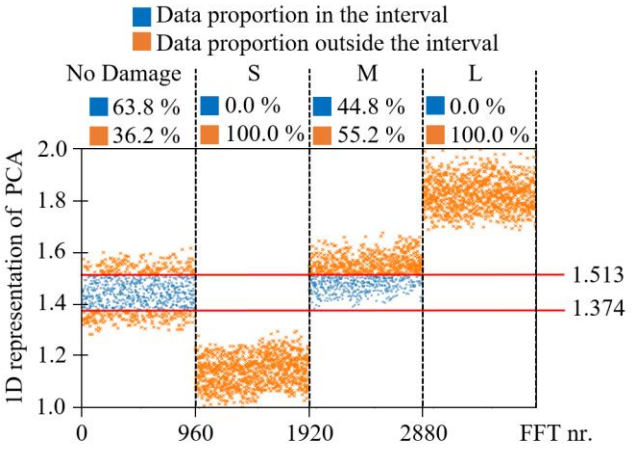

Figure 9. Encoding approach, 1st gear pair, 72 rpm, 30 Nm, 1st interval.

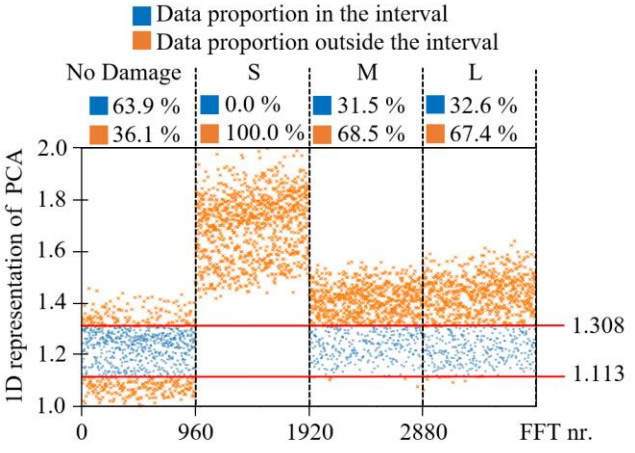

Figure 10. Encoding approach, 1st gear pair, 636 rpm, 18 Nm, 1st interval.

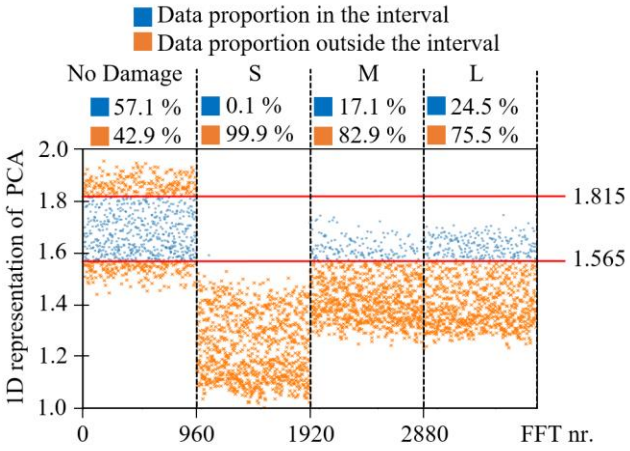

Figure 11. Encoding approach, 1st gear pair, 636 rpm, 24 Nm, 1st interval.

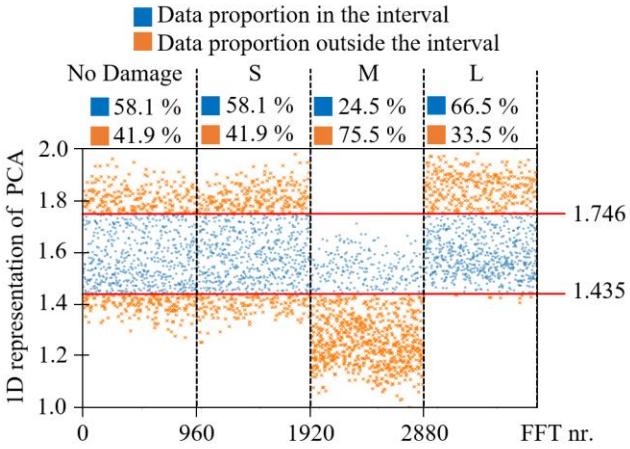

Figure 12. Encoding approach, 1st gear pair, 636 rpm, 30 Nm, 1st interval.

In addition to the encoding evaluation of the first gear pair using the first interval, the second and third intervals are also determined (see Eq. (12) and (13)). As mentioned, this is only used for comparison with the loss approach, as the detectability decreases as the interval increases. However, the aim is to evaluate how much the detectability decreases. For the operating condition 72 rpm and 18 Nm, this results in figure 13 (second interval) and figure 14 (third interval).

While for the first interval only 61.2 % of the data points without damage are within the limits (see figure 7), in the second interval 99.1 % (see figure 13) and in the third interval all data points (see figure 14) are within the limits. As the limits therefore have a greater distance, it is more difficult to detect a difference to the data points of the experiments with damage. Even in the evaluation with the second interval, only 1.7 % of the data points for pitting size S are outside the interval (see figure 13). If the third interval is used for the evaluation, no difference is recognizable, as all data points of pitting S are within the interval (see figure 14). Pitting sizes M and L are also more difficult to detect as the interval increases.

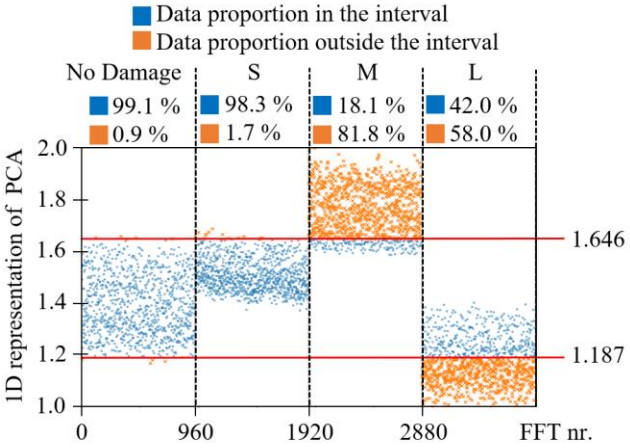

Figure 13. Encoding approach, 1st gear pair, 72 rpm, 18 Nm, 2nd interval.

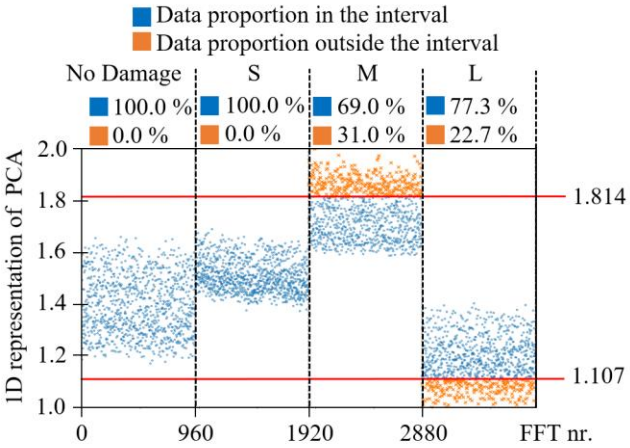

Figure 14. Encoding approach, 1st gear pair, 72 rpm, 18 Nm, 3rd interval.

Figure 15 presents the evaluation of the encoding approach for all operating conditions of the first gear pair. The proportion of data points for damage sizes S, M and L that are outside the respective interval is shown.

When using the second interval, some pitting can no longer be detected (pitting S at 72 rpm and 18 Nm, pitting M at 72 rpm and 24 Nm, pitting S and L at 636 rpm and 30 Nm) or less clearly (13.4 % for pitting M at 72 rpm and 30 Nm). For all other pitting and operating conditions, at least 40.8 % of the data points are always outside the limits of the second interval. If the third interval is used for detection, the detectability of the pitting decreases significantly.

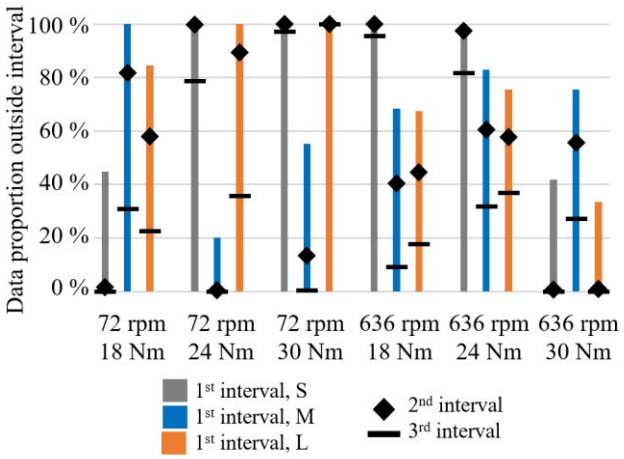

Figure 15. Encoding approach, 1st gear pair.

Figures 16 and 17 present the results of the encoding approach for the second and third gear pair in all operating conditions.

Considering the second and third gear pair, it is noticeable that the global tendency of the encoding approach corresponds to that of the first gear pair. When using the first interval, at least 39.8 % of the data for the second gear pair is always outside the limits, with one exception (28.6 % at 72 rpm and 30 Nm). For the third gear pair, a minimum of 44.9 % of the data is always outside the limits when using the first interval. If the second and third intervals are considered, the proportion of data points outside the limits decreases significantly for certain operating conditions. Especially with the third interval, some damage can no longer be detected.

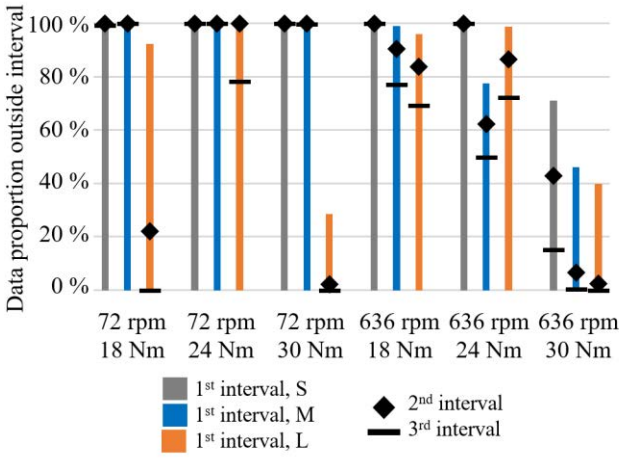

Figure 16. Encoding approach, 2nd gear pair.

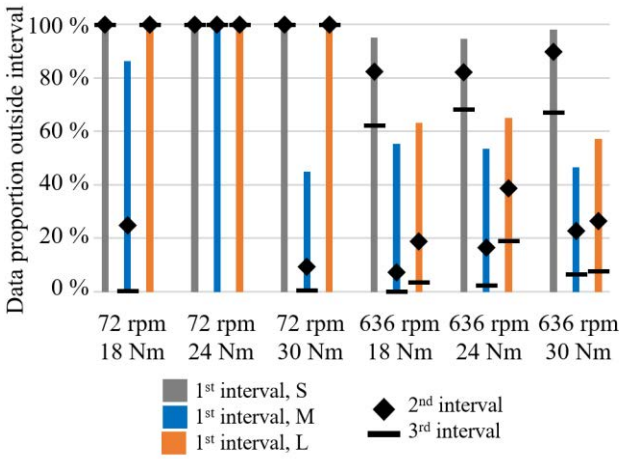

Figure 17. Encoding approach, 3rd gear pair.

3.2. Loss approach

The results of the loss approach of the first gear pair for each operating condition are given in figures 18 to 23. Again, the lower and upper limits of the first interval are determined using the data without damage (see Eq. (11)) and marked with a red line. The proportion of data points within and outside this interval is identified.

Overall, the results of the loss approach at the low speed level of 72 rpm have a low scatter of the data points. At the higher speed level of 636 rpm, larger scatter is recognizable. In all operating conditions, the data points of all pitting sizes are at least 96.8 % outside the limits – except for pitting L at operating condition 636 rpm and 18 Nm (77.0 %, see figure 21) and operating condition 636 rpm and 30 Nm (52.7 %, see figure 23). Overall, all pitting of the first gear pair can therefore be detected using the first interval of the loss approach.

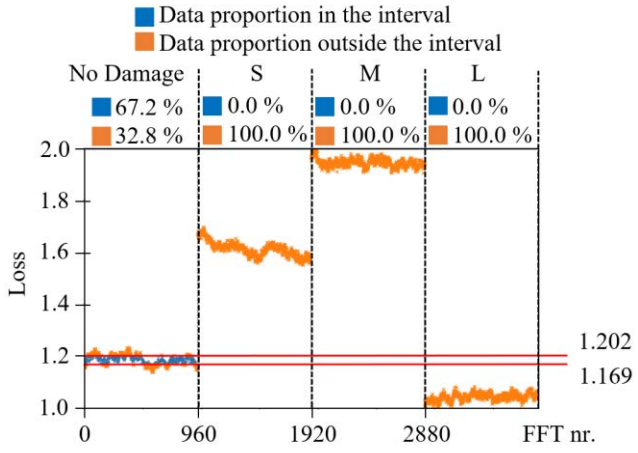

Figure 18. Loss approach, 1st gear pair, 72 rpm, 18 Nm, 1st interval.

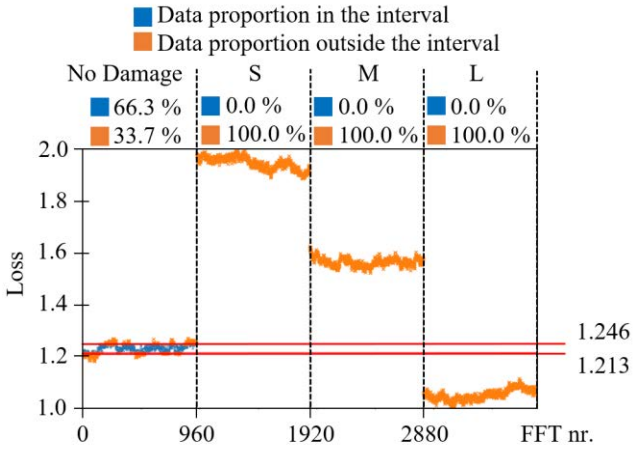

Figure 19. Loss approach, 1st gear pair, 72 rpm, 24 Nm, 1st interval.

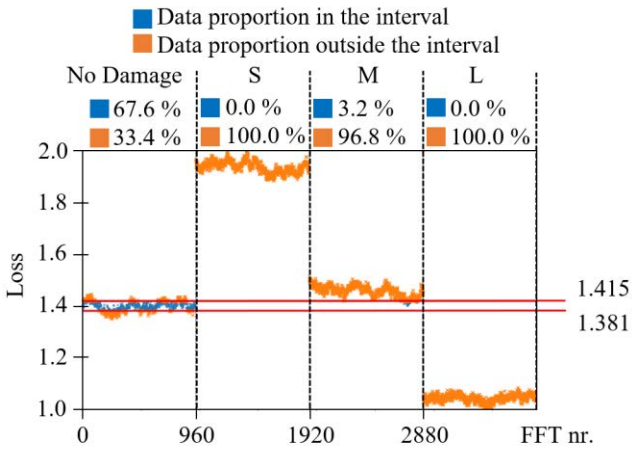

Figure 20. Loss approach, 1st gear pair, 72 rpm, 30 Nm, 1st interval.

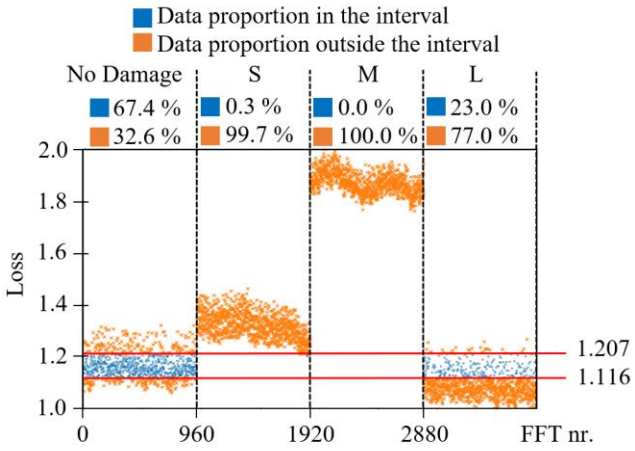

Figure 21. Loss approach, 1st gear pair, 636 rpm, 18 Nm, 1st interval.

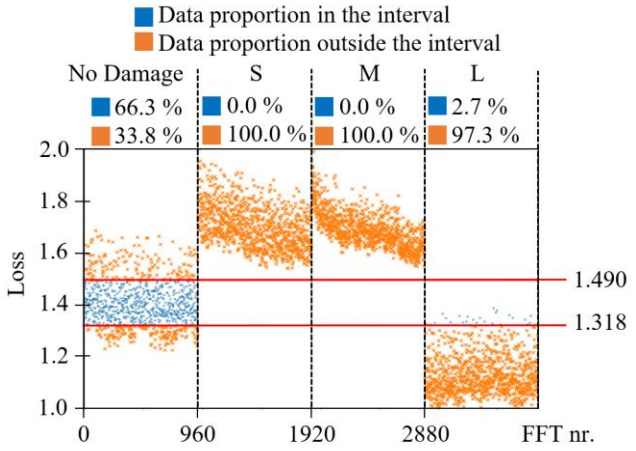

Figure 22. Loss approach, 1st gear pair, 636 rpm, 24 Nm, 1st interval.

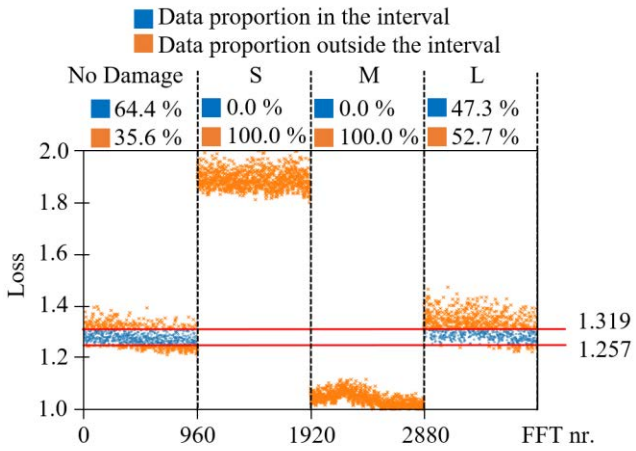

Figure 23. Loss approach, 1st gear pair, 636 rpm, 30 Nm, 1st interval.

In addition to the first interval, the second and third intervals are also determined for the loss approach (see Eq. (12) and (13)). The evaluation of all operating conditions of the first gear pair is illustrated in figure 24. The proportion of data points for damage sizes S, M and L that are outside the respective interval is shown.

When using the second interval, pitting L at operating condition 636 rpm and 30 Nm is the worst detectable pitting with only 16.4 % of the data outside the interval. Otherwise, at least 51,3 % of the data is always outside the limits. Using the third interval, pitting L is not detectable at operating condition 636 rpm and 30 Nm. Here, only 0.3 % of the data is outside the limits. Overall, pitting is more difficult to detect when using the third interval, especially at the higher speed level of 636 rpm.

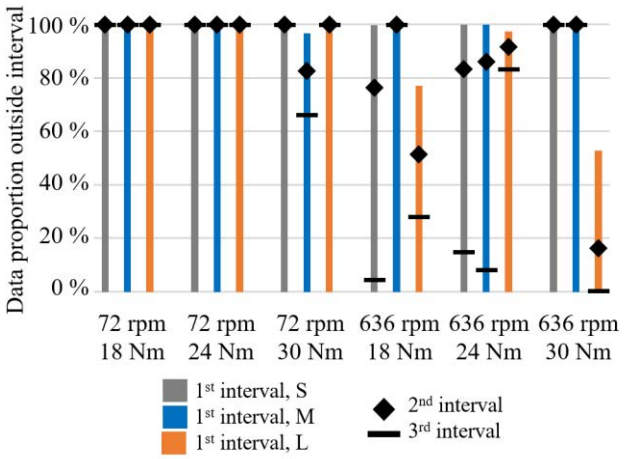

Figure 24. Loss approach, 1st gear pair.

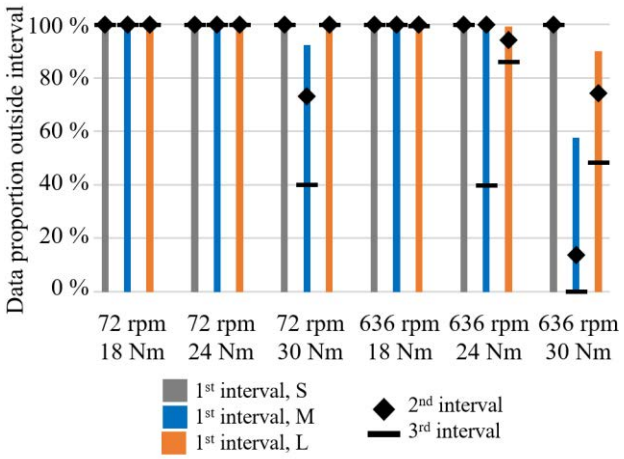

Figure 26. Loss approach, 3rd gear pair.

Figures 25 and 26 present the results of the loss approach of the second and third gear pairs for all operating conditions.

When using the first interval, at least 89.7 % of the data for the second gear pair is always outside the limits. For the third gear pair, a minimum of 57.7 % of the data is always outside the limits when using the first interval. If the second interval is calculated, 52.2 % of the data for the second gear pair is always outside the limits and 13.7 % for the third gear pair. When using the third interval, a decrease in the proportion of data points outside the limits for individual operating states and pitting sizes can be seen, similar to the first gear pair.

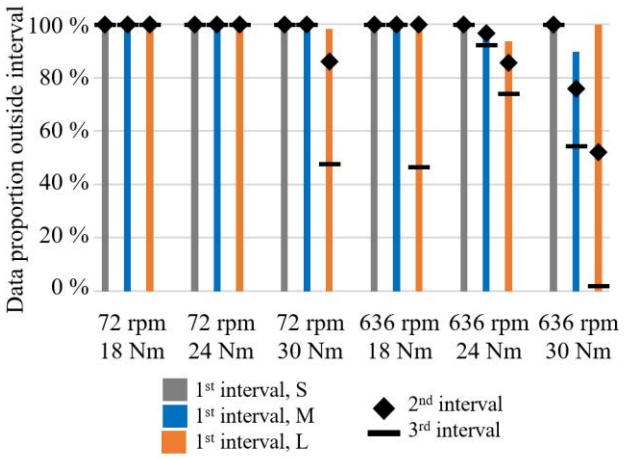

Figure 25. Loss approach, 2nd gear pair.

4. Discussion

Overall, the comparison of the encoding and loss approach shows that the data points scatter considerably more in the encoding approach. As a result, the upper and lower limits of the first interval are significantly further apart in the encoding approach than in the loss approach. When using the second and third intervals, this results in greater differences with the encoding approach because the limits are then frequently so far apart that pitting detection is no longer possible.

However, if the first interval is used for pitting detection with the encoding approach, a minimum of 20.2 % of the data points are always outside the limits for the first gear pair, 39.8 % for the second gear pair and 44.9 % for the third gear pair.

In total, the loss approach shows significantly better pitting detection than the encoding approach. When using the first interval, a minimum of 52.7 % of the data points are always outside the limits for the first gear pair, 89.7 % for the second gear pair and 57.7 % for the third gear pair.

A total of 18 cases are examined with the two approaches (3 pitting sizes in 6 operating states). In order to be able to compare the approaches even better, it is considered in how many of the 18 cases there is a significant deviation - i.e. at least 50 % of the data points outside the limits. The result can be found in figure 27.

For the first interval of the encoding approach, between 14 and 16 cases have a deviation greater than 50 %, depending on the gear pair. With the first interval of the loss approach, all damage sizes in all operating states of all gear pairs have a minimum deviation of 50 %. With the second interval of the encoding approach, the 50 % criterion only applies to 10 to 13 cases, depending on the gear pair. With the loss approach, it still applies to a minimum of 17 cases. When using the third interval, the number of cases in which at least 50 %

of the data points lie outside the interval is reduced for the encoding approach to between 5 and 12 cases. Large differences within the gear pairs can therefore also be seen here. In contrast, the loss approach shows 13 to 15 cases.

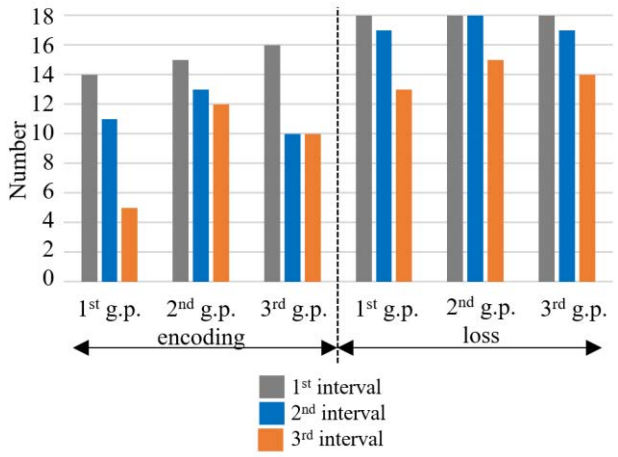

Figure 27. Number of cases with at least 50 % of the data outside the interval, per approach and gear pair (g.p.).

Overall, the loss approach is much better suitable for recognizing a clear difference between the tests without and with damage. In the second interval of the loss approach, a minimum of 50 % of the data points are still outside the limits in at least 17 cases. The encoding approach does not even achieve this for the first interval. In addition, the loss approach is not only less sensitive to different damage sizes and operating conditions, but also to different gear pairs. However, this paper does not consider how well false positives can be excluded with the two approaches.

Regardless of the comparison of the two approaches, even the smallest investigated pitting with a size of 0.61 % (1st gear pair), 0.51 % (2nd gear pair) and 0.78 % (3rd gear pair) could be detected in the context of this study. In contrast to the approach presented in (Binanzer et al., 2023), in which an AE was combined with a Long Short Term Memory (LSTM) network, detection is also possible with a purely unsupervised algorithm. This offers the advantage for the application that no labeled training data is required. Only data from a test without damage is required for training.

The detectable pitting sizes in the scope of this work are a significant improvement on other investigations. There are various approaches for pitting detection in gearboxes using vibration sensors. The approaches differ on the one hand in the investigated pitting size and in the methods of sensor data evaluation.

Qu, M. He, Deutsch and D. He (2017) investigated one row of pitting damage along the tooth width of one tooth. A stacked autoencoder network was used to perform the dictionary learning in sparse coding and automatically extract features from the raw vibration data. With these features a backpropagation neural network was trained to identify the damage.

Fan, Zhou, Wu and Guo (2017) developed a gear damage detection and localization approach by analyzing the vibration signal of an individual tooth and Support Vector Machines (SVM). The dispersion degree and vibration accelerations of the waveform of an individual gear tooth were studied to investigate the characteristics of gear tooth under normal, small failure (< 5 % damaged tooth area) and serious failure (> 5 % damaged tooth area) conditions.

An unsupervised feature extraction method called disentangled tone mining was presented by Qu, Zhang, M. He, D. He, Jiao and Zhou (2019). This method was able to identify the fault level directly from the frequency spectrum of the measured vibration data. Pitting sizes between 4.33 % and 24.91 % were investigated in a single stage spur gearbox.

Medina, Cerrada, Cabrera, Sanchez, Li and Oliveira (2019) used a LSTM network for classifying nine levels of pitting. The smallest investigated pitting had a size of 4.16 %.

Pitting sizes of less than 1 % were detected by Grzeszkowski, Nowoisky, S., Scholzen, Kappmeyer, Gühmann, Brimmers and Brecher (2020) using a SVM classifier. A disadvantage of the SVM classifier is that it is a supervised algorithm and therefore requires labeled training data.

Damage detection with purely physically based data evaluation, with pitting sizes between 6.3 % and 41.7 %, was presented by Sowana und Chandrasekaran (2020). In each case, the root mean square (RMS) value of the structure-borne noise data in the time domain of the undamaged and damaged gear was compared.

Sarvestani, Rezaeizadeh, Jomehzadeh and Bigani (2020) also examined the detection of naturally occurring pitting damages with a size of 30 %, 60 % and 90 % using purely physically based methods. The frequency spectrum of the structure-borne noise data was divided into six ranges. The damage was best detected in the second gear mesh harmonic range.

Häderle, Merkle and Dazer (2024) presented another physically based data analysis approach. It is shown that the greatest percentage difference between undamaged and damaged gears can be determined for the harmonics of the gear mesh frequency (GMF) and the sidebands between 24,000 Hz and 40,300 Hz. Thus, it was possible to detect very small pitting sizes between 0.42 % and 1.83 %.

5. Conclusion

In order to increase the service life of gearboxes, avoid unexpected failures and thus reduce overall operating, maintenance and labor costs, comprehensive PHM has to be implemented in gearbox applications. Adaptive operating strategies can even extend the RUL without any loss of performance. In order for the PHM of gearboxes to achieve its full

potential, damage detection at the earliest possible stage is essential.

In this study, two unsupervised machine learning approaches (encoding and loss approach) were developed and the detection of artificially manufactured damage on the tooth flank of a test gearbox was investigated.

In particular, the loss approach is more capable of identifying a difference between no damage and damage than the coding approach, regardless of the size of the pits and operating conditions. The loss approach is also less sensitive to different gear pairs, which have slightly different properties due to material and manufacturing tolerances.

Overall, it can be stated that the main contribution of this work is that existing Machine Learning tools have been applied to the challenge of a very early damage detection in gearboxes. Without the need of complex physically based evaluation methods of the vibration data, the smallest pitting of about 0.5 % could be detected regardless of the operating condition. The use of the sparse AE was described in detail and two evaluation methods were compared.

ABSTRACT

Combining physical and domain knowledge in artificial intelligence (AI) models has been gaining attention in various fields and applications. Applications in machine prognostics and health management (PHM) are natural candidates for such hybrid approaches. In particular, they can be efficiently exploited for high fidelity anomaly detection in technical and industrial systems. A natural way for hybridization is using physical models to generate representative data for the training of AI models. Depending on the level of domain knowledge availability, data augmentation can compensate for scarcity of real data from the field. This is particularly attractive for anomaly detection tasks, in which data from the abnormal regimes is limited by definition. On top of this inherent data limitation, many real-world systems suffer from data limitations even within the normal regimes.

In this paper we propose a physics-informed deep learning algorithm for fault detection in grid scale photovoltaic power plants. We focus on a common data scarce scenario that emerges from a low asset monitoring granularity: instead of monitoring the power production of each solar string, the power output is monitored only at combiner-box or even inverter level (monitoring a large number of strings with a single sensor). As a result, the signatures of single local faults can become very subtle and challenging to detect. We show that in this case a physics-informed AI approach significantly outperforms the alternative of a purely data-driven anomaly detection model. This enables high fidelity fault detection in larger solar power plants, that are often limited in the granularity of their condition monitoring data.

1. INTRODUCTION

Utilizing physical information and domain knowledge in conjunction with AI models has become a popular approach to deal with some of the known limitations of AI (Karniadakis et al., 2021), such as the lack of interpretability of AI models and their data-hungry nature. The field of equipment prognostics and health management (PHM) is an ideal application field for such hybrid approaches (Rausch, Goebel, Eklund, & Brunell, 2005; Wu, Sicard, & Gadsden, 2024). For many of the systems, a detailed physical model is already in use for design purposes (Chao, Kulkarni, Goebel, & Fink, 2019; Huber, Palmé, & Chao, 2023), and can be exploited also for PHM. In other systems the fault or degradation mechanisms are well understood and allow for a microscopic or a phenomenological model (Rai & Mitra, 2021; Zgraggen, Guo, Notaristefano, & Goren Huber, 2023).

A typical challenge in PHM tasks is the severe lack of historical failure data. In these cases, the use of physical information to compensate for data scarcity becomes even more attractive than in other application domains. One particularly common approach is to augment the training data using physical models (Frank et al., 2016; Wu et al., 2024). Such models can be used either for operational regimes that are scarce on data (Chao, Kulkarni, Goebel, & Fink, 2022; W. Li et al., 2021), or to directly model fault mechanisms that are rarely seen in operation (Kohtz, Xu, Zheng, & Wang, 2022; Bansal et al., 2022).

In our previous work we took the latter approach (Zgraggen, Guo, Notaristefano, & Goren Huber, 2022). We developed a physical model that corrupts data from a normally operating photovoltaic (PV) plant, thereby generating data with syn-

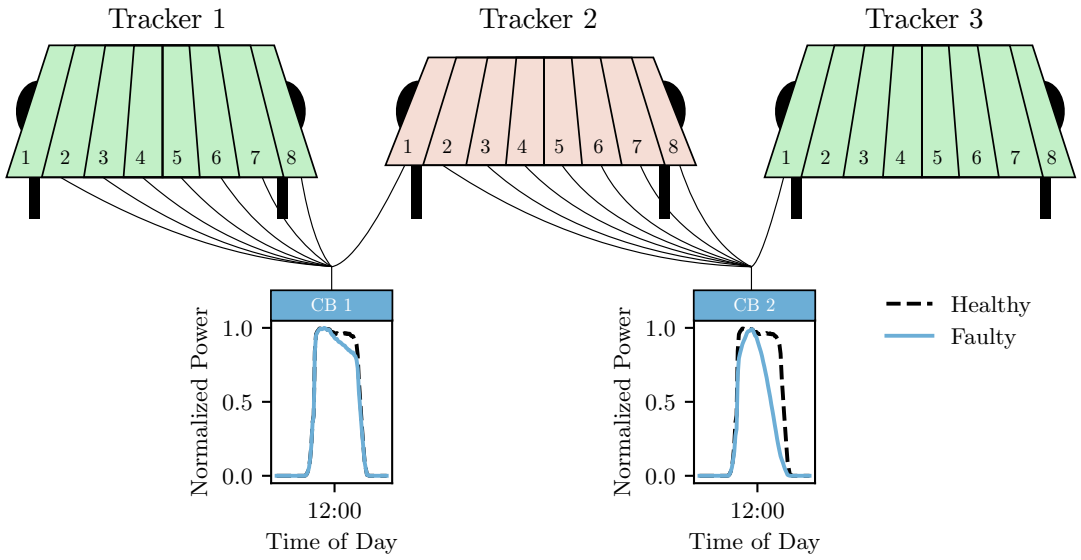

Figure 1. The challenge of low data granularity for tracker fault detection. The eight strings that are mounted on the faulty tracker 2 contribute their power to two different combiner boxes (CBs): CB1 is affected by only one of these strings. Its power profile (bottom left, solid blue) suffers a mild loss compared to the daily reference (dashed black). CB2 is affected by seven of the faulty strings, and suffers a more significant power loss (bottom right).

thetic faults. In this paper we extend this method to allow its applicability under data scarcity in real-world scenarios. The proposed hybrid approach profits from both worlds: on one hand it demonstrates a high ability to mimic the effects of rare faults, without the need for real faults in the data. On the other hand, it does not require a complex physical model of the normal system, as all complex (environmental and operational) effects are already captured by the field data. As opposed to previous approaches to solar plant fault detection, our method is independent of lab data (Chen, Chen, Wu, Cheng, & Lin, 2019; B. Li, Delpha, Diallo, & Migan-Dubois, 2021; Gao & Wai, 2020), simulation data (Chine et al., 2016), or designated data-collecting hardware (Daliento et al., 2017; Amaral, Pires, & Pires, 2021), and was carried out using existing operational data only. Our Physics-Informed Deep Learning (PIDL) approach was shown to perform very accurately with no need for fault data (Zgraggen et al., 2022), and even in a fully unsupervised setting, where the data may be contaminated by unlabeled anomalies (Zgraggen et al., 2023). Moreover, the approach does not require any irradiance measurements, but merely the standard 15-minute measurements of the power output from individual PV strings. Also in this respect our work is rather unique: most of the published work related to PV plant fault detection (Mellit, Tina, & Kalogirou, 2018; Triki-Lahiani, Abdelghani, & Slama-Belkhodja, 2018; Pillai & Rajasekar, 2018; Mansouri, Trabelsi, Nounou, & Nounou, 2021) relies on data at single module or cell resolution, rather than the operationally relevant string-data, often containing dozens or hundreds of modules.

In grid-scale solar power plants, it is often impractical to monitor data at string level due to the large number of PV strings involved. As a result, individually monitoring each string often becomes unfeasible. In this case, the output power is monitored and recorded only at a higher spatial granularity level, for example at the level of combiner boxes or even inverters, gathering a large number of strings in a single sensor reading. As shown below, this lower monitoring granularity inevitably leads to a reduced effectiveness in detecting local faults. To the best of our knowledge, there are no previously published studies that address fault detection at combiner-box or inverter level in PV power plants.

In this paper we address the above common scenario of low data granularity by extending our previous PIDL approach. We use a physical model to transfer the method from assets with a high data granularity to assets with a low data granularity. We show that in the case of data scarce assets, the physics-informed (PI) approach is of an even higher benefit compared to purely data-driven anomaly detection.

The contribution of this paper is two-fold. For solar power plant condition monitoring, it offers a high fidelity method to detect anomalous power losses by combining physical knowledge and AI in real-world operational conditions. In a more general context, the paper demonstrates the effectiveness of physics-informed AI for fault detection in data-scarce scenarios, which are common in various application fields. In particular, we show that physical knowledge can be utilized for transfer learning between domains with abundant data and domains with scarce data.

In Section 2 we describe the solar tracker use-case on which

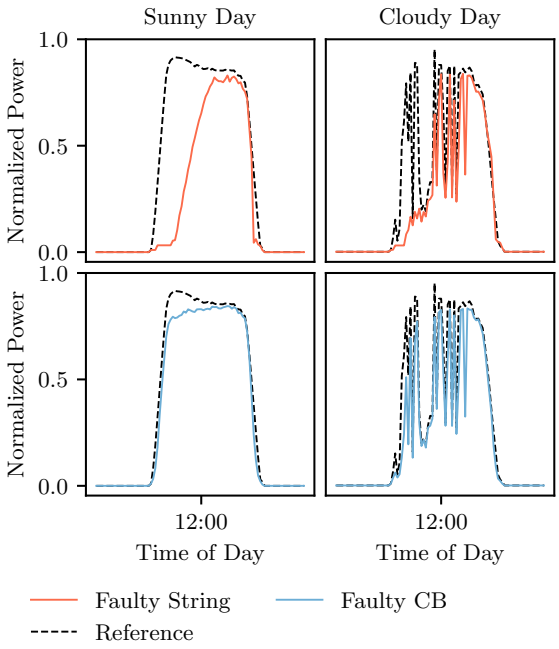

Figure 2. The effect of low data granularity on the measured output power. The signature of a real tracker fault on the daily output power of a single string (upper panels) and of the entire combiner box (CB, lower panels). A clear-sky day (left panels) is contrasted with a cloudy day (right panels). The fault signatures are considerably smaller and harder to detect, if only CB-level power data is available.

we demonstrate our approach. In Section 3 we provide the details of the PIDL approach. Finally, the results are shown and discussed in Section 4.

2. Description of the Use Case

The proposed PIDL approach is demonstrated here for the early detection of faults in the tracking system of solar power plants. Solar trackers are rotating units on which PV panels are mounted in order to adjust their orientation during the day according to the position of the sun, thus ensuring maximal power production at any given moment (Racharla & Rajan, 2017). In a common fault mechanism of solar trackers, the trackers get stuck at a certain orientation instead of following the sun. This fault has an immediate implication on the power production, which is significantly reduced compared to the optimum, given certain irradiance and weather conditions. Thus, an automatic early detection of the fault by closely monitoring the power production patterns can significantly reduce the resulting energy losses.

In our previous work (Zgraggen et al., 2022) we developed an algorithm for early detection of tracker faults based on power profiles of PV strings. The algorithm is thus applicable to power plants in which the power production is monitored for each PV string individually. However, a large fraction of the operational PV power plants nowadays are monitored at a lower granularity, that is, at the level of combiner boxes (CB) or even inverters. In such cases, historical power data is only available for single CBs or inverters, summing up the power of up to tens of individual strings. The single string power is no longer available, thus the previously proposed fault detection algorithm is not directly applicable.

To understand the fault detection challenge posed by the lower data granularity, an example is illustrated in Figure 1, showing two CBs with their related trackers. Since a CB extends over a large area, its strings are typically mounted on several different solar trackers, in this case trackers 1,2 and 3. Thus, if one tracker is faulty, only a fraction of the CB power originates from a string that is affected by the fault while the rest of the strings of this CB do not display any signatures of the tracker fault. In the illustration of Figure 1, Tracker 2 is faulty, while Trackers 1 and 3 are normally functioning. Combiner box CB1 receives its input from 7 strings which are unaffected by the tracker fault (as they are mounted on Tracker 1) and one string which is affected by the fault (as it is mounted on Tracker 2). As a results, the CB power profile (shown at the bottom left in blue) is only mildly impacted by the fault, compared to the reference profile (dashed black). On the other hand, CB2 receives its input from 7 affected strings (mounted on Tracker 2) and only one unaffected string (on Tracker 3). The resulting CB2 power profile (bottom right in blue) shows a much stronger fault signature than the one of CB1. Note that the black dashed profiles are the daily reference power production, calculated from the entire plant data (see explanation in Sec. 3). Moreover, it should be noted that the example is illustrated for a sunny day with clear sky, whereas the effectiveness of the proposed method is shown below under any weather and operational conditions.

As argued above, typical fault signatures on CB power profiles are much more subtle than on string power profiles, and require a higher anomaly detection sensitivity to identify and locate them. Figure 2 demonstrate this effect using data from a real operational PV plant, under different weather conditions. The signatures of a tracker fault on the measured output power are shown at the two monitoring levels: string level vs. CB level. In the upper panels we display (normalized) daily power profiles of a single string which was mounted on a faulty tracker, compared to the daily reference (dashed black). In the lower panels we assume that string level data is unavailable and display the power profiles of the entire CB containing the same string of the upper panels. Since this CB sums up the power of both faulty and intact strings, the signature of the tracker fault is smaller and harder to detect. This is particularly true under cloudy weather conditions, as shown at the right column.

The focus of this paper is the transfer of the tracker fault

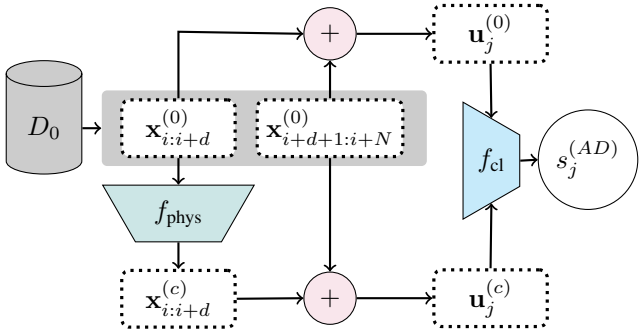

Figure 3. The proposed Physics-Informed AI fault detection algorithm.

detection algorithm from string level monitoring data to CB level monitoring data, thereby addressing the high fault detection sensitivity challenge.

3. METHOD

In order to achieve high fidelity fault detection of tracker faults for CB-level monitoring data we introduce an extension of our previous string-level PIDL model. The proposed PIDL algorithm for tracker fault detection includes two steps: (i) Data augmentation using a physical model that synthetically generates abnormal power profiles. (ii) Training a binary classifier to distinguish normal from abnormal daily power profiles.

3.1. Physics Informed Data Augmentation

Due to the rare occurrence of tracker faults, real operational power data which is affected by these faults is very scarce. However, data from normal functioning solar power systems is abundant. We exploit this fact, and use operational power data from normally functioning solar plants in order to generate synthetic power profiles under tracker faults. Since the tracker fault mechanism is well understood, we develop physical equations that enable a simple transformation of a healthy power profile into a faulty one. In this way we can simulate diverse fault scenarios and augment the training data with a large number of realistic tracker fault examples. In a second step, the augmented data containing both healthy and faulty power profiles is used to train a binary classifier that distinguishes between normal and abnormal power profiles, thereby enabling identification and localization of tracker faults in large power plants. In the following we describe the physics informed data augmentation method.

A tracker fault affects the power production of the solar strings that are mounted on the faulty tracker. Neighboring strings, if mounted on healthy functioning trackers, remain unaffected. In particular, a common situation (as illustrated in Figure 1) is that out of the N strings that are combined into one CB, only $d < N$ are mounted on a faulty tracker and the rest $N - d$ strings are mounted on healthy trackers.

In order to synthetically generate CB power profiles that correspond to various types of tracker faults, we model d faulty string power profiles that result from a tracker getting stuck at an angle θ_0. This is done using a physical model f_{phys} of the fault mechanism that "corrupts" normal power profiles of single strings, turning them into faulty profiles. The d synthetically generated faulty profiles are added to $N - d$ real healthy string profiles from the operational system, to obtain a synthetic CB profile which is partially affected by a tracker fault, as depicted in Figure 3.

The generation of a faulty string power profile $x^{(c)}(t)$ out of a healthy string profile $x^{(0)}(t)$ is done using the equations

$$\begin{aligned} x^{(c)}(t) &= c_p \left[(1-\gamma) g(\theta_0, \theta^*_{\text{i}}(t)) + \gamma\right] x^{(0)}(t) \\ g(\theta_0, \theta^*_{\text{i}}(t)) &= \frac{\cos\theta_0 \cdot f_{\text{IAM}}(\theta_0)}{\cos\theta^*_{\text{i}}(t) \cdot f_{\text{IAM}}(\theta^*_{\text{i}}(t))}. \end{aligned} \tag{1}$$

with $f_{\text{IAM}}(\theta_{\text{i}}) = 1 - b_0(1/\cos\theta_{\text{i}} - 1)$ and where $\theta^*_{\text{i}}(t)$ is the optimal tilt angle of the tracker at time t, θ_0 is the stuck angle of the faulty tracker, b_0 and γ are model parameters estimated empirically using the data, by fitting 10 samples of faulty profiles from the operational data of the string-level PV plant (we note that such profiles are only needed for a single plant, and are not required for the target plant at CB level). The parameter c_p is a degradation loss coefficient, assumed to range between 0.8 and 1 in order to simulate slight losses which are unrelated to tracker faults, and may exist also in healthy strings. For details of the physical model we refer the reader to (Zgraggen et al., 2022).

By adding up d faulty and $N - d$ normal string profiles, a synthetically generated faulty CB power profile $u^{(c)}(t)$ obtains the form

$$u^{(c)}(t) = \frac{1}{d}\sum_{i=1}^{d} x_i^{(c)}(\theta_0, \gamma, b_0, c_p; t) + \frac{1}{N-d}\sum_{i=d+1}^{N} x_i^{(0)}(t) \tag{2}$$

where $x_i^{(c)}(\theta_0, \gamma, b_0, c_p; t)$ is the ith corrupted string profile and $x_i^{(0)}(t)$ is the ith healthy string profile. The model parameters θ_0, γ, b_0 and c_p are sampled from uniform distributions within realistic ranges to represent all physically viable configurations (see (Zgraggen et al., 2022) for details), but are kept identical for all of the strings that belong to the same CB. The number of corrupted strings d is drawn randomly from the range $1...N$ in order to cover all possible configurations under the constraint of N strings in one CB (which is given by the plant configuration).

In addition to the generation of faulty CB profiles, we generate an equal amount of healthy CB profiles by simply adding N healthy adjacent string profiles. Note that we follow the modelling approach described in (Zgraggen et al., 2022), in which we randomly introduce mild physics-informed modifications to the healthy profiles in order to mimic the ef-

fects of small power losses that are unrelated to tracker faults. As shown in (Zgraggen et al., 2022), allowing this physics-inspired stochastic variability in the training data, increases both the accuracy and the robustness of the model predictions.

The proposed data augmentation process ensures a large diversity of tracker faults with different intensities, stuck angles and under various soiling or degradation conditions. Moreover, an important advantage of our approach is its mathematical structure, that enables using real operational power profiles and transforming them into faulty profiles by mathematically "injecting" a known fault mechanism into them. As a result, complex features of the model inputs, such as diverse weather effects, are already accounted for, and do not need to be modeled.

We note that the CB-level model described above uses string power profiles to generate CB power profiles. As such, it assumes the availability of normal data from one power plant which is monitored at string level. The results we show below were obtained after training on data from a string-level plant (the source plant), but tested on an operational power plant with CB monitoring only, in a different geographic location (the target plant). With this we demonstrate that effective fault detection is transferable to the target plant without string-level data availability, owing to the physics informed modeling approach.

3.2. CNN fault classifier

The empirical-physical model of the fault mechanism is used to augment the normal data set, such that it now contains healthy as well as faulty power profiles at CB level, $u_j^{(0)}(t)$ and $u_j^{(c)}(t)$ respectively. Each daily profile is a time-series of size 96 (due to a 15 minute resolution of the original sensor data). At a next step, the augmented data set, containing balanced healthy and faulty samples is pre-processed by subtracting from each power profile the daily reference profile, calculated as the 0.9 quantile over the entire plant at any given moment in time (see (Zgraggen et al., 2022) for details). The resulting power deviation profiles are used to train a 1d-CNN classifier f_{cl} that assigns an anomaly score $s_j^{(\text{AD})}$ to each daily profile, as depicted in Figure 3. This allows to detect faulty combiner boxes (thereby locating the related faulty trackers) at the end of each day, which is the relevant time resolution for decision making in practice. The CNN contains three one-dimensional convolutional layers followed by two fully-connected layers, with a total of around 30'000 trainable parameters. The network architecture was optimized using a grid search to tune the number of layers and filters and the learning rate.

We trained the classifier with 700'000 CB power profiles, half of which include synthetic tracker fault effects. All profiles originate from one single PV power plant during a time period of one year. The test data originates from another PV power plant, monitored at CB level, and includes 5349 CB power profiles collected during a time period of two months and containing 857 known faulty profiles, labeled manually by domain experts.

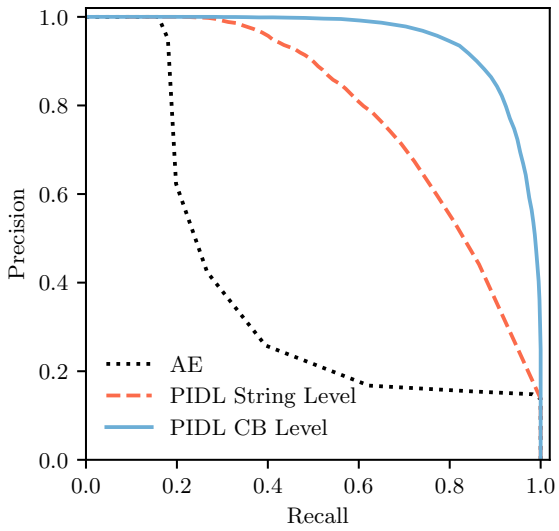

Figure 4. Fault detection evaluation using precision-recall curves. The performance of the proposed CB-level PIDL model (solid blue) is compared with a simpler string-level PIDL (dashed red) and a purely data-driven convolutional AE model (dotted black).

Baselines. We compare the performance of the proposed algorithm with two baseline methods. The first one is a similar PIDL algorithm which is trained using the original string level profiles, rather than CB-level profiles, with and without synthetic faults. This enables us to examine the transferability of the learned features from string to CB level.

The second baseline we compare to is a purely data-driven approach, not making use of any physics-based modeling. In this case we train a convolutional Autoencoder (AE) neural network to reconstruct power profiles. The AE is trained with the normal part of the data only, not including any tracker faults. The normalized reconstruction errors are then used as fault indicators, with a threshold typically set at the tail of the training distribution of reconstruction errors. The feature extraction layers of the AE are four 1d-convolutional layers, similarly to the PIDL network described above, with a similar number of 46'000 trainable parameters.

4. Results

The performance of the proposed PIDL classifier is evaluated in Figure 4 using a precision-recall curve (PRC). The PRC of the CB-level PIDL method is shown in solid blue, and is

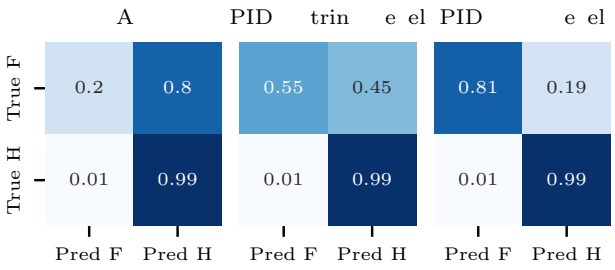

Figure 5. Fault detection evaluation using confusion matrices. The performance of the proposed CB-level PIDL model (right) is compared to the ones of a string-level PIDL (middle) and a purely data-driven AE (left). For all 3 models, the detection thresholds were set to yield a false positive rate of 1%.

contrasted with the PRC of the string-level PIDL approach (dashed red), and the PRC of the pure data-driven AE model (dotted black). It is evident that a pure data-driven approach does not exploit the physical knowledge of the fault mechanism and thus reaches a much poorer performance than both of the PI approaches. In the case of string-level PIDL, the inputs are not aggregated to mimic CB power profiles whereas in the case of CB-level PIDL the string power profiles are aggregated in various ways such that different tracker fault configurations are simulated in the synthetic data. In this way, also configurations that lead to subtle fault signatures are introduced at training, and can be detected at inference time. As seen from the PRC results, this leads to a significant improvement in the fault detection performance, with an average precision (AP) of 0.95 for the proposed CB-level PIDL, compared to 0.79 for the string-level PIDL. As expected, the purely data-driven AE model is significantly inferior in its fault detection performance, with an AP of 0.38. It should also be noted that the performance of the CB-level PIDL is only slightly worse than the one we reported for the string-level PIDL when tested on string-level data (with an AP of 0.97, see (Zgraggen et al., 2022)).

In addition to the PRC, we compare the fault detection performance using confusion matrices shown in Figure 5. The confusion matrix of the CB-level PIDL model (right) is compared with the ones of the string-level PIDL (middle) and the data-driven AE (left). For the sake of model comparison, all three confusion matrices were generated by selecting a detection threshold that guarantees a low false positive rate of 1%. This is a practically sensible threshold, that reduces the false alarms to a minimum. Fixing the threshold to produce this false positive rate on the test data in all three methods, we obtain a false negative (missed detections) rate of 0.8 with the pure data-driven approach, a rate of 0.45 with the string-level PIDL and a significantly lower rate of 0.19 with the proposed CB-level PIDL algorithm.

The complexity of the fault detection task is demonstrated in Figure 6 using CB power test data from the target power plant. Each panel displays a CB daily power profile (solid blue) compared with the daily reference (dashed black). The upper six panels are examples of CB power profiles with no tracker faults, whereas the six lower panels were labeled as suffering from power losses due to tracker faults. The power profiles in the 6 panels at the left half of the figure were all correctly classified by the proposed PIDL algorithm, as well as by the purely data-driven convolutional AE. Indeed, the fault signatures of the three profiles at the bottom left are rather strong and could be clearly assigned to tracker faults by both models. This stands in contrast to the 6 panels on the right hand side of the figure, which were all correctly classified by the PIDL model, but misclassified by the AE. Here, physical information about the tracker fault mechanism clearly helped to distinguish between true tracker faults (lower panels) and power losses due to other reasons, unrelated to the solar trackers (upper panels). This is despite the fact that such unrelated power losses may be rather high, as seen in the three upper right panels. In all three cases, due to their high power losses compared to the reference, the AE produced high reconstruction errors, leading to false positives. On the other hand, the low power losses of the truly faulty profiles at the bottom right led to missed detections (false negatives) by the AE, because of reconstruction errors that are similar in magnitude to the ones of the training data. Despite their low power losses, and their mild fault signatures, these power profiles were correctly detected as suffering from tracker faults by the CB-level PIDL algorithm.

To conclude, the CB-level PIDL includes a physics-informed data augmentation step that captures important nuances in the fault features, even in case of low data availability that leads to very mild fault signatures. The same data augmentation framework can be easily generalized to any monitoring level, provided the structure of the monitoring data at the operational plant (i.e number of strings per combiner-box or inverter). The only prerequisite is the availability of string level power profiles from a normal functioning power plant that can serve as the baseline for data augmentation. Moreover, one of the advantages of our approach is that it does not require complex measurement and/or modeling of the solar irradiance under various ambient conditions, but relies entirely on a single measured variable: the output power.

The proposed approach of physics-informed data augmentation is generally applicable in systems with some understanding of the fault mechanism. However, we believe that this physical understanding does not need to be complete or to amount to a full microscopic model of the fault mechanism. In many cases, a phenomenological model of the fault signatures on the observed data may be sufficient in order to achieve superior fault detection performance compared to purely data-driven approaches.

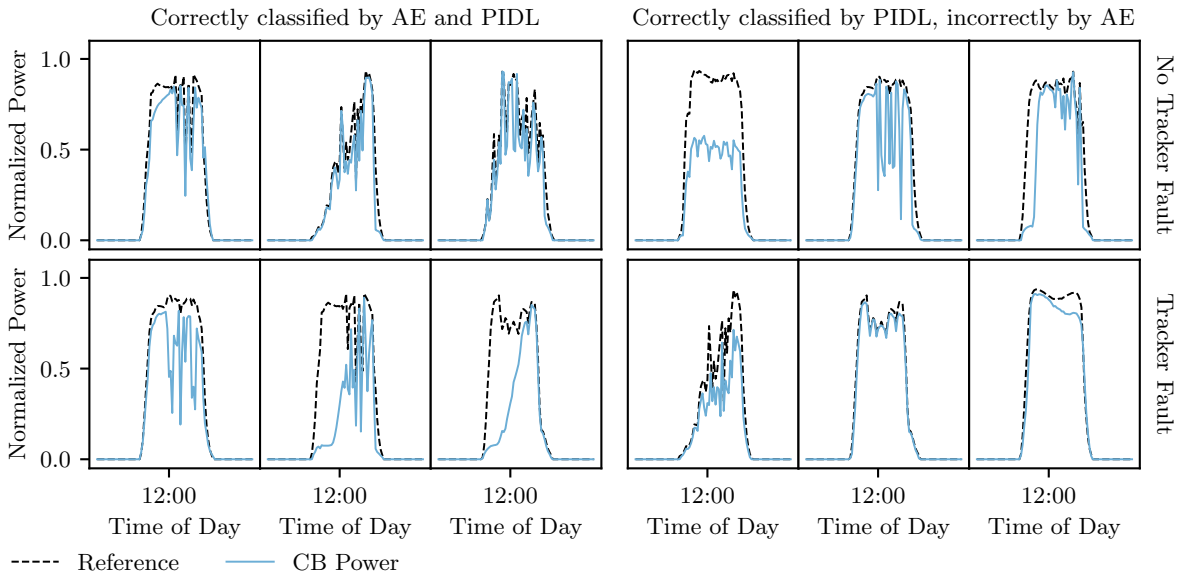

Figure 6. Classification outcomes of the PIDL compared with a purely data-driven AE model. Each panel displays a CB power profile (solid blue) together with the daily reference profile (dashed black). True labeled profiles with tracker faults (bottom row) are contrasted with profiles with no tracker faults (top row). The 6 panels on the left half were correctly classified by both the PIDL and the AE models, whereas the 6 panels on the right were classified correctly only by the proposed PIDL and misclassified by the AE model.

5. Conclusions

Scarcity of condition monitoring data is a common challenge for practical deployment of fault detection algorithms. Data scarcity may be due to missing data, due to a low time resolution of the data or due to a low spatial resolution. The latter is a common situation in large scale PV power plants, in which condition monitoring data is often available at a low spatial granularity level, e.g. aggregating the monitored power production over a large number of individual assets. However, a similar situation applies to other large infrastructures, where the data volume is often reduced using a more coarse-grained aggregation when monitoring the assets.

In order to enable high fidelity fault detection despite the data scarcity challenge, we introduced a physics-informed artificial intelligence algorithm. With this approach, physical information is exploited in order to transfer the data augmentation from a domain with abundant data to a domain with scarce data. We demonstrated the high performance of the algorithm on operational data from a PV power plant with a low data granularity, and showed its clear superiority over a purely data-driven approach. Moreover, we showed that its performance is similar to our previous results achieved on a high data granularity power plant. Future research directions include an extension of the approach to additional fault and power loss mechanisms, aiming at effective diagnostics of the power loss root cause.

ABSTRACT

The integration of particle or Kalman filters with machine learning tools like support vector machines, Gaussian processes, or neural networks has seen extensive exploration in the context of prognostic and health management, particularly in model-based applications. This paper focuses on the Multi-Layer Perceptron Particle Filter (MLP-PF), a data-driven approach that harnesses the non-linearity of MLP to describe degradation trajectories without relying on a physical model. The Bayesian nature of the particle filter is utilized to update MLP parameters, providing flexibility to the method and accommodating unexpected changes in the degradation behavior.

To showcase the versatility of MLP-PF, this work demonstrates its seamless integration into diverse use cases, such as lithium-ion battery analysis, virtual health monitoring for turbofans, and the assessment of fatigue crack growth. We illustrate how it effortlessly accommodates various contexts through slight parameter modifications. Adjustment includes variation in the number of neurons or layers in the MLP, threshold adjustments, initial training refinements and the adaptation of the process noise. Addressing different degradation processes across these applications, MLP-PF proves its adaptability and utility in various contexts.

These findings highlight the method's versatility in adapting to diverse use cases and its potential as a robust prognostic tool across various industries. MLP-PF offers a practical and efficient means of estimating remaining useful life and predicting degradation in complex systems, with implications for advancing prognostic tools in diverse applications.

1. INTRODUCTION

Prognostic and Health Management (PHM) plays a crucial role in engineering by aiming to estimate the health state, detect early failures, and predict the remaining useful life of systems or components (Zio, 2022). Implementing PHM algorithms allows for condition-based or predictive maintenance strategies, ultimately optimizing maintenance frequency and reducing operational costs (Bailey, Sutharssan, Yin, & Stoyanov, 2015). Traditional physics-based methods in PHM rely on known equations, and demand extensive domain knowledge while generally being computationally expensive, limiting their real-time applicability (Chang, Fang, & Zhang, 2017).

In contrast, the rise of data availability in recent years coincides with the exploration of data-driven methods such as neural networks, random forests, and support vector machines (Wang, Jin, Deng, & Fernandez, 2021; Hu, Xu, Lin, & Pecht, 2020; Vanem et al., 2023). However, these methods often face challenges related to data quantity, quality, and generalization across unseen conditions. To overcome these hurdles, hybrid approaches have been proposed (Cancelliere, Girard, Bourinet, & Broggi, 2023; Li et al., 2024), aiming to combine the strengths of data-driven and physics-based methods.

Among the hybrid approaches, a common one consists of integrating particle or Kalman filters with machine learning tools like neural networks or support vector machines (Dong, Jin, Lou, & Wang, 2014; Jha, Bressel, Ould-Bouamama, & Dauphin-Tanguy, 2016). In these frameworks, machine learning tools act as surrogates for physics-based models, reducing the need for extensive domain expertise. Meanwhile, Bayesian filters allow to quantify the uncertainties associated with the prediction, enhancing the robustness of the approach. Other works, such as (Ma, Karkus, Hsu, & Lee, 2020) or (Ge, Sun, & Ma, 2019) proposed combination of PF with, respectively, recurrent neural network (RNN) and long-short term memory

network (LSTM). A more comprehensive review of combination of PF and data driven techniques can be found in (Reza et al., 2024).

A combination of radial basis functions with particle filters, initially proposed by (Sbarufatti, Corbetta, Giglio, & Cadini, 2018), presented a novel approach to estimate the state of charge of lithium-ion batteries, which was later extended to predict the end of life for batteries by replacing the surrogate model with a Multi-Layer Perceptron (MLP) neural network (Cadini, Sbarufatti, Cancelliere, & Giglio, 2019). This adaptation, called Multi-Layer Perceptron Particle Filter (MLP-PF), capitalizes on the non-linear nature of MLPs to describe system degradation trajectories and leverages the Bayesian framework of particle filters to adjust to incoming measurements.

The primary contribution of this work lies in the application of the MLP-PF to three different case studies. By demonstrating the versatility of MLP-PF, this study showcases its seamless integration into diverse applications, starting from the case of lithium-ion batteries, then changing to the estimation of a virtual health indicator for turbofans, and the assessment of fatigue crack growth. Through minor parameter modifications such as variations in MLP architecture, threshold adjustments, initial training refinements, and adaptation of process noise levels, MLP-PF effortlessly accommodates various contexts.

Differing from conventional data-driven approaches, this study adopts a single historical degradation trajectory as training for the MLP neural network. The training serves merely as a starting point for the (PF) to explore the state-space, relying on its Bayesian nature to discern the hidden degradation dynamics. This approach furnish the algorithm with exceptional adaptability while significantly mitigating the need for extensive historical data, a primary drawback of traditional data-driven methods.

To evaluate the algorithm's performance, various metrics including Relative Accuracy, Confidence Interval Coverage (Jules, Cancelliere, Mattrand, & Bourinet, 2023), and the β Metric (Lall, Lowe, & Goebel, 2013) are employed. These metrics assess not only accuracy and precision but also consider the uncertainty associated with the predictions, providing a comprehensive evaluation framework.

Addressing various degradation processes across different applications highlights the adaptability and utility of the MLP-PF. These findings emphasize the method's versatility in accommodating diverse use cases and underscore its potential as a robust prognostic tool across multiple industries. MLP-PF provides a practical and efficient means of estimating remaining useful life and predicting degradation in complex systems, thereby advancing prognostic tools across a broad spectrum of applications.

The structure of this paper is the following: Section 2 briefly describes the proposed method and the metrics used to evaluate performance. Following this, Section 3 introduces the three use cases addressed in this study, while Section 3.1, Section 3.2 and Section 3.3 present the results corresponding to each case. Finally, Section 4 draws conclusions and provides perspectives on this work.

2. Multi Layer Perceptron Particle Filter

The method employed in this work was first proposed by (Sbarufatti et al., 2018), where a combination of radial basis function neural networks and particle filters was used to estimate the state of charge of lithium-ion batteries. The method was later improved by (Cadini et al., 2019), where it was extended to estimate the state of health of the battery. In this work, the method is applied to three different use cases to showcase its ability to adapt to different contexts with slight changes in the hyperparameters.

The multi-layer perceptron neural network is used as a surrogate for the given degradation model, such as the turbofan VHI or the batteries' capacity. In all cases, it consists of a single input, which is the discrete time step k, and a single output $\tilde{g}$, representing the predicted value at the given time step. The decision to use a simple neural network, such as an MLP, is driven by the necessity for flexibility and the desire to minimize the number of parameters estimated by the PF. Despite its simplicity, an MLP remains capable of capturing the nonlinearities inherent in the data. This choice strikes a balance between model complexity and computational efficiency, enabling effective integration with the PF framework.

The internal architecture of the network (number of layers, number of neurons per layer, and the activation functions) is case-dependent, particularly on the shape of the degradation trajectories and to ensure computational times are compatible with the given context (higher the network complexity, higher the computational time). The parameters of the network, meaning its weights and biases, are then packed into a vector x_k. The starting parameters x_0 are obtained by training the network based on a known run-to-failure degradation process, as can be observed in the (a) figures of the three cases.

The particle filter (Arulampalam, Maskell, Gordon, & Clapp, 2002) is a sequential Monte-Carlo algorithm that generates a set of particles which are used to estimate the posterior probability density function (PDF) of a hidden state, which in our case are the parameters x_k. Hence, a set of N_s copies (i.e particles) of x_0 is generated based on:

$$x_k^i = x_{k-1}^i + \omega_{k-1} \tag{1}$$

where i is the index of the particles and ω is the process noise, which is an hyperparameter that has to be carefully tuned. Each x_k^i contains the parameters of a MLP, which,

when propagated through the network, generates a prediction of a possible degradation trajectory. The PF operates by applying a prediction-update recurrence. The predictions at time step $k-1$ serve as the prior PDF, which is updated at each subsequent time step k upon the arrival of new observations. The update of the particles is performed by computing their likelihood, which indicates how close the i^{th} degradation trajectory is to the actual observations. The likelihood $\mathcal{L}_k^i$ of each particle i is computed as:

$$\mathcal{L}_k^i = p(z_{0:k}|x_k^i) = ((2\pi)^{k+1}|\Sigma_\eta|)^{-0.5} \exp\left\{-\frac{1}{2}\left(z_{0:k} - \tilde{g}(x_k^i, 0:k)\right)^{\mathrm{T}} \Sigma_\eta^{-1} \left(z_{0:k} - \tilde{g}(x_k^i, 0:k)\right)\right\} \tag{2}$$

where $z_{0:k}$ are the observations from 0 to k, $\tilde{g}(x_k^i, 0:k)$ is the prediction of the network for the i^{th} particle and Σ_η is the diagonal covariance matrix, with diagonal element equal to η, representing the measurement noise and assumed Gaussian. $\mathcal{L}_k^i$ is the probability of obtaining the measurement z_k given the i^{th} prediction $\tilde{g}_k$, and it is used as importance weight w_k^i for the particles.

To finally construct the posterior pdf the sampling importance resampling (SIR) algorithm is employed (Doucet, Godsill, & Andrieu, 2000): the weights are normalized, and the particles are resampled based on the normalized weights $\tilde{w_k}$. The closer the prediction is to the measurements, the higher the normalized importance weight of that particle, meaning that the particle is more likely to be resampled, which signifies that it is closer to the actual degradation trajectory of the observed process.

The importance weights of the particles are also utilized to enforce specific conditions, ensuring that particles adhere to desired behaviors. One example is imposing the monotonicity of the trajectory or setting bounds on the output value (e.g., ensuring it is always greater than 0). If a particle violates the specified condition, its weight is set to zero, indicating that it will not be resampled. Instead, it is replaced by a particle with a higher importance weight, thereby maintaining compliance to the desired conditions.

The collection of normalized particles at time step k, each representing a potential degradation trajectory, enables the computation of the posterior probability density function of the degradation state in future time steps. Consequently, it becomes possible to calculate statistics related to predictions, such as the mean and relative uncertainties. Additionally, by establishing a threshold for the end of life of the system, it becomes feasible to determine the distribution of the End of Life $p(\mathrm{EOL}_k|z_{0:k})$, and consequently the RUL_k as:

$$\mathrm{RUL}_k = \mathrm{EOL}_k - k \tag{3}$$

To evaluate the performance of the algorithm we use three different metrics. The first one is the cumulative relative accuracy, defined as:

$$\mathrm{CRA} = \frac{1}{T_{fail}} \sum_{k=0}^{T_{fail}} \left(1 - \left|\frac{\mathrm{RUL}_k^{\text{actual}} - \mathrm{RUL}_k^{\text{pred}}}{\mathrm{RUL}_k^{\text{actual}}}\right|\right) \tag{4}$$

where T_{fail} is the time step at which the system fails. This represents the distance of the prediction to the actual EOL, evaluated at each time step. A perfect prediction has a value of 1.

The second metric is the confidence interval coverage (Jules, Cancelliere, et al., 2023), which is used to assess the prediction considering the confidence interval, and is defined as:

$$CIC = \frac{1}{T_{fail}} \sum_{k=0}^{T_{fail}} \mathbb{1}_{RUL_k^{actual} \in \widehat{CI_k}} \tag{5}$$

where $\mathbb{1}_{RUL_k^{actual} \in \widehat{CI_k}}$ is the indicator function that takes one if the actual RUL lies in the predicted confidence interval, 0 otherwise. If the prediction at each time step include the RUL^{actual}, the CIC is going to be 1, while 0 if the true RUL is always outside the confidence interval.

The last indicator is called the β metric (Lall et al., 2013), which represent the area of the predictions that falls inside the α bound.

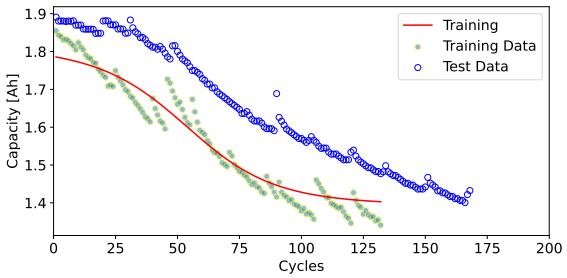
$$\beta_k = \frac{1}{T_{fail}} \sum_{k=0}^{T_{fail}} \int_{\mathrm{RUL}_k - \alpha}^{\mathrm{RUL}_k + \alpha} \mathrm{PDF}(\mathrm{RUL})\, d\mathrm{RUL} \tag{6}$$

The α bounds are defined as $RUL^{actual} \pm \alpha$. The β metric evaluates the accuracy of predicted RUL bounds compared to true RUL bounds, considering a specified uncertainty level (α). It quantifies the overlap between predicted and true RUL bounds normalized by the true RUL length. Higher values indicate better agreement between predicted and true bounds, reflecting improved prediction accuracy.

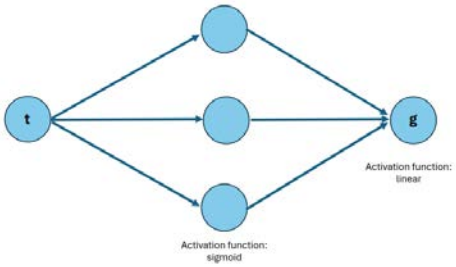
3. USE CASES

The proposed approach will now be applied to three use cases: estimating the end of life of lithium-ion batteries based on their decreasing capacity, propagating a virtual health indicator developed to estimate the state of health of turbofans, and modeling the growth of a fatigue crack in a panel. Although these cases share a time-dependency, their degradation processes differ significantly in terms of shape and rapidity. Therefore, we employ three different MLP network architectures, each tailored to the specific characteristics of its respective case.

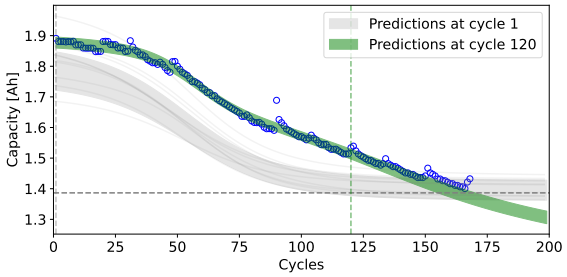
For consistency and comparison, in each cases we use the same number of particles, $N_s = 1000$, and the same number of epochs for the initial training (epochs = 500). Additionally, we employ a decreasing variance, defined as:



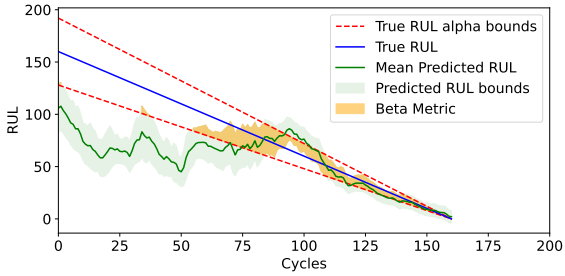
(a) Training and testing dataset for Li-Ion batteries. The red line is the output of the trained MLP.



(b) Architecture of the MLP neural network used for the Li-Ion batteries case.



(c) Two instant of time of the simulation. The grey dotted line is the end of life threshold.



(d) Remaining Useful Life prediction in terms of mean and uncertainty bounds.

Figure 1. Lithium-Ion Battery case.

$$\omega_k = \sigma_0 e^{-\frac{k}{\sigma_1}} + \sigma_2 \tag{7}$$

Here, ω perturbs the MLP parameters, as described in Eq. (1).

The use of a decreasing process variance is crucial for the convergence of the algorithm. Initially, a higher variance (which practically signifies a higher perturbation of x_k in Eq. (1)) is necessary to explore the state space and adapt to the first incoming observations, especially if these are significantly different from the training data. As more observations become available, the variance is reduced to reflect the increased information about the actual system. This reduction in variance helps prevent a single observation, especially a noisy one, from excessively perturbing the prediction. This strategy ensures a balanced adaptation process, enabling the algorithm to remain robust against noisy observations while gradually refining its predictions.

Given that the complexity of the network correlates with the number of parameters, using the same ω value for different architectures will lead to different perturbation. Specifically, higher complexity requires lower perturbation (i.e. lower ω) to prevent degeneration. If the MLP parameters change too rapidly, they may lose meaning and connection with prior information. Hence, the σ parameters and the measurement noise η, responsible for computing the particule likelihood in Eq. (2), vary across different cases.

Furthermore, in all three cases, we opt to use a single trajectory for the initial training. This choice aims to demonstrate the algorithm's ability to adapt to varying conditions and its capacity to achieve satisfactory performance in predicting the RUL without requiring a large amount of data. The proposed metrics are evaluated throughout all the degradation process and in the last 25% of life. This evaluation demonstrates that the algorithm's performance improves over time as more information becomes available, and it converges to the target data even when the initial training data differ significantly.

3.1. Lithium-ion Batteries

The dataset used for the first use case is the one developed by NASA for the prognostic and diagnostic analysis of batteries (Saha & Goebel, 2007). The capacity of batteries decreases over time due to usage and electrochemical reactions occurring inside the battery. The end of life of batteries is typically defined when the capacity drops below 80% of the initial capacity. However, to make the most of the dataset, in this work, we set a threshold of 1% higher than the last point, which is 1.42 Ah. In Fig. 1(a) the two batteries used for the initial training of the network (battery 18 of the dataset) and for testing (battery 7) are shown.

The architecture of the network consists of a single hidden layer with 3 neurons, where the activation functions are a sigmoid for the hidden layer and linear for the output layer. The network structure is depicted in Fig. 1(b). This results in a total of 6 weights and 4 biases, which, after training, are stacked

Figure 2. Virtual Health Indicator case.

in the vector x_0, resulting in 10 parameters. The output of the trained network with these parameters is represented by the red line in Fig. 1(a).

The initial process noise is taken as $\sigma_0 = 5 \times 10^{-2}$, while the floor value is set to $\sigma_2 = 10^{-5}$, with a decreasing rate σ_1 of 50. The measurement noise is set to $10^{-}2$. Due to the simplicity of the network, the initial value σ_0 is relatively high, providing more flexibility to the algorithm. Furthermore, the adaptability of the algorithm is necessary due to the intrinsic nature of lithium-ion batteries, which can perform differently from one another, as observed in Fig. 1(a). The initial perturbation, obtained by applying Eq. (1) to each of the N_s particle can be observed in Fig. 1(c) as the grey lines.

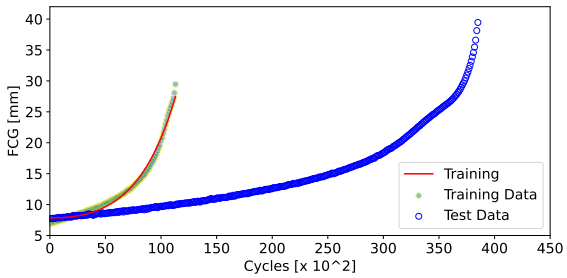
The results of the simulation are presented in Fig. 1(c) and Fig. 1(d). In the first, two instances of time, at the beginning and about the end of the simulation, are shown, highlighting the adaptability of the algorithm. Starting from the initial training, the algorithm adapts to incoming measurements and estimates the new degradation behavior. The last figure shows the results in terms of remaining useful life estimation. Initially, the predictions were more related to the training data, which has a faster end of life, while converging to the actual RUL at about the halfway point of the battery's lifetime. The evaluation of the algorithm's performance is reported in Table 1, where it can be observed that all the metrics improved when evaluated in the last 25% of the lifetime. Particularly, the Confidence Interval Coverage 25 has a value of 1, indicating that the actual RUL has always been inside the predicted bounds.

3.2. Virtual Health Indicator

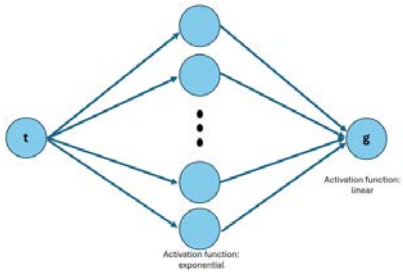
The second use case proposed here involves the estimation of the future behavior of a virtual health indicator developed for estimating the state of health of turbofans (Jules, Mattrand, & Bourinet, 2023). This VHI measures the degradation of turbofans, thus, opposite to the batteries case, it exhibits an upward trajectory, where a higher value indicates higher degradation. Similarly to the previous case, the end-of-life threshold has been set to utilize the maximum available number of cycles from the test dataset.

Upon observing the historical data of the VHI, it can be noted that initially, it exhibits a flat trajectory, remaining nearly at zero until the degradation process begins, after which it adopts an exponential-like trajectory. To accommodate this, the proposed network for this case consists of two hidden layers with 3 neurons each. The first layer employs a scaled exponential linear unit (SELU) activation function, while the second layer employs an exponential activation function. The output layer uses a linear activation function. The structure of this network (see Fig. 2(b)) is thus more complex, consisting of a total of 22 parameters (15 weights and 7 biases).

As mentioned in Section 2, certain conditions can be enforced on the particles to help them meet specific constraints. In this case, since the VHI has been designed to be greater than 0



(a) Training and testing dataset for FCG. The red line is the output of the trained MLP.



(b) Architecture of the MLP neural network used for the FCG case with 20 neurons in the hidden layer.

(d) Remaining Useful Life prediction in terms of mean and uncertainty bounds.

Figure 3. Fatigue Crack Growth case.

and monotonous, these two conditions have been enforced by eliminating particles at each iteration that did not adhere to them. With more parameters, the initial process noise had to be slightly reduced, and particularly, we set the value of $\sigma_0 = 10^{-2}$. The other values (floor noise σ_2 and the measurement noise η) remained unchanged.

Fig. 2(a) displays the training and test data, as well as the output of the trained network. It can be observed that the shape of the two trajectories is similar; however, the rate of degradation varies notably, with the training dataset exhibiting a slower trend. Additionally, the initial flat plateau adds complexity to the prediction task since the algorithm receives measurements close to the expected values, resulting in high likelihood. This behavior is illustrated in Fig. 2(d), where initially, the predicted RUL decreases almost constantly, indicating little variation in prediction. Once the measurements from the VHI start to increase, signaling the onset of degradation, the algorithm quickly adapts to the new degradation behavior and converges to the actual RUL.

Even in this case, all metrics improved when evaluated in the last quarter of the lifetime. We note a relatively low CIC in this case, which can be attributed to the narrow prediction bounds. On the other hand, this led to a relatively high value of the β Metric of the last quarter.

3.3. Fatigue Crack Growth

The last use case concerns the propagation of a crack in a rectangular plate of commercial 316L steel (Langlois Raphael, 2018) subjected to a fatigue load. The dataset comprises two tests of identical plates, with a cycling tensile loading applied with a frequency of 10 Hz and a R ratio of 0.1. The first one is subjected to a maximum force of 15 kN (test data, see Fig. 3(a)) and the second to a maximum force of 22.5 kN (training data, also in Fig. 3(a)), with a As expected, the higher the applied force, the faster the crack propagates.

The trajectories follow an exponential-like function. Therefore, the proposed architecture for this problem consists of a single hidden layer with an exponential activation function (see Fig. 3(b)). To enforce the exponential behavior of the MLP (and also to challenge the algorithm), the hidden layer consists of 20 neurons, nearly tripling the number of parameters to 61.

Due to the higher number of parameters, the values of σ_0 and σ_2 have to be significantly decreased. For this simulation, they have been set to $\sigma_0 = 5 \times 10^{-4}$ and $\sigma_2 = 10^{-6}$. As in the VHI case, the monotonicity of the curve is enforced, particularly since this is a physical constraint.

In contrast to the VHI case, we use the faster degradation as training data while attempting to estimate the slower trajectory. This poses a challenge for the algorithm since extrapolating future data without prior examples is inherently

Table 1. RUL Evaluation Metrics.

	Li-Ion	VHI	FCG
CRA	0.703	0.474	0.489
CRA 25	0.772	0.762	0.240
CIC	0.475	0.140	0.425
CIC 25	1.000	0.294	1.000
β	0.326	0.277	0.273
β 25	0.465	0.737	0.404

complex for data-driven algorithms. Nonetheless, even in this case, we observe that the algorithm adapts quite rapidly, with the remaining useful life initially remaining constant (see Fig. 3(d)), indicating that the algorithm recognized early on that the training degradation was faster. As the correct RUL is approached around the halfway point of the lifetime, the algorithm is able to capture the new trajectory and remains consistent with the prediction.

In terms of metric, we note that the CRA is low, especially in the last 25%. This is mainly due to the relative error in the very last points, where even a small error in the average predicted RUL leads to a significant penalization of the CRA, as the actual RUL is a small number. In contrast, we observe a perfect coverage in the last quarter, as the actual RUL has always fallen within the predicted bounds during that period.

4. Conclusions

The proposed methodology, combining multi-layer perceptron neural networks and particle filters, demonstrated its adaptability and effectiveness in estimating the remaining useful life across diverse engineering systems. By applying the method to three distinct use cases – estimating the end of life of lithium-ion batteries, predicting the behavior of a Virtual Health Indicator in turbofans, and analyzing the propagation of fatigue cracks in steel plates – we showcased its versatility and accuracy in capturing degradation processes. The utilization of a single training history for each case underscores the robustness of the algorithm and its adaptability even when limited data about the target system are available. Evaluation metrics such as Cumulative Relative Accuracy (CRA), Confidence Interval Coverage (CIC), and the β metric provided valuable insights into the accuracy, coverage, and uncertainty of predicted RUL bounds. These findings emphasize the practical implications of accurate RUL estimation in predictive maintenance, enabling proactive decision-making to optimize maintenance schedules and reduce operational costs. Further research can explore enhancements to the methodology and its application to additional use cases beyond time-dependent applications, thus enhancing its utility and effectiveness in real-world scenarios

ABSTRACT

This paper introduces a data-driven approach for estimating the remaining useful life of the neutron generator component in logging-while-drilling tools. The approach builds on identification of the incipient failure modes of the neutron generator and constructing a health indicator that serves as a statistical representation of the component's deterioration over time. Afterwards, a K-nearest neighbors algorithm is trained to establish the relationship between the extracted health indicator values and the corresponding remaining useful life. The effectiveness of the presented approach is verified through the utilization of real-world data gathered from oil well drilling operations. The study is part of a long term project aimed at developing a digital fleet management system for drilling tools.

1. INTRODUCTION

The multifunction logging-while-drilling (LWD) tool shown in Fig. 1 is an industry-leading formation evaluation technology developed for oil well drilling applications (SLB, 2023).

Figure 1. Multifunction LWD service

During the drilling operations, this LWD tool collects information related to formation evaluation as well as equipment diagnostics, and some of this information is transmitted in real time via mud pulses, depending on the operational requirements. The full quantity of raw information is stored in a memory board for additional analysis upon the tool returning to surface after completing drilling operations.

This multifunction LWD tool integrates functionalities that were previously achieved by two or three LWD tools, resulting in significantly reduced drilling rig operating time, fewer electrical and communication failures due to physical tool-to-tool connections, and improved geological data quality from simultaneous and co-located measurements.

One of the other critical factors that places the technology ahead of all other competitors is the inclusion of a pulsed neutron generator (PNG), as shown in Fig. 2. The PNG is an electron neutron generator that produces high-energy neutrons five times higher in energy than conventional americium-beryllium chemical sources. The PNG produces neutrons by particle fusion reaction. Multiple security locking logic has been added to the PNG firmware and hardware and is contained in operation manuals, making the use and transportation of the PNG safe. The high-energy neutron emission also allows for a variety of additional and advanced formation measurements for the customer.

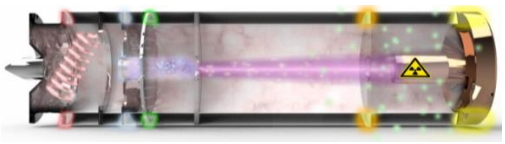

Figure 2. Pulsed neutron generator

The electrical and physical complexity of the PNG system makes it very demanding for a technician to become proficient in maintaining and troubleshooting the system and a failure of analysis would potentially result in critical field operation failures and jeopardize the company's reputation. Therefore, developing an automated fault diagnosis and degradation assessment tool to determine the health status of PNGs accurately and consistently is essential. This assessment tool can significantly reduce the potential for human error and enable users to make efficient and effective decisions (Zhan, Ahmad, Heuermann-Kuehn, & Baumann, 2010) (Isermann, 2006). This paper will focus on building data-driven remaining useful life estimation (RUL) for PNG systems, so appropriate actions can be taken for preventative replacement of the asset. The novelty and academic contributions of this study are highlighted by the fact that there has been no prior work related to RUL prediction for PNG systems, making this research a pioneering effort in the field.

The next section of this paper provides a detailed overview of the PNG system and discusses previous work and research relevant to this study. Research problem is formulated in the following section. The next two sections present the modeling approach and experimental results, respectively. A conclusions section completes the paper.

2. Pulsed Neutron Generator System

2.1. Description

For many years, the oil and gas industry has employed high-energy neutron generators in neutron-gamma-ray or neutron-neutron logging (Tittle, 1961). These generators offer several advantages over conventional chemical sources, including the ability to deactivate the PNG and eliminate radiation risks when not in use downhole. Additionally, the generators enable precise control over neutron output, facilitating more accurate measurements of formation properties.

In the field of nuclear well logging, achieving accurate formation measurements hinges on emitting neutron pulses to irradiate the Earth's formations and detecting the resulting radiation from the interaction between the Earth's formation atoms and the emitted neutrons. Understanding the characteristics of the neutron pulse, including its output and timing, is crucial for achieving precision. Ideally, the neutron pulse should exhibit a substantially square wave shape. The PNG, depicted in Fig. 3, proves instrumental in overcoming these technical challenges and facilitating the generation of desirable neutron pulses. Serving as a stand-alone particle accelerator, the PNG utilizes fusion reactions to produce neutrons.

Conducting a failure investigation and root cause analysis revealed two major failure modes of the PNG:

1. Internal cathode wire discontinuity due to overheating
2. Reduced neutron generation flux due to doped target wear

These failure modes can potentially compromise the functionality of the PNG and even lead to the failure of the LWD tool.

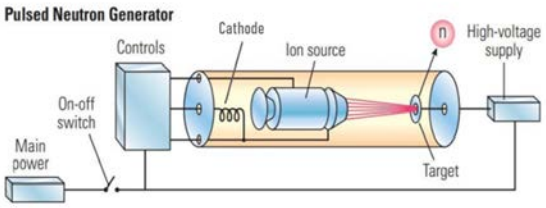

Figure 3. PNG architecture

2.2. Previous Work and Research

In prior research, a data-driven fault detection model for the PNG subsystem was introduced (Mosallam, Laval, Youssef, Fulton, & Viassolo, 2018). This approach involved creating a univariate representation known as a health indicator (HI). Subsequently, a classifier utilizing the decision tree method was trained to distinguish healthy and failed runs of PNGs. The method demonstrated high accuracy, providing quick and precise assessment for maintenance and field engineers.

Following that, a data-driven fault diagnostics method for the PNG system was introduced, specifically focusing on the detection of failures associated with the power supply boards (Mosallam, Kang, Youssef, Laval, & Fulton, 2023). This work complements the previously published fault detection model for the PNG subsystem (Mosallam et al., 2018) by providing detailed information indicating which electronic board or boards failed. The method extracts features from data channels capturing fault symptoms and builds support vector classifier models for each board. Experimental results showed an average accuracy of about 99% for all boards, reducing troubleshooting time and enabling automatic triggering of maintenance procedures for faulty boards.

The latest publication concentrated on the data-driven degradation modeling of the PNG system, emphasizing one of its incipient failure modes (Mosallam, Youssef, et al., 2023). The method extracts HI values from data channels quantifying component health degradation utilizing a random forest classification model. Experimental results demonstrate an average accuracy of 90.4%. The algorithm enables the identification of degradation stage of the PNG, empowering better planning for the equipment usage and avoidance of the failure during downhole operations.

However, in order to foster decision-making even more precisely, the necessity for a RUL estimation persists. This paper focuses on predicting the reduction of neutron generation flux due to doped target wear over time and determining the remaining useful time of the system. Integrating RUL estimation will enable proactive maintenance planning, better

decision-making on well sites, and future manufacturing forecasts and equipment delivery optimization based on worldwide RUL of active PNGs.

3. Problem Formulation

The main objective of prognostics is to minimize the equipment or system downtime by forecasting the RUL of the system (or critical components of the system), as shown in Fig. 4. The RUL prediction methods can be broadly classified into three categories: physics model based, data-driven, and hybrid (Medjaher, Tobon-Mejia, & Zerhouni, 2012)(Lei et al., 2018). Physics model based methods use mathematical models to describe the system's or component's physical behavior and predict its RUL. Although these methods require a deep understanding of the failure mechanisms and effective estimation of model parameters, they can provide accurate RUL estimation. On the other hand, data-driven methods use pattern recognition algorithms to learn patterns from historical data and make RUL predictions. The data-driven methods do not require a comprehensive understanding of the system failures but require high-quality data. Hybrid methods combine the strengths of both methods to improve RUL predictions.

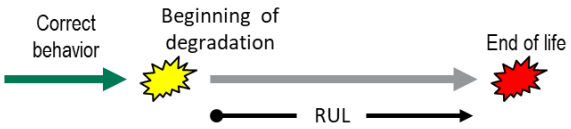

Figure 4. RUL forecast schematic

The PNG system being studied is highly complex, which limits the use of physics model-based and hybrid methods for predicting the PNG's (or PNG component's) RUL. Thus, the goal is to create a data-driven prognostic model that incorporates data related to the incipient failure modes of the PNG target. This model will estimate the target's RUL along with its confidence level as shown in Fig. 5.

There are two primary methods for building data-driven prognostic models: direct RUL mapping and cumulative degradation prognostics (Mosallam, Medjaher, & Zerhouni, 2016). The direct RUL mapping approach uses empirical models to directly correlate sensor data with the end of life (EOL) value, eliminating the need to determine the health status of the monitored component (see Fig. 6).

In contrast, the cumulative degradation prognostics approach uses empirical models to describe the system's degradation progression. This degradation information can then be used to estimate the health status of the system and predict the RUL based on the system's expected future behavior (see Fig. 7).

This study introduces a novel approach for predicting RUL using the direct RUL mapping approach. The primary objective is to establish a model that effectively captures the correlation between sensor measurements and end-of-life states, thereby enabling RUL prediction without relying on predefined alarm thresholds. Predefined alarm thresholds do not effectively capture the correlation between sensor measurements and EOL states, which can lead to less accurate predictions of RUL. The proposed method builds on the extraction of health indicators from historical training data, which serve as foundational reference models. Upon encountering new data, the approach employs a K-nearest neighbors (KNN) classifier to identify the most closely resembling HI within the database, subsequently leveraging it as a reliable RUL predictor.

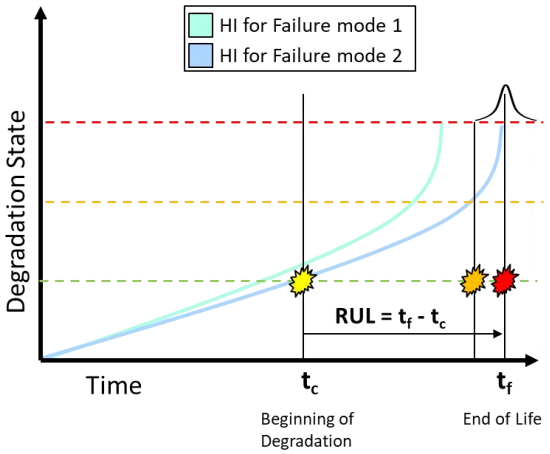

Figure 5. HIs for a system with two different failure modes

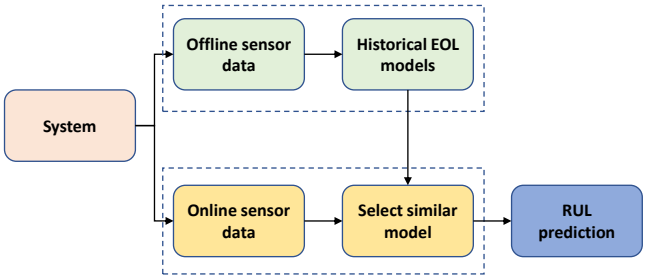

Figure 6. Direct RUL mapping approach

4. Proposed Method

The objective of the proposed method is to construct an HI based on sensor data that efficiently captures the PNG deterioration information. The HI values with RUL assignment are then modeled using a machine learning algorithm, which can estimate the RUL of the PNG. The proposed method is divided into four main steps: channel selection, preprocessing, HI construction, and modeling.

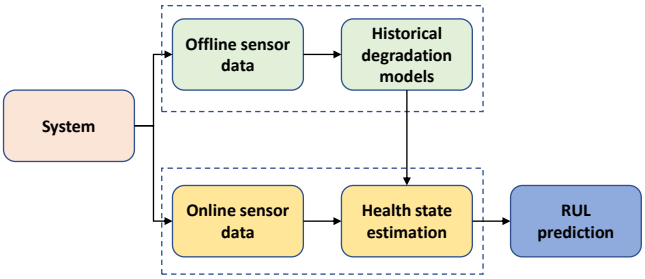

Figure 7. Cumulative degradation approach

4.1. Channel Selection

As highlighted in Section 1, the LWD tool generates a substantial number of high-resolution data channels during each drilling operation, leading to millions of data points. However, not all of these channels contribute information pertaining to the degradation of PNG over time. Enhancing the efficiency and precision of the HI involves the removal of irrelevant data channels. The selection of pertinent data channels relies on the expertise of subject matter experts with domain knowledge in nuclear physics and instrumentation. This process is crucial for optimizing the relevance of the data considered for the HI.

For the target failure mode, the following two data channels were selected:

- BLD: The internal high voltage in the PNG's minitron that enables the particles' acceleration to the target. The higher the BLD, the better the fusion reaction.
- BEAM: The particle beam current. The higher the BEAM, the higher the neutron emission.

Raw data for BLD and BEAM channels are presented in Fig. 8. The HI will be constructed using the data from the channels after the preprocessing step that will be described in the upcoming subsection. Note that the duration of each run is different according to the drilling job requirements, and the data of the sixth and eighth run before EOL are missing.

4.2. Preprocessing

The LWD data acquisition system commences recording data as soon as a field engineer initializes it for the forthcoming drilling operation (or run). The LWD tool follows the subsequent steps:

1. Tool initialization: the field engineer configures the acquisition parameters for the upcoming job, formats the tool memory, and begins the tool recording.
2. Shallow hole test: the field engineer confirms that the tool is functioning as expected inside the well before deploying the tool to the full well depth.

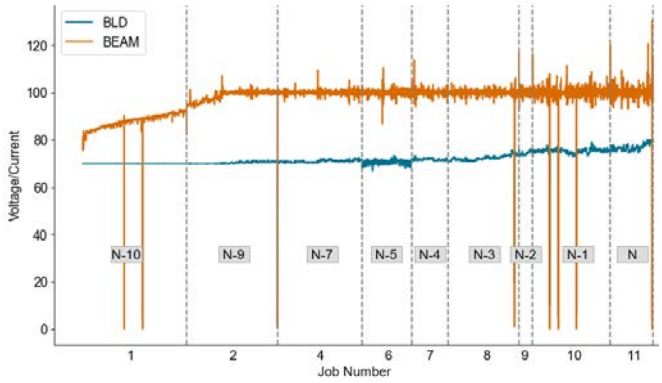

Figure 8. Raw data of the selected channels of eleven consecutive runs before EOL, where N denotes the last run, N-1 denotes the first run before EOL, N-2 denotes the second run before EOL, and so on.

3. Casing logging for caliper calibration: The field engineer calibrates the tool's ultrasonic measurement by using the known internal diameter of the metal casing connecting the rig to the wellbore and the known drilling fluid properties.
4. Drilling operation: The field engineer places the tool behind the drill bit for measurement acquisition during the physical drilling of the well.

For each run, the data collected during the initial three steps lack information pertaining to PNG degradation and are consequently excluded. Additionally, during periods when the PNG does not fire, the firmware generates dummy records to fill data channel gaps, known as missing values. All missing values must be disregarded as they do not provide any insights into faults. The duration of each drilling job varies. Let T represent the duration of a given drilling job. Consequently, the next step is undertaken to facilitate the extraction of a consistent statistical representation of the signal. Each time series of BLD and BEAM, denoted as

$$X = [x_1, \ldots, x_T]$$

and

$$Y = [y_1, \ldots, y_T]$$

respectively, generated throughout the run is segmented into $N = 200$ windows, determining the window size based on the duration of the run

$$w = \left\lfloor \frac{T}{N-1} \right\rfloor,$$

where each of $1, \ldots, N-1$ windows are of window size w and the last window is of a size $T \mod N-1$. Within each of 200 windows the minimal mode of each channel is extracted. To define the process of extracting the minimal mode, the function $g(Z)$ is denoted as the minimum of the mode of

Z, and is expressed as:

$$g(Z) = \min(\text{mode}(Z)).$$

For BLD channel, the minimal mode is extracted as follows:

$$x'_{i+1} = \begin{cases} g([x_{iw+1}, \ldots, x_{(i+1)w}]), & \text{if } i \in \{0, \ldots, N-2\} \\ g([x_{iw+1}, \ldots, x_T]), & \text{if } i = N-1 \end{cases}$$

resulting in

$$X' = [x'_1, \ldots, x'_N].$$

The same process is applied to BEAM channel, with the formula given by:

$$y'_{i+1} = \begin{cases} g([y_{iw+1}, \ldots, y_{(i+1)w}]), & \text{if } i \in \{0, \ldots, N-2\} \\ g([y_{iw+1}, \ldots, y_T]), & \text{if } i = N-1 \end{cases}$$

resulting in

$$Y' = [y'_1, \ldots, y'_N].$$

Finally, a median filter is applied to the sequence X' and Y' to smooth the signals, with $\tilde{X}$ and $\tilde{Y}$ denoting the smoothed X' and Y', respectively. Fig. 9 presents the raw signals of BLD and BEAM shown in Fig. 8 after preprocessing.

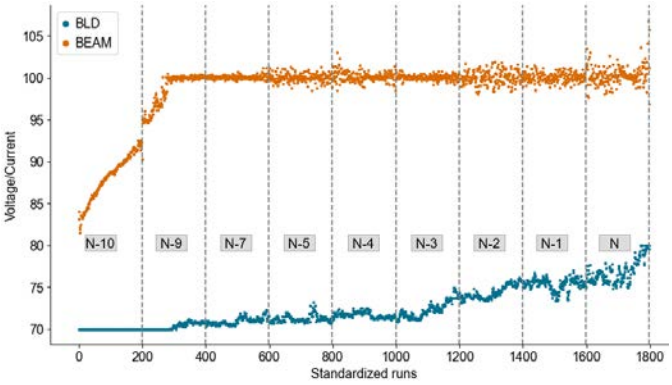

Figure 9. Preprocessed BLD and BEAM signals

4.3. Health Indicator Construction

In this algorithm step, an HI is constructed using the preprocessed data. The main objective of deriving this HI is to represent the system's degradation in a 1D array format. The HI is extracted as a result of element-wise addition of the preprocessed BLD and BEAM signals, which can be represented by the formula

$$HI = \tilde{X} + \tilde{Y}.$$

The decision to extract the HI by summing two channels comes from the fact that this approach ensures the HI has several key characteristics necessary for effectively monitoring health status of the PNG. These include sensitivity to degradation, monotonicity, predictive power, noise robustness, and consistency across conditions. Additionally, this method is computationally efficient and easily interpretable. Fig. 10 presents the HI values constructed using the Fig. 9 example data.

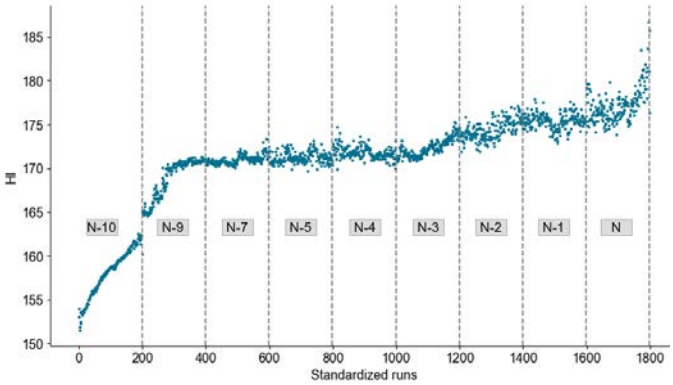

Figure 10. Constructed HI

It is important to highlight that the input data utilized reflects the incipient failure mode. Consequently, the resulting HI acts as a numerical gauge of the system's condition in a monotonic manner. Put simply, the HI offers a numerical representation of the system's health, enabling further analysis or decision-making processes.

4.4. Modeling

The HI constructed from the data collected during each drilling job results in 1D array representation, independent of the actual run duration. Thus, the RUL estimation problem can be converted into a regression problem if the array of each run has RUL assigned. To accomplish that, the usage of the PNG in hours estimated for each run is used, and respectively summed up over a lifespan. The formula for the RUL assignment is the following:

$$RUL_t = EOL - t, \forall EOL > t, \quad (1)$$

where t is the current time. The RUL labels serve as a target variable for each run. Specifically, this paper uses a KNN classifier to establish the relationship between the input HI values and their corresponding RUL i.e., $RUL_t = f(X_t)$, where

$$X_t = [x_{1,t}, x_{2,t}, \ldots x_{200,t}] \quad (2)$$

5. Experimental Results

A dataset containing operational data from 89 different LWD tool runs in different locations was collected to validate the proposed method. The dataset consists of historical runs from 16 different PNGs that reached the EOL. However, each PNG can operate different number of runs and the data availability highly varies between the PNGs. As mentioned in Section 2.2, in the previous work, the health state estimation model was developed (Mosallam, Youssef, et al., 2023). This algo-

rithm is applied for the PNG and enables distinguishing five degradation states: healthy, lightly degraded, moderately degraded, severely degraded and EOL. The dataset utilized for estimating the RUL differs from that used in previous studies, primarily due to an increased number of EOL cases captured in the current research. Previously, without a health state estimation model, the usage of the PNG until late stages of degradation was scarcely feasible, rendering RUL estimation impossible at that time. It is important to note that the main focus of this work is to predict the RUL when the PNG's degradation has already started, ad therefore, we train the model only from a certain degradation state. The RUL estimation is thus performed for the four stages of the PNG degradation being lightly degraded, moderately degraded, severely degraded or reaching EOL.

To assess the performance of the proposed method, the mean absolute percentage error (MAPE) evaluation metric is calculated. Let RUL_i be the actual remaining useful life and RUL_i^* be the predicted remaining useful life for $i = 1, \ldots, n$ where n is the total number of runs performed by all PNGs. The MAPE is defined as follows:

$$MAPE(\%) = \frac{100\%}{n} \cdot \sum_{i=1}^{n} \left| \frac{RUL_i - RUL_i^*}{RUL_i} \right| \quad (3)$$

To assess and compare the performance of the models, as well as to validate their ability to generalize the learned patterns, the dataset was split into a training set of 14 PNGs corresponding to 75 runs, and a test set of 2 PNGs resulting in 14 runs. Additionally, a specialized form of k-fold cross-validation is employed in the training phase. This method involves iterating through the PNGs, with each iteration leaving out one PNG for validation along with all its corresponding runs while training the model on the runs from the remaining $k - 1$ PNGs. This approach allows for efficient validation of how the model performs across various stages of PNG degradation, reducing the bias in performance estimation.

To select the best-performing model, two groups of algorithms were tested to estimate the RUL of the PNG: regressors and classifiers (Mosallam, 2014). The following algorithms were evaluated within each group: KNN, decision tree, random forest, and gradient boosting. Additionally, hyperparameter tuning was conducted to determine the best-performing algorithm.

The two best-performing algorithms: KNN and gradient boosting regressor (GBR) were selected for the further evaluation based on the overall MAPE presented in the Table 1. The selection of the single, most-suitable and best-performing algorithm is done based on both the MAPE overall and the MAPE calculated across various RUL intervals presented in Table 2. This approach ensures that the chosen model accurately predicts system behavior not only throughout its operational lifespan but also specifically as it approaches EOL conditions.

Table 1. MAPE of the LOOCV set for the trained algorithms

Algorithm name	MAPE (%)
K-Neighbors Classifier (K=2)	16.64 %
Gradient Boosting Regressor	17.26 %
K-Neighbors Classifier (K=3)	17.57 %
Random Forest Regressor	17.67 %
K-Neighbors Regressor (K=3)	17.78 %
K-Neighbors Regressor (K=2)	17.91 %
K-Neighbors Regressor (K=4)	18.40 %
K-Neighbors Classifier (K=4)	18.69 %
Random Forest Classifier	21.54 %
Decision Tree Classifier	21.92 %
Decision Tree Regressor	25.82 %
Gradient Boosting Classifier	30.18 %

Table 2. MAPE of the RUL intervals for the best performing algorithms

RUL interval	GBR MAPE (%)	KNN MAPE (%)
(0, 100]	26 %	13 %
(100, 200]	20 %	19 %
(200, 300]	16 %	20 %
(300, 400]	21 %	22 %
(400, 500]	8 %	11 %
(500, 600]	13 %	10 %
(600, 700]	6 %	5 %
(700, 800]	6 %	13 %

Taking into consideration the results of overall MAPE and MAPE calculated for the specified intervals, the KNN model outperforms other algorithms. The accuracy of prediction for the RUL in the interval $(0, 100]$ is significantly higher for KNN with $k = 2$, which is crucial as the PNG approaches the EOL. As previously stated, the objective is not solely to reduce the overall MAPE, but also to ensure the accuracy of predictions as the PNG approaches the end of its lifespan. The final phase of model validation involves training the model on the entire training set and evaluating its performance on the left-out test set. The MAPE for the test set is showcased in Table 3, confirming the consistent performance of both models.

Table 3. MAPE of the test set for the best-performing algorithms

Algorithm name	MAPE (%)
K-Neighbors Classifier (K=2)	16.24 %
Gradient Boosting Regressor	11.85 %

In conclusion, the KNN algorithm outperformed the GBR and other algorithms, as evidenced by the LOOCV outcomes and its superior accuracy in predicting the RUL of PNGs as they

approach the end of their lifespans. Furthermore, the KNN algorithm demonstrated strong performance on the test set, and offers greater explainability than GBR due to its straightforward methodology and direct reliance on training data points. Therefore, this model got selected for the implementation. Fig. 11 presents the RUL estimated by KNN model for all the available runs for one of the PNGs, resulting in MAPE of 11.1%.

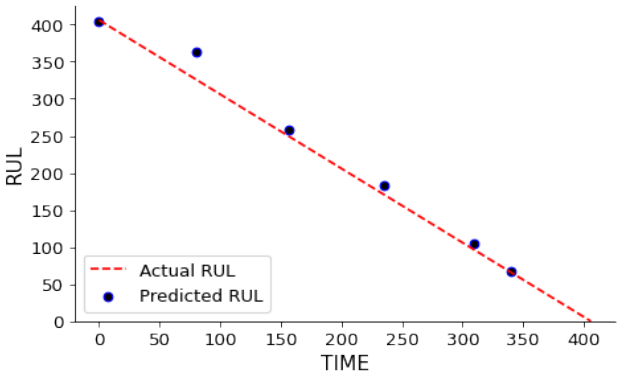

Figure 11. KNN prediction for selected PNG

6. Conclusions

This paper has presented a data-driven approach for RUL estimation of the PNG system in LWD tools. The method provides a quantitative measure of the component's deterioration by extracting the HI from BLD and BEAM data channels related to identified incipient failure mode of PNG. These HI values are used to build a KNN classification model to estimate the PNG RUL, which has been deployed as part of the health analyzer software for the LWD tool. Experimental results on actual operational data collected from the field resulted in the MAPE for LOOCV of 16.6%, and MAPE for the test set of 16.2%, demonstrating the effectiveness of the method. This method can assist maintenance engineers in promptly determining the PNG's remaining operational lifespan, reducing troubleshooting time; enable automatic triggers for maintenance activities for replacing faulty nuclear components; and improve decision making. Regarding future endeavors, there are intentions to address the second incipient failure mode of the PNG, with the aim of improving the prognostics model for the PNG.

ABSTRACT

In this paper, we develop a model for detecting defects in fabric products based on an object segmentation algorithm, including a novel image data augmentation method to enhance the robustness. First, a vision-based inspection system is established to collect image data of the fabric products. The three types of fabric defects, such as a hole, a stain, and a dyeing defect, are considered. To enhance defect detection accuracy and robustness, a novel image data augmentation method, referred to as the defect-area cut-mix, is proposed. In this method, the shapes that are the same as each defect are extracted using the masks, and then they are added to non-defective fabric images. Second, an ensemble process is implemented by combining the results of two models, one with high sensitivity in defect diagnosis and the other with lower sensitivity. The results demonstrated that the model trained on the augmented dataset exhibits improved metrics such as intersection over union and classification accuracy in defect detection on the test dataset.

1. INTRODUCTION

Recently, there has been a surge in demand for automation in the product manufacturing and inspection processes across various sectors within the manufacturing industry. However, due to the considerable time and cost, product inspection by small and medium manufacturers is usually done manually with the human eye. Meanwhile, human inspections can lead to inconsistent test results based on the examiner's skill level and fatigue. Recently, thanks to artificial intelligence (AI) technology, manufacturing companies have actively applied automated inspection processes that can be adapted to different types of products (Jung et al., 2021). In order to conduct automated inspections of products with diverse geometries, it is necessary to develop a robust image-based inspection algorithm and an imaging system that is robust to external factors, including lighting conditions.

Research on image-based product inspection algorithms can be divided into many approaches: statistical approach, AI model-based approach and hybrid approach (Hanbay et al., 2016). Among various approaches, the statistical approach involves using image processing techniques (such as frequency decomposition or filtering) to extract features from images, while the hybrid approach combines statistical methods and modeling techniques to leverage the strengths of both. Therefore, these can be recategorized as follows: those based on combined image processing and those based on deep learning models such as convolutional neural networks (CNN) (Bhatt et al., 2021). For combined image processing algorithms that involve a mix of image processing steps, it is possible to achieve high inspection accuracy only for specific products with the same geometries. However, this approach has a drawback: if the product type or capturing environment changes, we must adjust the algorithm's parameters or create a new algorithm from scratch. On the other hand, algorithms based on deep learning models can respond to various products and environments depending on the training dataset and can achieve high inspection accuracy. However, since the performance of the inspection model greatly depends on the quality of the dataset (number of data points, diversity, etc.), developing a robust model requires investing time and effort to collect a large number of images of defective products (Russakovsky et al., 2015).

Combined image processing algorithms are primarily used when the shooting environment is consistent and the variety of inspected products is limited. Tong et al. (2016) presented an optimal Gabor filter for inspecting woven fabrics. Zhou (2019) focused on inspecting defects in semiconductor wafers. They applied a median denoising process to images to extract favorable features for defect detection and proposed algorithms using machine learning techniques such as KNN and SVM to classify images. Deep learning model-based algorithms require significant computing resources and longer processing times compared to combined image processing algorithms. However, they offer the advantage of creating robust models that are resilient to variations in

shooting environments and product types, depending on the quality of the training dataset. Tabernik et al. (2020) presented a novel segmentation network and decision network trained on the Kolektor Surface-Defect-Dataset (KolektorSDD), containing product surface defects, to infer surface defects with higher accuracy. Ho et al. (2021) proposed a step-by-step algorithm where an object detection model locates defects, and an instance segmentation model infers the shape of defects in woven fabrics. Deep learning model-based algorithms are generally evaluated to have higher robustness compared to combined image processing algorithms.

However, if the feature distribution of the images in the training dataset (such as brightness, types of products, defects, etc.) is not sufficiently diverse, the model may only accurately infer data within the feature distribution of the training data. For instance, assuming a specific defect in the training dataset has a radius of 0.1~0.2mm and appears darker than its surroundings, the detection may become challenging if the defect is larger than 0.2mm in radius or if the product's color is darker than the training images. This is due to the new data displaying features not seen in the training. To address this issue, collecting more data would be one solution. However, as mentioned earlier, for small and medium-sized enterprises, investing significant time and resources without immediate productivity gains can be challenging. Therefore, there is a need to generate unseen data using observed feature distributions within the dataset.

Therefore, in this work, we present a novel defect data augmentation method, referred to as the defect-area cut-mix, to improve the accuracy and robustness of deep learning-based fabric defect detection models from the perspective of dataset quality. In addition, an ensemble process is applied by combining high and low sensitivity models in the fabric defect diagnosis. Figure 1 shows the schematic diagram depicting the research methodology in this paper.

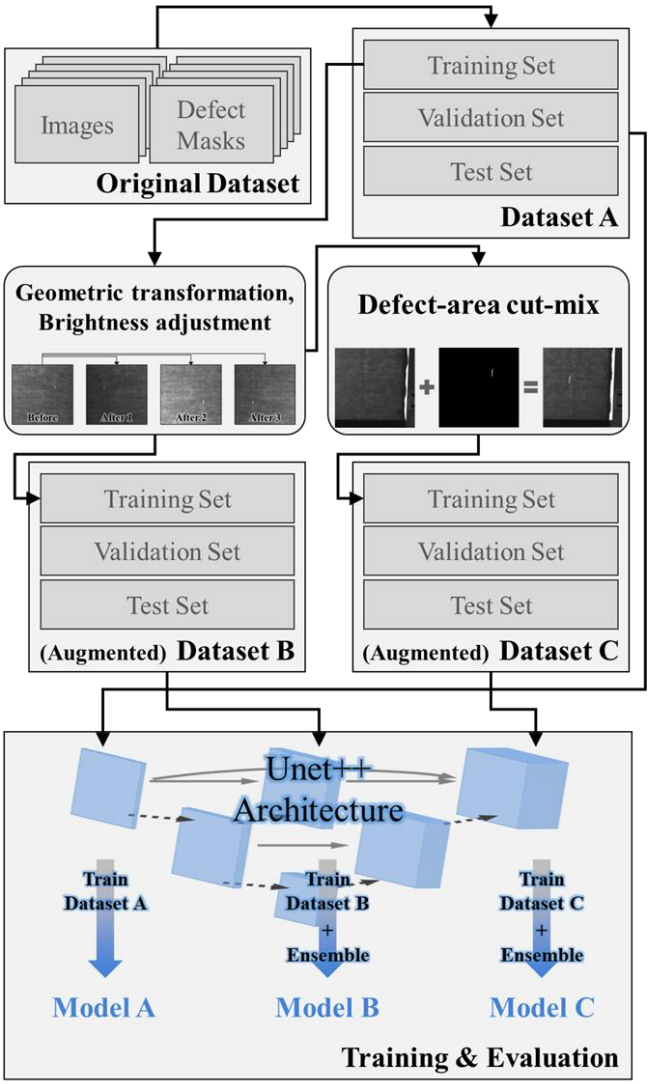

Figure 1. Schematic overview of the research methodology

2. MODEL CONSTRUCTION AND DATA AUGMENTATION

2.1 Image Data Collection and Model Construction

In this section, the research methodology for image collection and defect detection model construction is explained. There are three steps, as follows:

Step 1. Collection of fabric defect image data using vision cameras in the fabric inspection machine.

To collect the fabric defect image data, two single-channel machine vision cameras were installed on the fabric inspection machine, as shown in Figure 2. The fabric inspection machine was designed to inspect the fabric rolls while they were continuously rotating. The three fabric types were black denim, blue denim, and light blue fleece. All images were collected while moving the fabric at a speed of approximately 30 cm per second, like in the actual fabric inspection environment.

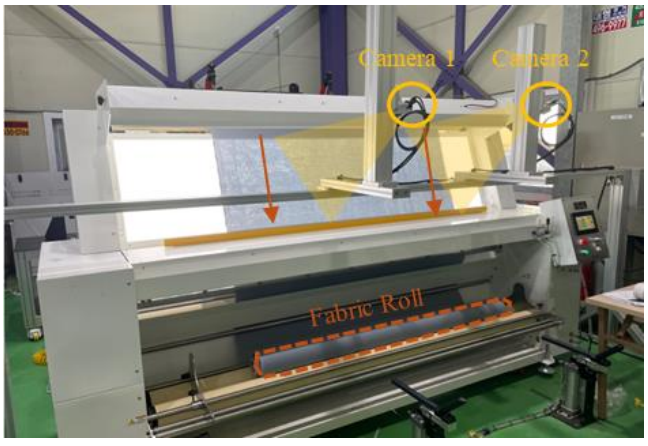

Figure 2. Image data collection using fabric inspection machine

Step 2. Construction of the original datasets and defect-augmented datasets through image patching and masking of defect areas. (Masking and labeling are conducted using CVAT, which is a well-known open-source annotation tool.) (OpenCV et al. n.d.)

The collected original images have dimensions of 3000 pixels in height and 4080 pixels in width. Due to their large size, it is inefficient for deep learning models to process them directly, necessitating resizing or patching. When resizing the original images directly, as shown in Figure 3, small defect areas may become significantly reduced and thus may not be detected. To avoid this issue, we performed patching in a grid of 3 (vertical) by 4 (horizontal) patches and resized each patch to 320x320 pixels. Subsequently, masking was applied to all patches containing defects to construct the dataset.

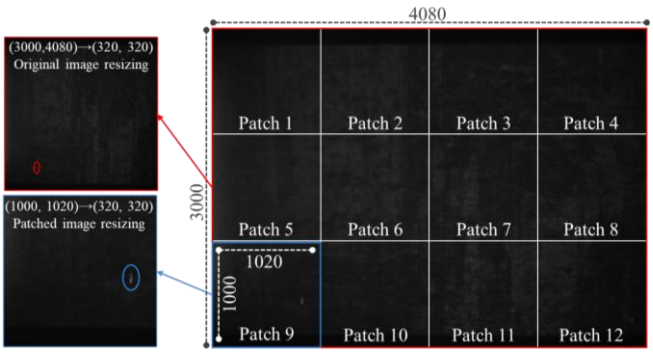

Figure 3. Image patching and resizing

Step 3. Design and construction of the defect detection model architecture for training.

This dataset was then divided into training, validation, and testing sets, as shown in Table 1. Both the training and validation datasets were composed entirely of patches containing defects. For the testing dataset, we included both patches with defects and patches without defects to assess the tendency for false positives in detecting defects on normal (non-defective) patches.

Table 1. The number of images of original patched dataset

Defect type	Without defect	Hole	Stain	Dyeing	Total
Training	0	468	109	71	648
Validation	0	465	95	95	655
Testing	6312	80	45	3	6440

Deep learning-based defect inspection commonly uses object detection and instance or semantic segmentation models. In this study, we selected a semantic segmentation model to reflect the characteristic of quantitatively calculating the area of defects during the quality assessment of fabric products.

We designed our own Unet++ architecture, which has recently demonstrated strong segmentation performance in the biomedical field, to build the model as depicted in Figure 4. The model specifically takes an image input size (320,320) and outputs masks (320,320,4) corresponding to non-defective regions and each defect. Additionally, the input image undergoes four rounds of down-sampling and up-sampling, with skip connections applied between all feature maps (Zhou et al. 2019). To ensure performance in both pixelwise classification and defect classification during model training, we employed the BCE Dice loss function, calculated as Eq. (1).

By using both BCE (Binary Cross-Entropy) and DICE loss functions, it is possible to accommodate diversity in loss calculations while leveraging the stability provided by BCE. In semantic segmentation tasks, x_n and y_n are both binary images (masks), representing the ground truth and the predicted mask, respectively.

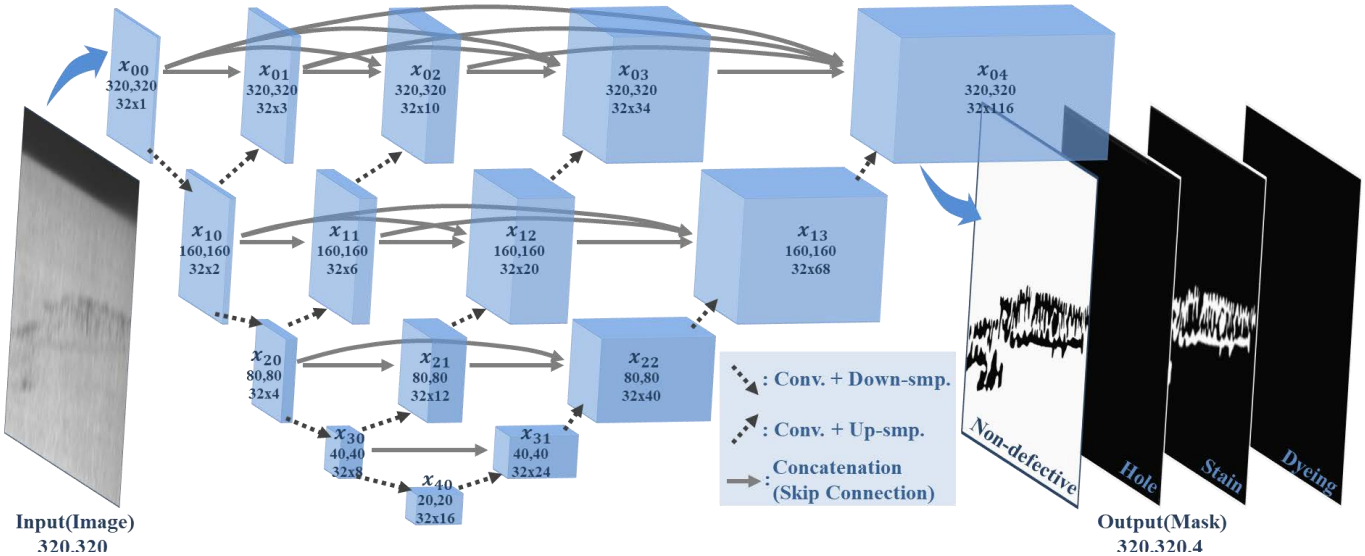

Figure 4. Architecture of fabric defect detection model.

$$\text{BCE Dice Loss} = \text{BCE loss} + 0.5 \times \text{Dice loss}$$

$$\text{BCE Loss} = -\sum(y_n \log \sigma(x_n) + (1 - y_n) \log(1 - \sigma(x_n))) \quad (1)$$

$$\text{Dice loss} = \sum\left(1 - \frac{2 \times y_n \times x_n}{x_n^2 + y_n^2 + 10^{-5}}\right)$$

2.2 Defect Data Augmentation

The number of images within a dataset to ensure the basic performance of CNN-based deep learning models can vary depending on several factors (Luo et al., 2018; Israel et al., 2021). However, models used in industrial applications often face limitations on the available data within their own manufacturing environments. Thus, transfer learning using pre-trained weights on custom datasets is a commonly used strategy to ensure robustness (Redmon et al. 2016). However, even in such cases, it is generally recommended to have at least 1000 images per class (Cho et al., 2015). Therefore, it is necessary to apply a proper data augmentation approach to ensure enhanced performance of the defect detection model.

In the dataset created by patching the collected original images in this study, the numbers of defect instances are highly imbalanced, as shown in Table 1. Additionally, the absolute number of images is insufficient. The most frequently observed defect in both the training and validation datasets is "hole," occurring more than four times as frequently as "stain" and "dyeing" defects combined. Even when combining the training and validation datasets, the total number of images does not exceed 1500. Therefore, image data augmentation is essential, and it is necessary to reflect the characteristics of each defect in the augmentation process. Stain defects exhibit various shapes and intensities within the defect areas, while dyeing defects primarily appear as broad horizontal stripes. Hole defects typically manifest as long, uniformly shaped vertical openings. Figure 5 shows examples of images depicting each type of defect.

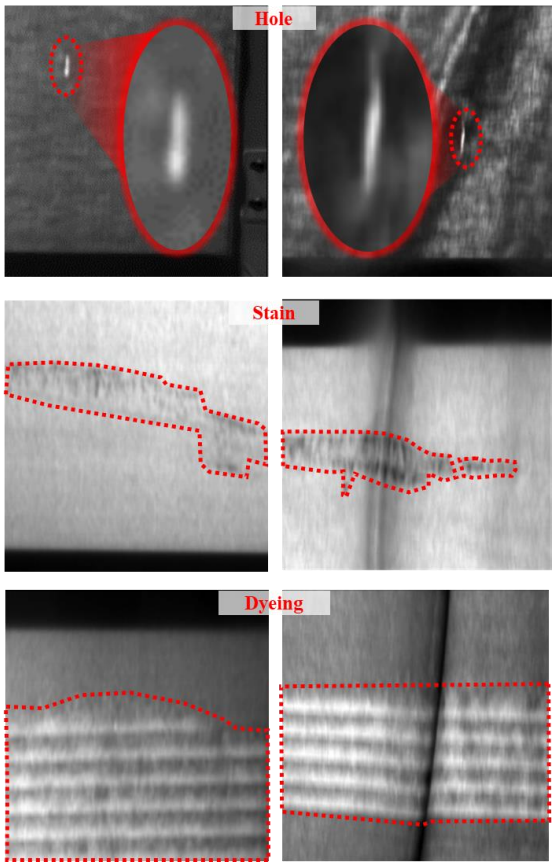

Figure 5. Example images of each type of defects.

Commonly used methods for image augmentation include geometric transformations (such as flipping, rotating, and affine/perspective transformations) and brightness adjustment (such as histogram equalization). These methods are advantageous because the operations applied to the

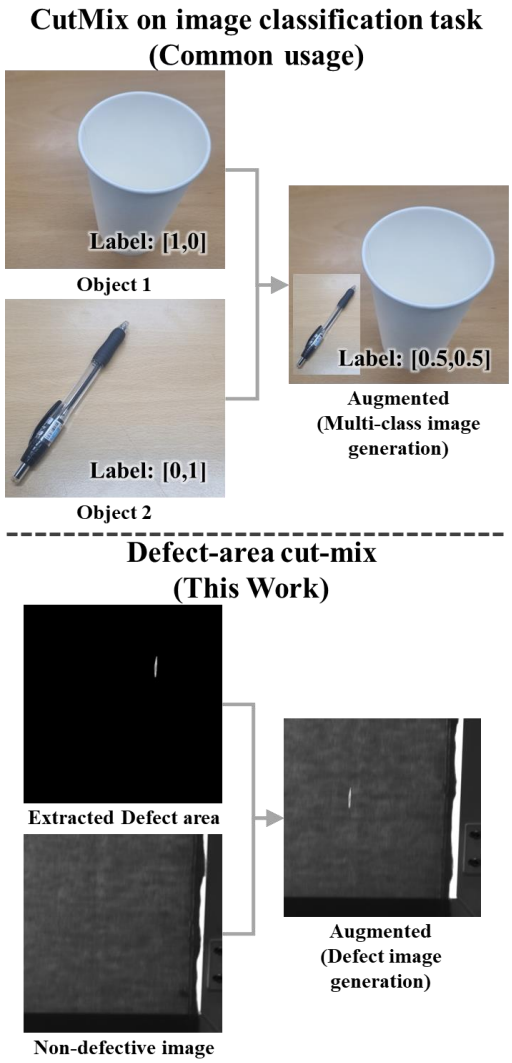

Figure 6. Comparison of conventional cut-mix and defect-area cut-mix.

images are simple, allowing for the rapid generation of new images. However, these methods alter the shape and brightness information of defects along with the surrounding background area, making it challenging to reflect cases where the model inputs unseen shapes of defects.

Therefore, in this study, to overcome the limitations of such data transformations, the cut-mix augmentation technique was applied specifically to defect areas. The cut-mix augmentation is a technique proposed to improve the generalization performance of image classification models by encouraging the model to better learn the local features of each class (Yun et al., 2019). Figure 6 illustrates the difference between the conventional cut-mix augmentation method and the approach used in this study, referred to as "defect-area cut-mix." While the original cut-mix augmentation mixes rectangular regions of different class images directly, in this study, only the defect areas were cut out and overlaid onto images without defects to create new images with defects. This approach allows for the assumption of situations where the shape and location of defects may change from the dataset's perspective.

– Extract defect areas using defect masks and images.

– Select images without defects and overlay defect areas directly or randomly, depending on the characteristics of the defects. Here, the characteristics of the defects refer to the area or shape of the defect areas.

Specifically, for hole defects (see Figure 7), where the defect size is relatively small, the defect areas can be randomly overlaid in portions of the fabric that are not occupied by the fabric. However, manual overlay position selection is required for stain and dyeing defects, where the defect regions' forms and areas vary considerably and may occupy a significant portion of the image.

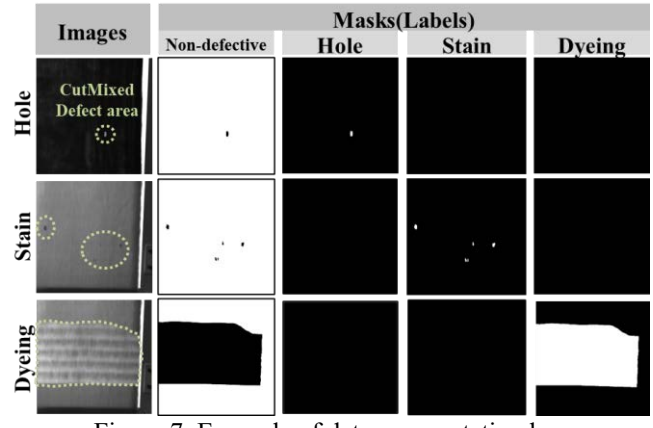

Figure 7. Example of data augmentation by defect-area cut-mix.

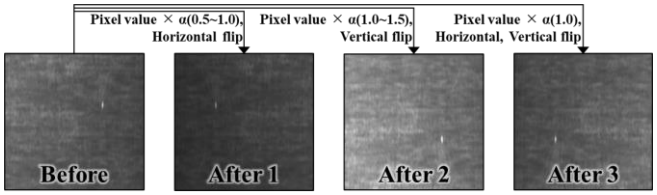

Figure 8. Example of data augmentation by geometric transformation and brightness adjustment.

After applying the defect-area cut-mix as described above, geometric and brightness adjustments were applied to the dataset. The following three image processing techniques were independently applied with a certain probability: brightness adjustment to reflect changes in external lighting conditions during image capture (random alpha values within the range of 0.5 to 1.5 multiplied by the entire image), horizontal flip, and vertical flip. Figure 8 illustrates examples of data augmentation.

To assess the performance difference caused by augmentation, the composition of the final datasets constructed by applying augmentations to the original patched dataset in Table 1 is presented in Table 2 and Table 3 (datasets B and C). To validate the effectiveness of defect-area cut-mix augmentation, augmentations depicted in Figure 7 without defect-area cut-mix were applied to dataset B. On the other hand, every augmentation containing geometric transformation, brightness adjustment, and defect-area cut-mix was applied to dataset C. All augmentations were applied only to the training dataset. However, for stain defects, it was empirically confirmed that applying the defect-area cut-mix technique was not effective due to the diverse shapes of the defects. Therefore, this augmentation was applied to the hole and dyeing defect only. Additionally, to avoid misdiagnosing defects on images without defects, images without defects and with temporary wrinkles (which are not considered defects) were added to the training and validation datasets. Compared to the original patched dataset, the augmented datasets partially alleviated the class imbalance between defect types.

Table 2. Composition of the augmented dataset B

Defect type	Without defect	Hole	Stain	Dyeing	Total
Training	930	549	491	186	2156
Validation	7200	465	95	95	7855
Testing	6312	80	45	3	6440

Table 3. Composition of the augmented dataset C

Defect type	Without defect	Hole	Stain	Dyeing	Total
Training	930	702	907	314	2853
Validation	7200	465	95	95	7855
Testing	6312	80	45	3	6440

3. PERFORMANCE EVALUATION

Through a series of steps, three datasets were constructed before and after augmentation (naturally, the original patched dataset is a subset of the augmented dataset). Each of the three different datasets was trained on our self-designed architecture of the Unet++ model, as depicted in Figure 3. For convenience in description, the model trained on the pre-augmented data will be referred to as Model A, the model trained on the augmented dataset without defect-area cut-mix will be referred to as Model B, and the one trained on the augmented dataset containing defect-area cut-mix will be referred to as Model C. By training a strict model and a less strict model independently, and then using an ensemble method, we were able to avoid incorrectly classifying defect-free fabric data as defective in Model B and Model C. To produce the segmentation results, the ensemble applied to Model B and Model C used soft voting on the pixel-wise classification probabilities of two distinct models.

The identical testing dataset was used to test Models A, B, and C. Masks for the defect and non-defective areas were inferred by the models. The mean Intersection over Union (IOU) score for each patch of each image was used to assess the performance metrics for defect identification, with a 0.7 threshold. This measure evaluates each model's ability to identify defects and distinguish defective regions from non-defective ones.

Furthermore, the confusion matrix depicted in Figure 8 was used to calculate the models' precision, recall, accuracy, and F1 score in order to assess their performance in defect identification. Note that false positives represent instances where non-defective regions were incorrectly predicted as defective, while false negatives represent instances where defects were present but not detected. These metrics provide insights into the classification performance of the models in both non-defective and defective regions. Classification among different types of defects showed a 100% accuracy for all models. This high accuracy can be attributed to the clear characteristics of each type of defect, as described earlier.

Overall performance metrics for Model A, B and C are presented in Table 4. Model C, trained on the augmented dataset with defect-area cut-mix, demonstrated superior performance across all metrics compared to Model A and Model B. Among the performance metrics for defect detection, Recall exhibited the smallest change, indicating that both models excelled at detecting actual defects with minimal variation.

The effects of geometric transformation and brightness adjustment augmentation, as well as additional training on defect-free images, were evident in the difference between models A and B. Comparing the confusion matrix of Model B with that of Model A shows that all metrics improved. Notably, the total number of false positives decreased significantly from 1252 to 181. This indicates a substantial

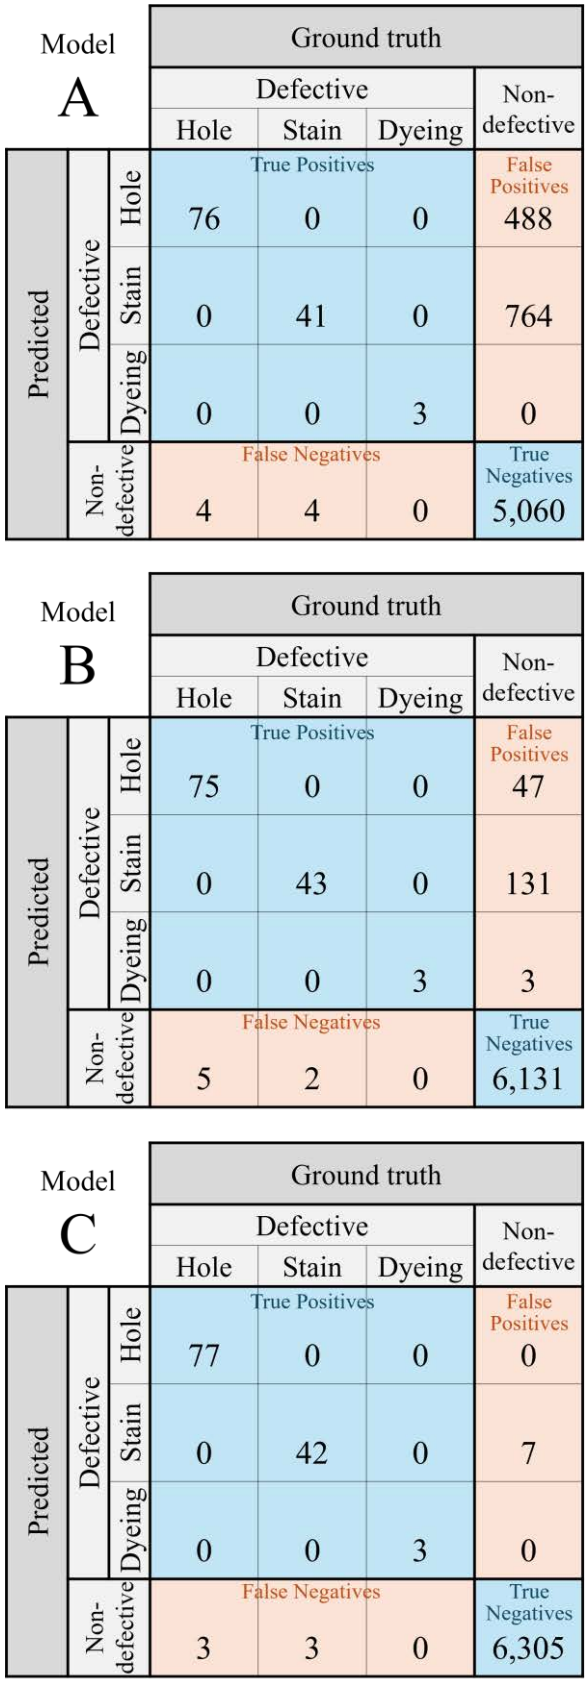

Figure 8. Confusion matrices of Model A, B and C

reduction in the model's tendency to incorrectly classify normal regions as defects. Moreover, the Mean IOU improved significantly from 0.375 to 0.704.

In the case of Model C, trained on a dataset where defect-area cut-mix was applied, the number of false positives decreased significantly compared to the other two models, with only 7 false positives in the Stain defect category. (It is interesting to note that the cut-mix was not applied to the Stain defect.) Furthermore, Model C achieved a more robust test result, with a mean IoU of 0.902, compared to the other two models.

In summary, the augmentation proposed in this study and ensemble techniques led to a significant improvement in defect detection performance compared to model without these enhancements. This demonstrates that the proposed defect-area cut-mix technique can enhance the robustness of deep learning models in image-based defect detection tasks.

Table 4. Metrics comparison of model A, B and C

Model	A	B	C
Mean IOU	0.375	0.704	0.902
Precision	0.086	0.401	0.946
Recall	0.938	0.945	0.953
F1 score	0.160	0.281	0.950
Accuracy	0.804	0.971	0.998

4. CONCLUSION

This study proposed the novel image data augmentation method, referred to as the defect-area cut-mix, for enhancing defect detection accuracy and robustness of the deep learning-based fabric inspection system. In the defect-area cut-mix method, the defect shapes that are the same as actual fabric defects (hole, stain and dyeing defect) were extracted using the masks, and they were added to the non-defective fabric images for an augmentation. To demonstrate the effectiveness of the proposed defect-area cut-mix augmentation method, three data sets were prepared, such as the original dataset with augmentation (dataset A), that with conventional geometrical augmentation and brightness adjustments (dataset B), and that with defect-area cut-mix, geometrical augmentation, and brightness adjustments (dataset C). Then, the ensemble approach combining the deep-learning models with high and low sensitivity was applied to datasets B and C. Finally, it was found that the fabric defect diagnosis model with the dataset C and ensemble approach showed the best performance in terms of mean IOU, precision, recall, F1 score, and accuracy.

ABSTRACT

Electro-Mechanical Actuators (EMAs) are projected to revolutionize the flight control actuator paradigm, potentially replacing hydraulic-powered systems in the future. Consequently, the functioning of EMAs is destined to become critical for the safe and reliable operation of aircraft. Abnormal conditions of the mechanical components of EMAs can lead to their failure. The objective of this work is to develop a method for the early detection of abnormal conditions of the components of EMAs. The proposed method is based on a signal reconstruction model that estimates the motor position of EMA as expected in normal conditions of its components. Then, the presence of an abnormal condition is identified when the difference between the motor position and its reconstructed position in normal conditions exceeds a preset threshold. The signal reconstruction model employs a Physics-Informed Long Short-Term Memory network (PILSTM), whose architecture combines a physics-informed cell for the solution of the differential equations governing the EMA operation, and a data-driven Long Short-Term Memory (LSTM) cell which receives in input the output of the physics-informed cell and reconstructs the position expected in normal conditions. The proposed method is applied to data simulated by a high-fidelity model of EMAs. The results show that PILSTM is able to provide accurate, physics-consistent estimates of the motor position of EMA in normal conditions and the missed and false detection alarms are lower than those of other state-of-the-art methods.

1. INTRODUCTION

In Prognostics and Health Management (PHM), fault detection amounts to the identification of abnormal conditions in the monitored structure, system and components (SSCs). A common approach relies on signal reconstruction models that give in output the signal values in normal conditions of the SSC (Hines, Uhrig, & Wrest, 1998). The difference between the actual signal measurements and the reconstructed signal values (so-called residual) is analyzed for detecting the presence of abnormal conditions: the larger the residuals, the more the SSC behaviour deviates from that in normal conditions.

Signal reconstruction methods can be classified in model-based and data-driven (Yang, Ling, & Bingham, 2013). Model-based approaches typically use numerical simulators which code the specific laws of physics. They require a limited amount of data for model parameter calibration and retain the physical interpretability of the model output. In (Zhang, Foo, Don Vilathgamuwa, Tseng, Bhangu, & Gajanayake, 2013), a method combining physics-based model and extended Kalman filter has been developed to perform fault detection of induction motors. In (Sarikhani, & Mohammed, 2012), a back electromotive force estimator has been built using only laws of physics and the fault detection is performed by comparing the signal estimates and the

nominal values. The main limitations of model-based approaches are the difficulty of representing with a model the complexity of modern SSCs, the inevitable approximations made to build and solve the model and the computational efforts needed for numerical simulation. On the contrary, data-driven methods are typically simpler to implement since they do not require knowledge on the physics of the system and are able to discover complex nonlinear patterns in data. Recently, deep learning-based methods have gained popularity. In (Qi, Jang, Cui, & Moon, 2023), a data-driven model based on the use of gated recurrent units has been built to reconstruct the dynamic behaviour of stirred tank reactors in normal conditions. In (Xu, Baraldi, Lu, & Zio, 2022), a Generative Adversarial Network and an auxiliary encoder have been developed to detect anomalies in the operation of automatic doors of high-speed trains. Some limitations of data-driven methods are their difficulty of extrapolation outside the region covered by the training data and the lack of interpretability of their outputs, due to their black-box nature.

Hybrid methods combining model-based and data-driven methods have also been proposed. In (Chao, Kulkarni, Goebel, & Fink, 2022), sensor readings and estimates of unobservable parameters inferred by physics-based models have been used as input of a deep learning method for predicting the remaining useful life of turbofan engines. In (Shen, Lu, Sadoughi, Hu, Nemani, Thelen, ... & Kenny, 2021), a physics-informed deep learning approach has been developed for fault detection of bearings, in which the loss function contains a term that incorporates physical knowledge on the envelop spectrum. In (Yucesan, & Viana, 2021), recurrent neural networks embedded with physics-based models of fatigue and grease degradation have been developed to predict grease damage. In (Li, & Deka, 2021), a physics-informed autoencoder integrating the laws of physics relating current and voltage in the loss function is developed to detect high impedance faults in distribution grids. In (Chen, Rao, Feng, & Zuo, 2022), a physics-informed strategy for setting the hyperparameters of a Long Short-Term Memory (LSTM) network is developed for fault detection of gearboxes. It is based on the maximization of the discrepancy between healthy and simulated faulty patterns. Physics-informed methods have shown their capability of improving performance in fault detection, diagnostics and prognostics, while enhancing consistency with the law of physics, which can enhance trustability. Yet, their use for developing signal reconstruction models is still challenged by the difficulty of considering variable operating conditions and highly nonlinear relationships.

In this context, this work presents the development of a novel signal reconstruction method based on the use of Physics-informed LSTMs (PILSTMs) to perform fault detection. The basic idea behind the developed PILSTM is the combination of a physics-informed and a data-driven layers. The former solves the differential equations of the model of the system in normal conditions, whereas the latter layer receives in input the output of the physics-informed layer and reconstructs the signals in normal conditions. The developed approach is applied to data simulated using a high-fidelity model of EMAs, and its performance is compared to those of other state-of-the-art methods. The problem of fault detection in EMAs has been previously addressed in (Yang, Guo, & Zhao, 2019), where a LSTM-based model is developed for signal prediction and the residuals between predictions and measurements are used to detect abnormal conditions. In (Zhang, Tang, & Chen, 2021), a model based on an improved Gate Recurrent Unit (GRU) is developed to predict signal evolutions, which are then used to classify faults with a similarity measure. The two methods have been developed and verified considering a small set working conditions and command signals, which limits their applications to the real scenarios.

The rest of this paper is organized as follows. Section 2 formulates the problem. Section 3 presents the proposed fault detection method. Section 4 discusses the application of the proposed method to EMAs. Finally, the conclusions of the work are presented in Section 5.

2. PROBLEM STATEMENT

We consider the motor of an EMA, which is its most critical component, considering the frequency of its failures and their potential severity. The function of the motor is to provide the torque needed to actuate the aircraft aerodynamic surface (Berri, Dalla Vedova, & Maggiore, 2019). It is here modelled as a component that receives in input the three-phase current signals, $[x_{\tau,1}, x_{\tau,2}, x_{\tau,3}]$, and provides as output the motor position, y_τ (Baldo, Bertone, Dalla Vedova, & Maggiore, 2022) (Figure 1).

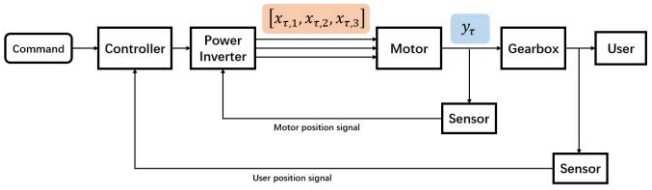

Figure 1. Input and output signals of the motor of an EMA.

We assume to have the available dataset $\mathcal{D}^{train} = \{X^r, y^r\}_{r=1,\dots,R}$ containing R input-output time-series of T time instants, $X^r \in \mathbb{R}^{T\times 3}$ and $y^r \in \mathbb{R}^T$, collected during the operation of an EMA in normal conditions. The generic vector $\vec{x}_t^r = [x_{t,1}, x_{t,2}, x_{t,3}]$ of X^r contains the value of the nth phase current signal at the tth time instant, whereas y_t^r indicates the value of the motor position signal. Each input-output time series $\{X^r, y^r\}$ corresponds to different operational conditions of the EMA.

The objective is the development of a fault detection method for the early identification of abnormal conditions in the EMA motor. The method is based on the development of a

signal reconstruction model $f: \hat{y}_\tau = f(X_\tau)$ that gives in output the value $\hat{y}_\tau$ that the motor position would have in normal conditions at the time τ, given the values of the input signals $X_\tau = [\vec{x}_t]_{t=1:\tau}$ measured from time 0 until the time τ. An anomaly indicator is, then, built considering the residual, $d_\tau = \hat{y}_\tau - y_\tau$, between the motor position reconstructed by the model and the actual measurement. The norm of d_τ is small if EMA is in normal conditions and large in case of abnormal conditions: therefore, the detection of an anomaly condition can be obtained by statistical analysis of the residuals.

3. METHOD

The signal reconstruction model, $\hat{y}_\tau = f(X_\tau)$ is a PILSTM, which is capable of dealing with large non-linearities in the dynamics of the time-series. The first layer is a physics-informed (PI) layer that implements numerical methods to estimate the motor position. The second layer is a traditional LSTM cell. Fully-connected (FC) layers are used to map the extracted hidden features to the output signal (motor position). The complete architecture of the signal reconstruction model is shown in Figure 2.

Section 3.1 describes the PI layer and Section 3.2 describes the LSTM layer of the PILSTM. Section 3.3 defines the anomaly indicator used for the detection of abnormal conditions.

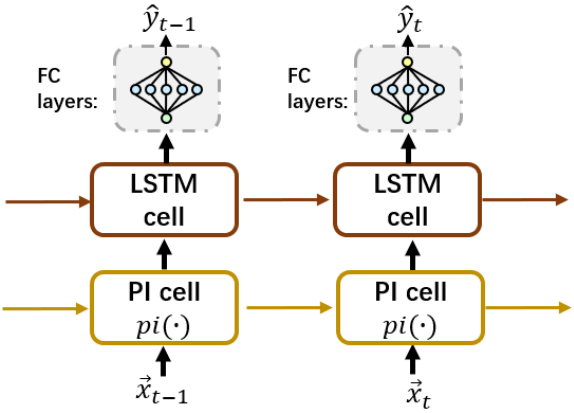

Figure 2. Architecture of the proposed PILSTM.

3.1. Physics-informed layer

The differential equation used to describe the operation of the EMA motor and transmission in normal conditions is (Baldo, Bertone, Dalla Vedova, & Maggiore, 2022):

$$F = (J_m + J_u^*)\ddot{y}_t + C_u\dot{y}_t + C_m(\pm\sqrt{|\dot{y}_t|}) \quad (1)$$

where y_t is the motor position, F is the motor torque, J_m is the motor inertia, J_u^* is the inertia of the gearbox following the motor and C_u is the viscous friction of the gearbox. F is computed from the current signals $x_{t,1}, x_{t,2}$ and $x_{t,3}$ as:

$$F = \sum_{n=1,2,3} x_{t,n} \cdot k_n \quad (2)$$

with

$$k_1 = -k_E \cdot \sin(\theta_e) \quad (3)$$

$$k_2 = -k_E \cdot sin\left(\theta_e - \frac{2}{3}\pi\right) \quad (4)$$

$$k_3 = -k_E \cdot sin\left(\theta_e - \frac{4}{3}\pi\right) \quad (5)$$

$$\theta_e = 2\pi\left(\frac{P \cdot y_t}{2\pi} - floor\left(\frac{P \cdot y_t}{2\pi}\right)\right) \quad (6)$$

where k_n is the nth-phase back-electromotive force (EMF) coefficient, P is the number of pole pairs and k_E is the back-EMF motor constant.

The EMA motion in normal conditions is, then, formulated as a 2-order differential equation:

$$\ddot{y}_t = g(\vec{x}_t, \dot{y}_t, y_t) \quad (7)$$

which is numerically solved by resorting to the 4-stage Runge–Kutta method (RK4) (Butcher, 1987). More details about the RK4 method are reported in Appendix 1. The customized RK4 cell solves Eq (1) by computing (Nascimento, Fricke, & Viana, 2020):

$$[y_t, \dot{y}_t] = pi(\vec{x}_t, y_{t-1}, \dot{y}_{t-1}) \quad (8)$$

The obtained y and $\dot{y}$ are hidden features $\vec{h}^{(1)}$ fed to the LSTM layer. To distinguish the estimates provided by the physics-informed layer and the actual measurements, the motor position and its first derivative computed by the physics-informed layer are indicated as y^{phy} and $\dot{y}^{phy}$ (Figure 3).

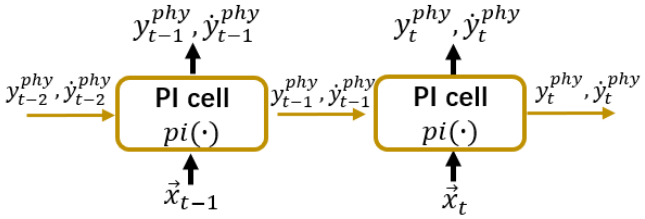

Figure 3. Architecture of the physics-informed layer.

3.2. LSTM layer

In the second layer of the PILSTM, data-driven LSTM cells are used to reconstruct the signal values. The cells receive in input the signal estimates $\vec{h}^{(1)}$ (Figure 4) and control the information flow using input, forget and output gates to remember, when needed, information for long periods of time.

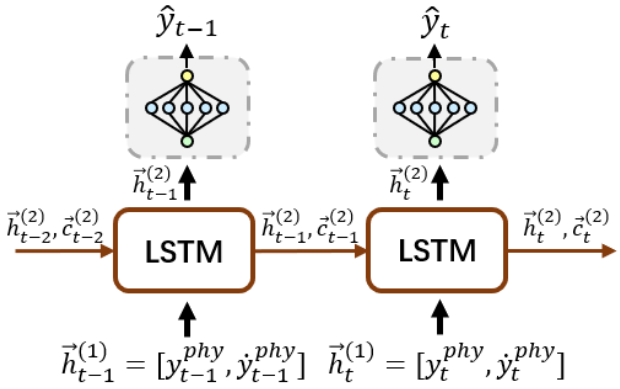

Figure 4. Architecture of LSTM layer.

Specifically, at time t, the LSTM cells receive in input $\mathbf{h}_t^{(1)}$, which is the concatenation of y_t and $\dot{y}_t$, process the temporal behaviour of the time-series and provide in output the vector of hidden features $\vec{h}_t^{(2)}$ and cell states $\vec{c}_t^{(2)}$. The following FC layers map the extracted features $\vec{h}_t$ into the estimates of the motor position $\hat{y}_t$. The structure and detailed operation of the LSTM cells are reported in Appendix 2.

The objective of the training of PILSTM is to identify the optimal combination of parameters values (weights and biases) that minimizes the error between the actual values of y_t and the estimates $\hat{y}_t$. To this aim, the following loss function is minimized on the training data in $\mathcal{D}^{train}$:

$$\mathcal{L} = \frac{1}{R \cdot T} \sum_{r=1}^{R} \sum_{t=1}^{T} \|y_t^r - \hat{y}_t^r\|^2 \qquad (9)$$

3.3. Definition of the anomaly indicator

The test time-series $X^{test} = \{x_{t,n}^{test}\}_{t=1,\dots,\tau,n=1,2,3}$, contains the measurements of the phase current signals until the present time τ, and it is rearranged in a set of $\frac{\tau-l}{ss} + 1$matrices $X_{t_k}^{tw} \in \mathbb{R}^{l\times 3}$, $t_k = (k-1) * ss + l$ with $k = 1,\dots,\frac{\tau-l}{ss} + 1$, each one containing the current signals $[x_{t,1}, x_{t,2}, x_{t,3}]$ in a time window of l time steps. Between one matrix and the following, a sliding step of ss time steps is applied. At present time τ, the residuals $D = [\hat{y}_{\tau-l+1}, \hat{y}_{\tau-l+2}, \dots, \hat{y}_\tau] - [y_{\tau-l+1}, y_{\tau-l+2}, \dots, y_\tau]$ are computed and used to define the anomaly indicator (AIND):

$$AIND = \|D\|_{L_2}^2 \qquad (10)$$

Finally, a threshold Thr for $AIND$ is defined: considering a validation set, and the occurrence of an abnormal condition is detected if $AIND$ exceeds Thr.

4. Case Study

The functioning of an EMA working in normal conditions has been simulated using the high-fidelity (HF) simulator described in (Berri, Dalla Vedova, & Maggiore, 2019). Specifically, $R = 60$ time-series with time length $T = 50$s of EMA operation in normal conditions have been generated for training the PILSTM model and verifying the signal reconstruction performance. Wavelet denoising has been applied to measured signals. The time series has been obtained at a frequency of 100Hz.

4.1. Signal reconstruction in normal conditions

The dimensionality of $\vec{h}_t^{(2)}$ is 10. The FC layers consist of 2 hidden layers with 10 and 5 neurons and 1 output layer with 1 neuron. The learning rate is set equal to 0.01 and the epoch is 250. The Adam optimizer is used to optimize the parameters of the LSTM layer and FC layers.

The $R = 60$ time-series in normal condition are divided into a training set containing 30 time-series and a validation set containing the other 30 time-series.

The performance of the proposed PILSTM is compared to two state-of-the-art methods: (1) a pure physics-based approach based on the solution of Eq. (13) with RK4 to compute the motor position; (2) a pure data-driven method, which uses a traditional LSTM to estimate the motor position. The most critical hyperparameters of the LSTM (number of layers, number of hidden states, learning rate) are optimized performing a grid-search with the objective of maximizing the reconstruction accuracy evaluated on a subset of the training set not used for the loss computation (Eq. (9)) during training. The optimal configuration is found to be 2 layers, 16 hidden states and a learning of 0.001. The Root Mean Squared Error (RMSE) is used as metric to evaluate the reconstruction performance.

Table 1. Comparison of the accuracy in the reconstruction of the motor position for EMA working in normal conditions. The RMSE is computed with respect to the time series of the validation set.

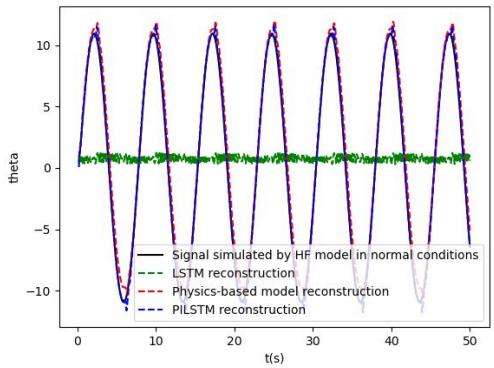
	PILSTM	Physics-based method	LSTM
RMSE	0.7087	0.9621	14.6087

Table 1 reports the obtained reconstruction accuracy on the validation data. An example of motor position estimates is shown in Figure 5. Note that: (1) the pure data-driven method provides the worst performance, which indicates that the training data are not providing enough information for the reconstruction of the input-output relationship; (2) the proposed PILSTM method provides the best performance, which is obtained by reducing the systematic error of the pure physics-based model in the position reconstruction when the motor is operating reversely (Figure 5). Due to the remarkably worst performance of the LSTM model, which makes reconstruction errors more than one order of

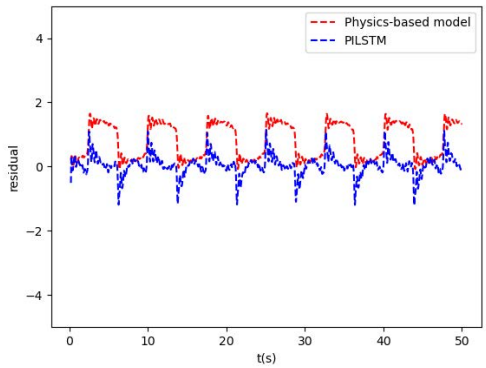
magnitude larger than the other approaches, the generated residuals by LSTM are not shown in Figure 5 (b).

4.2. Fault detection

A test set containing normal and abnormal conditions data has been generated by simulator. The set contains 9 time-series in normal conditions and 20 time-series in abnormal conditions obtained by assuming a dry friction of 20%, 35% and 50%, respectively, for a time interval of 50s. With respect to the anomaly indicator setting, the length of the time window is set equal to 100, which is the number of measurements collected in 1s, and the sliding step ss is set equal to 10 steps. An example of reconstruction of the motor position for an EMA operating in abnormal conditions is shown in Figure 6. As expected, the values of the residuals tend to be larger than the residuals in normal conditions (Figure 5 (b)) for both the physics-based model and the proposed method. Also, the residuals of the proposed method are remarkably larger than zero, which confirms its capability of distinguishing between normal and abnormal conditions.

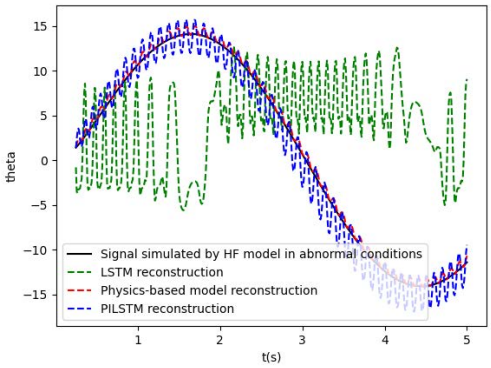


(a)

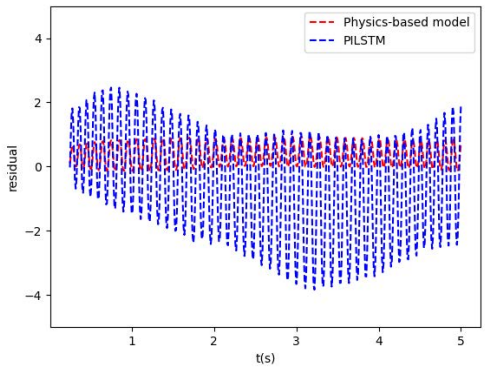


(b)

Figure 5. (a) reconstructions of the motor position and (b) corresponding residuals for an EMA in normal conditions.



(a)



(b)

Figure 6. (a) reconstructions of the motor position and (b) corresponding residuals for an EMA in abnormal conditions.

Figures 7, 8, 9 show the Receiver Operating Characteristic (ROC) curves obtained by varying the threshold of the anomaly indicator for the detection, considering the three levels of fault severity, separately. The x-axis reports the False Positive Rate (FPR), i.e., the rate of time windows in normal conditions identified as abnormal conditions and the y-axis reports the True Positive Rate (TPR), i.e., the rate of time windows in abnormal conditions identified indeed as abnormal conditions. The ideal performance is represented by the upper left corner point [0,1]. An overall measure of anomaly detection performance is the AUC (Area under the ROC Curve) whose most satisfactory value is 1, which indicates that all normal and abnormal time series are correctly identified.

Table 2. AUC considering the three levels of fault severity.

Fault severity	Proposed method: PILSTM	Physics-based method	Pure data-driven method LSTM
20% dry friction	0.7211	0.4590	0.4056

35% dry friction	0.7661	0.4637	0.5468
50% dry friction	0.9971	0.4892	0.4628

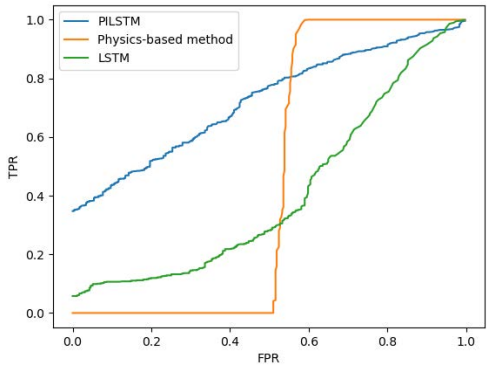


Figure 7. ROC curve made by normal condition data and 20% dry friction abnormal condition data in the test set.

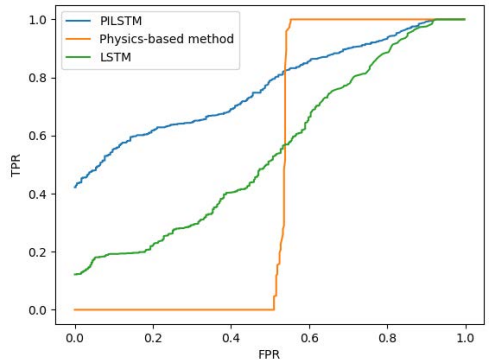

Figure 8. ROC curve made by normal condition data and 35% dry friction abnormal condition data in the test set.

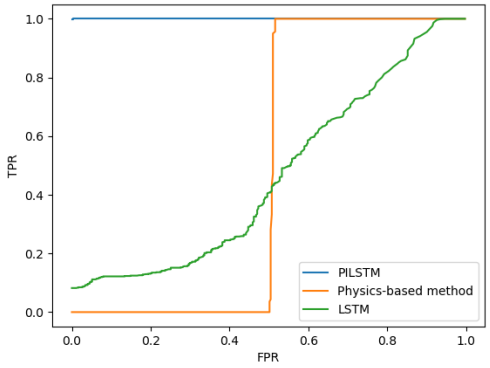

Figure 9. ROC curve made by normal condition data and 50% dry friction abnormal condition data in the test set.

From Table 2, it is seen that the developed PILSTM provides the best performance in all fault severities and the pure LSTM model shows the worst performance due to its poor capability of reconstructing the signals. As expected, the performance of PILSTM becomes better as the fault severity increases.

5. Conclusion

The present work has addressed the problem of fault detection in industrial components. A novel method for signal reconstructions has been developed based on a PILSTM model. Specifically, the PILSTM integrates an RK4 solver of the differential equation governing the EMA operation in normal condition into a LSTM hidden layer. A case study considering a simulated dataset of EMA operation has been considered. The proposed method has shown a more satisfactory accuracy in the signal reconstruction than pure data-driven and physics-based methods. The residuals between reconstructed and measured signals have, then, been used for the detection of abnormal conditions. The results show that the method is capable of detecting abnormal conditions of smaller severity than other comparison methods.

Future work will be devoted to optimally setting the threshold used for detecting the occurrence of abnormal conditions, with the objective of balancing false and missed alarms for fault detection according to the user demand. Also, the obtained results will be compared with those of other state-of-the-art methods for unsupervised abnormal condition detection, such as Deep Semi-supervised Anomaly Detection.

APPENDIX 1: 4-STAGE RUNGE–KUTTA METHOD

With the available physical knowledge of industrial components, a generalized form of 2-order differential equation that governs the industrial component can be defined:

$$\ddot{y} = g(\vec{x}, \dot{y}, y) \tag{11}$$

where $\vec{x}$ is the vector of input signals, y is the vector output signals, $\dot{y}$ and $\ddot{y}$ are first and second derivatives of y, respectively.

Considering the step-size h between time t and time $t+1$, RK4 is used to numerically integrate Eq. (11) over time with step h:

$$\begin{bmatrix} \dot{y}_{t+1} \\ y_{t+1} \end{bmatrix} = \begin{bmatrix} \dot{y}_t \\ y_t \end{bmatrix} + \frac{h}{6} \cdot \begin{bmatrix} k_1 + 2k_2 + 2k_3 + k_4 \\ l_1 + 2l_2 + 2l_3 + l_4 \end{bmatrix} \tag{12}$$

$$k_1 = g(\vec{x}_t, \dot{y}_t, y_t) \tag{13}$$

$$k_2 = g\left(\vec{x}_{t+h/2}, \dot{y}_t + \frac{h}{2} \cdot k_1, y_t + h \cdot \frac{l_1}{2}\right) \tag{14}$$

$$k_3 = g\left(\vec{x}_{t+h/2}, \dot{y}_t + \frac{h}{2} \cdot k_2, y_t + h \cdot \frac{l_2}{2}\right) \tag{15}$$

$$k_4 = g(\vec{x}_{t+h}, \dot{y}_t + h \cdot k_3, y_t + h \cdot l_3) \tag{16}$$

$$l_1 = y_t \tag{17}$$

$$l_2 = y_t + \frac{h}{2} \cdot l_1 \tag{18}$$

$$l_3 = y_t + \frac{h}{2} \cdot l_2 \tag{19}$$

$$l_4 = y_t + h \cdot l_3 \tag{20}$$

APPENDIX 2: LSTM CELL

LSTM cell structure at time *t* is shown in Figure 9. We differentiate output and states of LSTM cell denoted as $\vec{h}_t$ and $\vec{c}_t$, respectively. Vector size of the output and states is the same and it is defined by number of hidden states in the cell. Let denote p as number of hidden states, so $\vec{h}_t \in \mathbb{R}^{p\times 1}$ and $\vec{c}_t \in \mathbb{R}^{p\times 1}$. The $\vec{h}_{t-1}$ and $\vec{c}_{t-1}$ of LSTM cell at time $t-1$ will serve as an input to LSTM cell at time t, whereas the other input is $\vec{x}_t$. There are three gates that control the information flow within cell: (1) input gate $\vec{i}_t \in \mathbb{R}^{p\times 1}$ controls what information based on output $\vec{h}_{t-1}$ and $\vec{x}_t$ will be passed to memory cell, (2) output gate $\vec{o}_t \in \mathbb{R}^{p\times 1}$ controls what information will be carried to the next time step and (3) forget gate $\vec{f}_t \in \mathbb{R}^{p\times 1}$ controls how memory cell will be

updated. All LSTM cells that are used in the models are implemented as follows:

$$\vec{i}_t = \sigma(W_i\vec{x}_t + U_i\vec{h}_{t-1} + \vec{b}_i) \quad (21)$$

$$\vec{o}_t = \sigma(W_o\vec{x}_t + U_o\vec{h}_{t-1} + \vec{b}_o) \quad (22)$$

$$\vec{f}_t = \sigma(W_f\vec{x}_t + U_f\vec{h}_{t-1} + \vec{b}_f) \quad (23)$$

$$\vec{a}_t = tanh(W_c\vec{x}_t + U_c\vec{h}_{t-1} + \vec{b}_c) \quad (24)$$

$$\vec{c}_t = \vec{f}_t \circ \vec{c}_{t-1} + \vec{i}_t \circ \vec{a}_t \quad (25)$$

$$\vec{h}_t = \vec{o}_t \circ tanh\,(\vec{c}_t) \quad (26)$$

where variable weights and bias to be computed during training process are W_i, W_o, W_f, $W_c \in \mathbb{R}^{p\times L}$, U_i, U_o, U_f, $U_c \in \mathbb{R}^{p\times p}$, $\vec{b}_i$, $\vec{b}_o$, $\vec{b}_f$, $\vec{b}_c \in \mathbb{R}^{p\times 1}$. $\circ$ is element-wise multiplication of two vectors (Hadamard product). σ is element-wise logistic sigmoid activation function. Connection between different layers of LSTMs is achieved such that the output of former layer is as an input to the next layer.

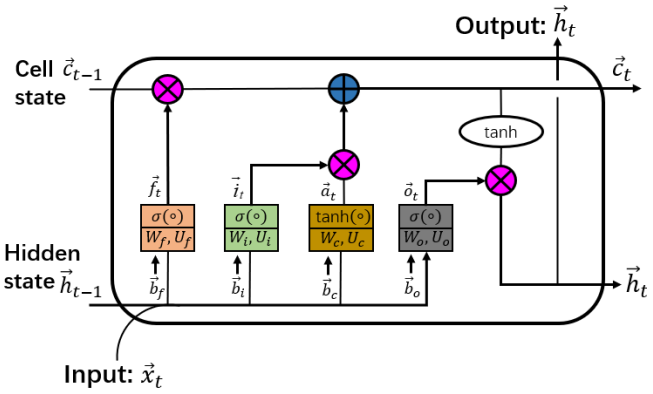

Figure 9. Single LSTM cell structure.

Development of a Feature Extraction Methodology for Prognostic Tasks of Aerospace Structures and Systems

ABSTRACT

The performance of prognostic models used for prognostic health management (PHM) applications heavily depend on the quality of features extracted from raw sensor data. Traditionally, feature extraction criteria such as monotonicity, prognosability, and trendability are selected intuitively. However, this intuitive selection may not be optimal.

This research introduces an innovative approach to transform raw data into 'high-scoring' data without the need for predefined feature extraction criteria. Our methodology involves generating a set of synthetic high-scoring time series. These synthetic time series, resembling the length and amplitude of target features, are created through Monte Carlo sampling (MCS) of a user-defined hidden semi-markov model (HSMM). We pair these synthetic time series with raw data/features from the signals and use them as targets to train a convolutional neural network (CNN). As a result, the trained CNN can convert input features into high-scoring ones, irrespective of their initial characteristics. So, this study provides the following contribution to PHM frameworks: it transforms raw data/features into high-scoring ones without relying on predefined criteria, rather on stochastically generated labels that resemble the nature of the degradation processes. It is worth noting, that the proposed FE technique is independent of the prognostic model that will be utilised, thus making it applicable to the established prognostic models.

We demonstrate and validate the effectiveness of this approach using acoustic emission (AE) sensor data for remaining useful life (RUL) estimation of open-hole CFRP specimens. We compare prognostic performance using cumulative AE features with their transformations via our proposed framework. The transformed features exhibit superior prognostic performance, underscoring the value of our innovative feature extraction framework.

1. INTRODUCTION

The current state-of-the-art feature extraction (FE) for prognostics relies heavily on deterministic targets chosen based on intuitively defined metrics such as monotonicity, prognosability, and trendability (Coble & Hines, 2009). These targets have shown efficacy in transforming raw data from sensors, providing a foundational approach for modelling degradation histories (Eleftheroglou, 2020; Moradi, Broer, Chiachío, Benedictus, & Zarouchas, 2023).

The literature-standard procedure for FE for prognostics includes the transformation of the noisy sensor data to high-scoring ones by utilising predefined deterministic labels. These labels are usually derived from simple functions such as second-degree polynomials, exponential and logarithmic. However, the inherent limitation of these deterministic labels lies in their assumption of certainty during the transformation process. This simplification potentially restricts their predictive accuracy and applicability, especially in scenarios characterised by complex and stochastic behaviours of system deterioration and noisy sensor measurements. Additionally, setting deterministic targets for transforming inherently stochastic signals, may significantly increase the complexity and computational time of the applied models (Xu et al., 2023; Chen, Qin, Wang, & Zhou, 2021; Ye, Zhang, Shao, Niu, & Zhao, 2022). These critical deficits motivate our research, highlighting a significant gap in existing methodologies. There is an evident need for enhanced feature extraction techniques that account for the

inherent noise associated with the sensor measurements.
Our research aims to fill this gap by introducing a novel approach integrating a stochastic labelling approach for noisy sensor signals with convolutional neural networks (CNNs). This method leverages Monte Carlo sampling (MCS) of predefined hidden semi-Markov models (HSMMs) to generate high-scoring degradation trajectories that serve as labels for transforming the sensor data utilizing the CNN. By doing so, the model is trained to transform the raw condition monitoring (CM) data into features suitable for prognostic health management (PHM) frameworks while accounting for the inherent noise of sensor measurements. The CNN is also trained on time windows of the data rather than the entire sequences. This attribute enables the model's applicability in real-world scenarios, allowing it to operate online.
The main contribution of the present study is the integration of MCS of HSMMs with CNNs to transform raw sensor data into stochastic degradation trajectories, thus incorporating randomness while being able to operate online in real-world use cases. By alleviating the ill-posed dependency of the FE methods on deterministic labels that stem from intuitive pre-defined metrics, we aim to create a simple and efficient online FE methodology able to transform raw sensor data into features with enhanced prognostic performance. This will ensure the accuracy and higher certainty of the applied PHM frameworks.
The remaining of this study is organised as follows:

- Section 2 delves into the core methodology of this research, providing insight into all of the different components of the proposed transformation methodology as seen in Figure 1.
- Section 3 presents a case study involving acoustic emission (AE) data and demonstrates the proposed methodology's practical application and efficacy. This section is crucial for illustrating the model's ability to handle real-world data.
- Section 4 discusses the research results, by first looking at the transformation of the data and then focusing on the prognostic outcomes. This section highlights the improved prognostic performance achieved using the transformed data by comparing these results against the baseline cumulative transformation of the raw data. This comparative analysis underscores the proposed transformation's enhanced performance in PHM tasks.
- Section 5 concludes the paper with a discussion of the implications of the research findings and proposes ideas for future works.

2. Aspects of the Feature Extraction framework

In this section, we will introduce the method for enhancing the performance of prognostic algorithms by transforming raw data signals into forms similar to those generated through Monte Carlo simulated data. The methodology unfolds over

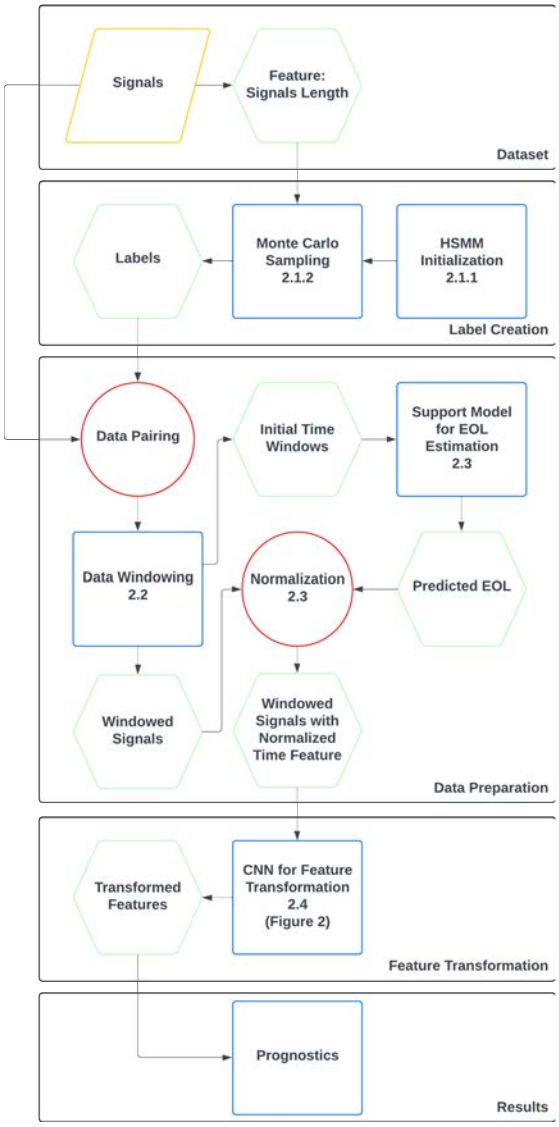

Figure 1. Flowchart of the proposed methodology.

four subchapters, detailing each critical phase of the transformation process:

1. **Label Creation via MCS an HSMM:** This section describes how MCS of HSMM generates labels with the same time length as the target signal. These labels serve as a reference for the desired signal characteristics.
2. **Data Windowing for Online Operation:** The necessity of data windowing is explored here, underlining its importance in developing a system capable of online operation. Data windowing segments the continuous data stream, facilitating real-time processing and analysis.
3. **Support Model for EOL Estimation and time feature normalization:** This part of the method involves creating a model to predict an asset's end of life (EOL). Knowing the EOL is crucial for normalizing the time feature across

all signals, ensuring consistency in the data transformation process.

4. **Convolutional Neural Network (CNN) Model for Feature Transformation:** The technique's culmination is developing a model capable of converting raw data signals into idealized forms. This model leverages the insights gained from the previous steps to enhance the raw signals, making them more suitable for prognostics.

Together, these steps outline a comprehensive approach to data signal transformation that will boost the predictive accuracy and reliability of prognostic tools.

2.1. Label Creation via MCS of HSMM

Our framework's data transformation is based on a supervised learning algorithm. To that end, we need to provide labels for our samples. These labels need to encapsulate the stochastic nature of the assets' degradation. The way to achieve that is by modelling the degradation process with an appropriately initialized HSMM and then utilising it to generate degradation histories of equal length to our training samples. In order to generate degradation histories from a pre-initialized HSMM, we utilize MCS. It is worth noting that the initialization of the HSMM is a short procedure that is explained thoroughly in Sections 2.1.1 and 3.3, and the MCS is a simple algorithm presented in Algorithm 1. Adding to that, the label creation procedure, as explained below, is only required during the training step of the FE procedure. During the online deployment, the transformation of the sensor signals is done in a sub-second time manner since it includes only the windowing of the incoming data and the inference part of the trained CNN. Therefore, the proposed frameworks applicability and scalability is not an issue. In the following, the HSMM's initialisation is discussed, a short introduction to MCS is provided, and finally, its utilization for the required label generation is presented.

2.1.1. HSMM Initialisation

As discussed previously, the first step is to properly initialise the HSMM model to resemble the degradation process. To that end, it's needed first to declare the Initialisation topology ζ (Eleftheroglou, Zarouchas, & Benedictus, 2020):

- **The number of the hidden states (N)**: representing the different levels of degradation.
- **Connectivity between hidden states (Ω)**: This parameter defines the connectivity between the states by defining the allowed transitions between them.
- **Condition Monitoring feature (I)**: The observation of the values of a single CM feature is considered to be the sole indicator of damage in the system.
- **Number of discrete monitoring values (V)**: In the case where the connection between the observation of the CM feature and the damage states is modelled in a non-parametric way, then it has to be converted to several discrete levels V.
- **Transition rate function (λ)**: This is the main characteristic of the degradation process since each transition will follow this function. This parameter can depend on the sojourn time of the current state, the transition between states, the total operating time or any combination of the above

So, in order to fully characterise the HSMM model, a set of parameters $\theta = \{\Gamma, B\}$ are needed where Γ are the degradation process parameters and B are observation process parameters. Γ parameters consist of the parameters needed to define the chosen λ function, and B parameters consist of the emission matrix $\mathbf{B}$. $\mathbf{B}$ is a matrix of dimension of $N * V$ containing the likelihood that every possible observation in the Z space will be emitted by a certain hidden state. After defining the HSMM, in order to generate the required sequences, MCS is utilized, which will be explained in Section 2.1.2.

2.1.2. Monte Carlo Simulated Data

Monte Carlo Sampling is a powerful statistical technique used across various fields. At its core, it leverages the power of randomness to solve complex problems, often too difficult or impossible to tackle with traditional deterministic methods. Monte Carlo Sampling operates on a simple yet profound principle: it uses randomness to approximate problems' solutions. Thanks to the law of large numbers, the more samples are used, the better the actual solution is estimated. Monte Carlo methods are useful when analytical solutions are complex or unavailable, providing a versatile tool for approximation and simulation across diverse applications (Lemieux, 2009). However, Monte Carlo sampling has two main disadvantages. Firstly, it can be computationally inefficient, especially when dealing with high-dimensional or complex problems. Since Monte Carlo methods rely on random sampling to estimate quantities, they may require a large number of samples to achieve accurate results, which can be computationally intensive and time-consuming. Secondly, Monte Carlo methods may struggle to estimate rare events or probabilities accurately with very low or very high values, leading to potential inaccuracies in the results.
In this framework, MCS is utilized to perform a "random walk" over the HSMM. Based on the random sampling and the predefined probability functions of the HSMM, a hidden state is picked for each time step, which in turn emits an observation. The observation is captured, and the "random walk" continues following the design of the model, until the transition to the final observed and terminating state occurs. So, in the context of the proposed methodology, Monte Carlo simulations take place in the training process, so the testing process does not require simulated data. Hence, computational inefficiency is not

a concern for applicability. Additionally, rare samples (events) are not a concern of the feature extraction process since the domain of condition monitoring techniques is predefined in most cases.
Finally, it is worth highlighting that this approach reverses the traditional training process for HSMMs. Instead of relying on multiple observation sequences to estimate parameters, the predefined parameters are used to produce the observation sequences. This method is detrimental to the stochastic generation of trajectories, which are later used as labels for our transformations. By transforming the raw data with these sequences, the predictive accuracy of prognostic algorithms can be significantly enhanced. This is attributed to the fact that this method provides a transformation based on statistical characteristics rather than the traditionally used deterministic labels as explained in the previous. The pseudocode for the implementation of the MCS of the HSMM is adapted from (Eleftheroglou, 2020) and presented in Algorithm 1.

2.2. Data Windowing for Online Operation:

After acquiring the observation sequences that will be used as labels for the transformation of the raw data, our methodology strategically segments both the signals and their corresponding labels into fixed-length time windows. This division is essential for facilitating the model's operation in an online environment, where it is impractical to process the entire signal simultaneously due to the streaming nature of data.

2.3. Support Model for EOL Estimation and time feature normalization

However, the previously mentioned segmentation introduces a challenge: the absence of a definitive feature indicating the end of the signal complicates the transformation process, potentially affecting the accuracy of the model's predictions. To address this issue, we propose developing a secondary model capable of supporting the transformation by predicting the end-of-life (EOL) of the asset, based solely on information from the initial time window. In doing so, we aim to normalise the time feature on a scale from 0 to 1. However, in practice, this normalisation will yield values ranging from 0 to a number close to 1, as it perfomrs only a rough estimation of the EOL, rather than an accurate prediction. This approach aids our model in effectively adapting to and processing signals in real time, paving the way for more accurate and reliable predictions.
To this end, we opted for a fully connected neural network (FCNN) tailored with a specific architecture to meet our predictive objectives. The model is stacked in this order:

- A fully connected layer of 200 neurons is designed to process 200-time-steps inputs of the condition monitoring feature.
- A rectified linear unit (ReLU) function to introduce non-linearity, enhancing its learning capability.
- A dropout layer is then applied to mitigate the risk of overfitting by randomly omitting a subset of neurons during the training phase.
- For the output layer, a single neuron layer is employed to output the predicted time, encapsulating the RUL estimation.

The FCNN is trained only on the first window of the training signals. This model's outputs are then used to normalise the time feature by dividing all time steps of every window by the predicted EOL value. We employ the Mean Squared Error (MSE) as the loss function and Adamax as the optimiser. The training regimen extends over 1000 epochs, with an Early Stopping mechanism in place to monitor progress. This mechanism halts training if no improvement is observed after 50 epochs, simultaneously recovering the best weight combination observed. This approach ensures that the model remains efficient and effective, capturing the essential predictive dynamics without succumbing to overfitting or underfitting tendencies.

2.4. Convolutional Neural Network (CNN) Model for Feature Transformation

After the labels are generated, the signal is split into windows and normalized over its length, the final step is its transformation. This is handled by the primary model, whose architecture is outlined as follows:

- **Convolutional Layer:** This layer has filters, each with a kernel size of 1, facilitating distinct feature detection across time series data without the need for padding. The Glorot uniform method initializes kernel weights, with biases set to zero.
- **Activation Layer:** This layer utilizes the Rectified Linear Unit (ReLU) for non-linear activation, enhancing the model's learning capabilities.
- **Dropout Layer:** A dropout rate is applied in the training phase to reduce overfitting by randomly omitting connections from the previous layer to the next.
- **Fully Connected Layer:** Encapsulated in a time-distributed wrapper, this layer selects the most relevant outputs from the filters, culminating in the final output.

Figure 2 illustrates the architecture of the CNN model, providing an intuitive understanding of its design and flow. This model provides the transformed CM data, concluding the proposed framework.

3. Case Study

In this part, the methodology proposed in Chapter 2 will be applied, showcasing in detail the steps to transform raw acoustic emission data of CFRP specimens under fatigue loading for predicting their RUL. The chapter starts explaining how

Algorithm 1 Pseudocode of Simulated Monte Carlo data generator (Eleftheroglou, 2020)

Inputs:
$M = \{$
ζ (int): model's initialization parameters
θ (array): degradation and the observation parameters
$\}$

Procedure:
$X_0 = 1$
$T_0 = 0$
$T_{age} = 0$
for $(c = 0; c < N; c++)$ **do**
  $i = X_c$
  $s = T_c$
  $j = i + 1$
  $a = U(0, 1)$
  $T_j = \Lambda_{i,j}^{-1}(s, -log(1 - a))$ where $\Lambda_{i,j}(s, t) = \int_0^t \lambda_{i,j}(s, u)\, du$
  $T_{age} = T_{age} + T_j$
  for $(t = T_c + 1; t < T_{age}; t++)$ **do**
    $a = U(0, 1)$
    for $(f = 2; f <= V; f++)$ **do**
      if $\sum_{z=1}^{f-1} b_{X_j}(z) < a < \sum_{z=1}^{f} b_{X_j}(z)$ **then**
        $y_t = f$
      else
        $y_t = 1$
      end if
    end for
  end for
end for

Output:
X_i, T_i (array): respectively the hidden state and the time at the n^{th} transition.
y_t (array): condition monitoring indicator at time $t \in [1, D]$.

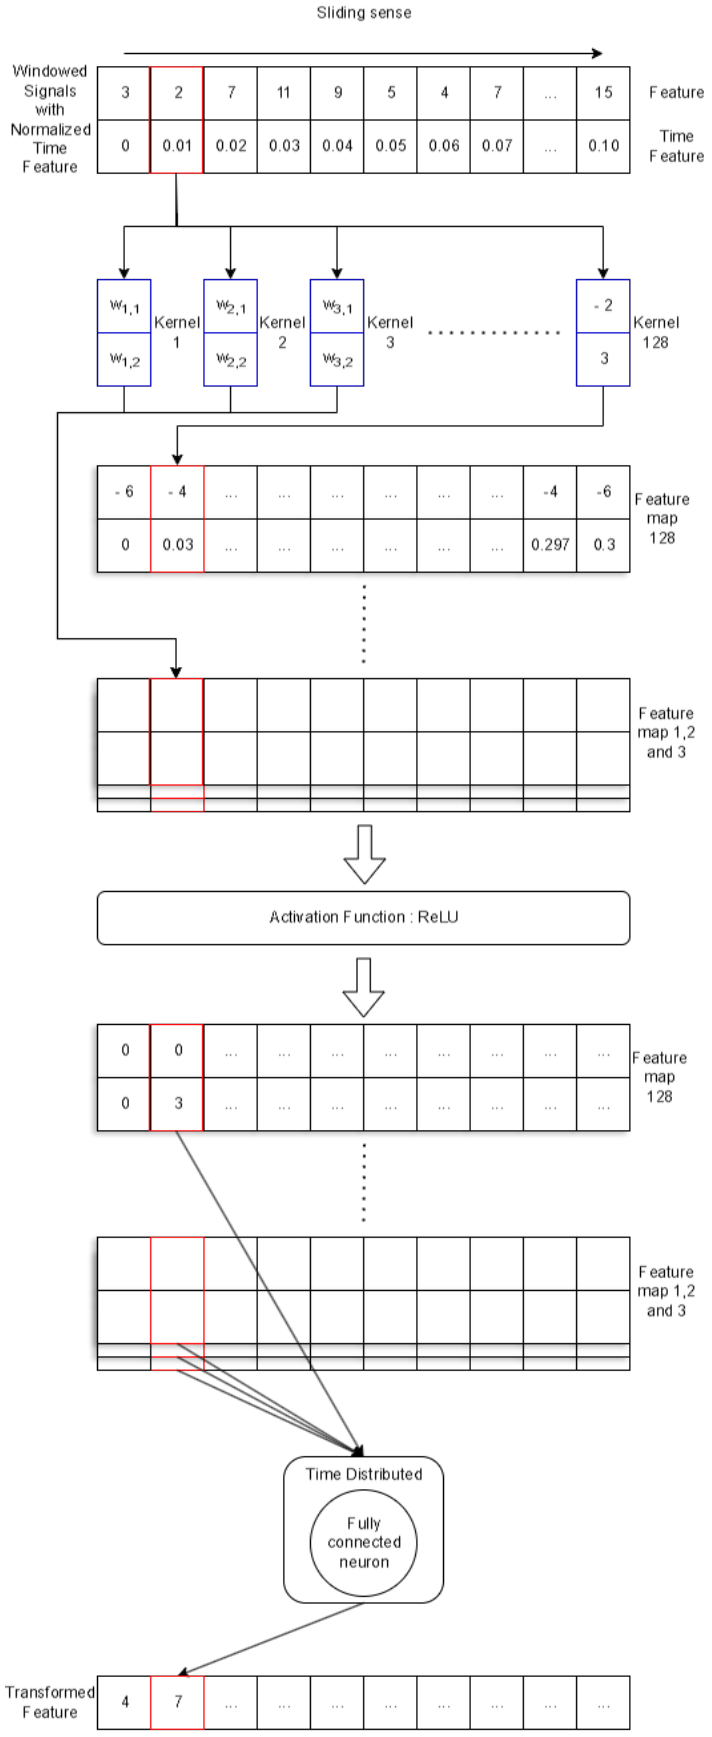

Figure 2. Architecture of the primary CNN model (2.4)

the data are created, preprocessed, labelled, sliced into time windows, and finally transformed.

3.1. Dataset

The acoustic emission (AE) dataset utilised in this research paper comes from the experiments performed in (Eleftheroglou et al., 2020). The dataset is derived from tests on open-hole carbon/epoxy samples, which were subjected to constant amplitude fatigue loading until failure. The specimens of dimensions $400x45mm^2$ are cut from plates manufactured from carbon/epoxy prepregs via the autoclave process. The stacking sequence is a quasi-static lay-up of $[0/45/90/-45]_{2S}$. A hole with a diameter of 10mm was drilled in the center of each specimen. One broadband piezoelectric transducer is attached to each specimen, and with the help of an AMSY-6 Vallen Systeme GmbH, 8-channel AE system, the acoustic emissions of the specimens are recorded and utilized as our CM feature. Hence, the training dataset consists of CM data obtained by utilizing AE sensors from seven samples under fatigue loading, and the testing dataset consists of an eighth specimen that is unseen during training.

3.2. Dataset Preprocessing

The preprocessing phase is designed to enhance the efficiency and effectiveness of model training. The primary objective was to purify the data from noise and scale it appropriately, ensuring that the subsequent steps in our machine-learning pipeline could properly process it. The first required step is to discretize the data. This is achieved by employing the K-means clustering technique (Lloyd, 1982). The entire discretization of the dataset was done by training the K-means with the training dataset, setting the number of clusters to 49, and clustering both the training and test signals with the trained model. This method played a pivotal role in cleaning the data by effectively grouping values into clusters, thereby reducing noise. Each cluster represented a range of values, allowing for a more structured and less noisy dataset. However, the process required careful consideration regarding the number of clusters; an insufficient number could lead to the loss of significant information from the signal. Additionally, this clustering approach ensures that the dataset and the labels are aligned on the same scale. As a final step of the preprocessing phase, we establish a uniform fail value across all signals by setting the final value of each signal feature to 50. The discretized raw data can be seen in Figure 3. By observing the figure, the necessity of transforming the data becomes apparent. The raw feature is highly fluctuating and presents no monotonicity whatsoever. Thus, it cannot be directly used to convey the degradation characteristics of the specimens.

3.3. HSMM initialisation for the case study

This paragraph will discuss the HSMM initialisation required for the Monte Carlo sampling to be performed. To initialise the HSMM, we must define a topology ζ as discussed in chapter 2.1.1.

- **The number of the hidden states (N)** is set at 20 (19 hidden + 1 observed).
- **Connectivity between hidden states (Ω)**: Soft and only left-to-right transitions (meaning that no self-healing or repair actions are modelled) and the final state is observed rather than hidden.
- **Condition Monitoring feature (I)**: The connection between the CM feature's values and the hidden states is modelled with a non-parametric discrete probability function, whose values are defined with the emission matrix in the following.
- **Number of discrete monitoring values (V)** are set at 50.
- **Transition rate function (λ)**: For the model of the degradation of the CFRP specimens under fatigue loading, the Weibull failure rate distribution is chosen as displayed in Equation 1.

$$\lambda(t) = \frac{\beta}{\alpha}\left(\frac{t}{\alpha}\right)^{\beta-1} \tag{1}$$

So, in order to fully describe the HSMM model, we need to define the $\theta = \{\Gamma, B\}$ parameters. Γ parameters consist of:

- **Matrix α**: a $(N-1) * N$ matrix of scale parameters for transitions between hidden states. Represented as a diagonal matrix with the first column as zeros. The diagonal is made with logarithmic spacing values from 12 to 6 into 19 values.

$$\alpha = \begin{bmatrix} 0 & 12 & \dots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \dots & 6 \end{bmatrix}$$

- **Matrix β**: a $(N-1) * N$ matrix of shape parameters for transitions between hidden states. Represented as a diagonal matrix with the first column as zeros as the previous one. The diagonal is made by linear spacing values from 64 to 25 into 19 values.

$$\beta = \begin{bmatrix} 0 & 64 & \dots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \dots & 25 \end{bmatrix}$$

To complete the initialisation process, we must also create the Emission Matrix **B**. This matrix has dimensions of $N * V$ and displays the probability of the i-th hidden state (rows) emitting

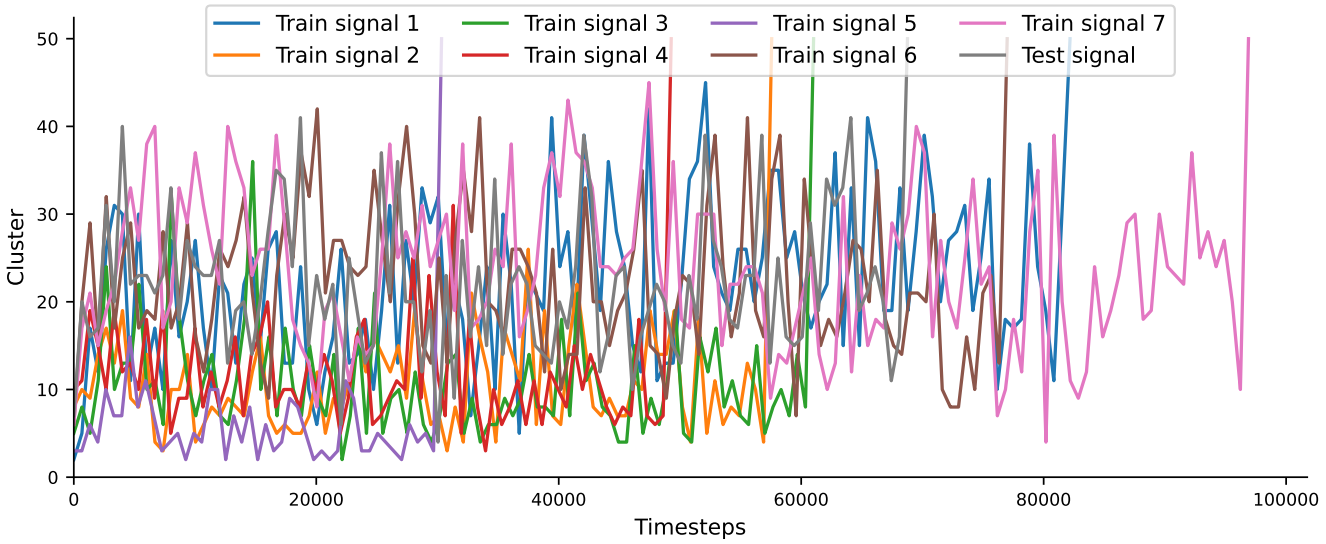

Figure 3. Raw discretized data of the real-world dataset

a specific observable state j-th (columns). The sum of the values in each row always adds up to 1. To fill the values, we have opted for the truncated Gaussian distribution $\mathcal{N}_{T[0,49]}(\mu, \sigma^2)$, which is truncated at 0 and 49 since the failure state is observed, rather than hidden. The standard deviation is equal to 3 for all states, and the mean of $\mathcal{N}_T$ is set in every row in such a way that it increases with the row index. Thus, the mean values of the rows are 19 linearly spaced values in the inclusive $[3, 49]$ range. We have made this decision to ensure that the first hidden states emit the first observable states and the last hidden states emit the last observable states, thus creating a monotonic observation sequence. The emission matrix is presented below:

$$B = \begin{bmatrix} \mathcal{N}^1_{T[0,49]}(3, 3^2) & \mathcal{N}^2_{T[0,49]}(3, 3^2) & \dots & 0 \\ \mathcal{N}^1_{T[0,49]}(5.42, 3^2) & \mathcal{N}^2_{T[0,49]}(5.42, 3^2) & \dots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \dots & 1 \end{bmatrix}$$

The aforementioned set of parameters is chosen empirically in order for the model to resemble the degradation process of composite specimens under fatigue loading. The user is free to use their own set of parameters that suit their application. So once the parameters are defined, the MCS Algorithm 1 can be run in order to generate the labels.

3.4. Data Windowing of the available data

The data are segmented into fixed-length time windows, as the user specifies. In this research paper, the selected time window is fixed at 200-time steps, corresponding roughly to 10% of the average total length. The size of the windows is chosen intuitively, but it can't be too small since the prediction of the EOL for the normalisation in the following steps will be inaccurate and not too big since doing so will remove the online applicability of the framework. The window advances by one step at each iteration, effectively creating an overlap of 199 timesteps. This allows us to increase the data available for training and testing our transformation model.

3.5. EOL estimations and time feature normalisation of the available data

As previously highlighted, the model's need to predict the EOL derives from our aim to normalize the time feature for the training of the transformation model. The results are presented in Table 1. It can be seen that the error of the estimations varies across the train specimens, with errors up to 20%. However, since this model is used to provide an initial rough estimation of the EOL for the normalization of the time feature, as presented in Section 4, its estimations are more than adequate.

Table 1. EOL Results with Corrected Error Percentages

Signal	Predicted	Actual	Error (%)
Train 1	84128	82176	2.38
Train 2	54304	57568	-5.67
Train 3	48320	61024	-20.82
Train 4	50624	49280	2.73
Train 5	34272	30336	12.97
Train 6	84416	76992	9.64
Train 7	96448	96896	-0.46
Test	77152	68768	12.19

3.6. CNN model architecture for the available data transformation

In developing our 1D CNN model, the choice of hyperparameters, loss function, and optimizer was deliberate and aimed at optimizing performance for our specific dataset characteristics.

- The decision to employ a kernel of dimension 1 ensures that the filter remains unaffected by padding, maintaining the feature map's dimensionality identical to the input. This approach guarantees continuity between successive windows, avoiding noisy spikes at the prediction's beginning and end. Given our transformation goal, this is a critical factor: the prognostic model can lead to wrong predictions.
- For our loss function, Mean Squared Error (MSE) was selected to precisely track the fluctuating nature of our labels, aiming for a regression model that closely mirrors the original data.
- After experimenting with various optimizers, Adamax emerged as the most effective, offering superior convergence properties for our scenario.
- The model architecture was kept minimal with a single CNN layer, a choice driven by the limited size of our signal dataset. This simplicity facilitated a more effective training process compared to deeper models.
- To counteract overfitting due to the high redundancy among the time windows (as detailed in Section 3.4), we implemented L1 regularization and dropout at standard values.
- Due to the non linearity of the labels, CNN is equipped with Rectified Linear Unit.

These choices collectively formed a robust framework for our model, tailored to the unique demands of our data.

3.7. Prognostics

To showcase the effectiveness of the proposed feature extraction for PHM tasks, the Remaining Useful Life (RUL) of the specimens will be predicted by utilising an HSMM. Any prognostic model can be utilized in this step since the data transformation framework is independent of the prognostic model. However, since the degradation process is modelled with an HSMM for the label generation, it is a straightforward choice to utilize a model from the same family. For the prognostics, the explicit duration modification to the HSMM is chosen. Thus, following the initialization procedure explained in Section 2.1.1, the following parameters are defined:

- **The number of the hidden states (N)**: It's considered a hyperparameter of the model, and in order to pick a value, the elbow method utilizing the Bayesian information criterion (BIC) was utilized. The optimal number of states was found to be 7.
- **Transition between hidden states ($\mathbf{\Omega}$)**: soft and left-to-right transitions, no self transitions are allowed.
- **Start probability matrix ($\boldsymbol{\pi}$)**: the process always starts from the first state.
- **Transition rate function ($\boldsymbol{\lambda}$)**: is assumed to be non-parametric and depends only on the current state.
- **Condition Monitoring feature (I)**: The connection between the hidden states and the values of the CM features are assumed to be described by Gaussian distributions $\mathcal{N}(\mu, \sigma^2)$ and represented by a mean and a standard deviation observation vector.
- **CM indicator space (Z)**: since the observation process is modelled with a continuous probability distribution (Gaussian), the indicator space consists of all the real numbers ($Z = \{z \in \Re\}$).

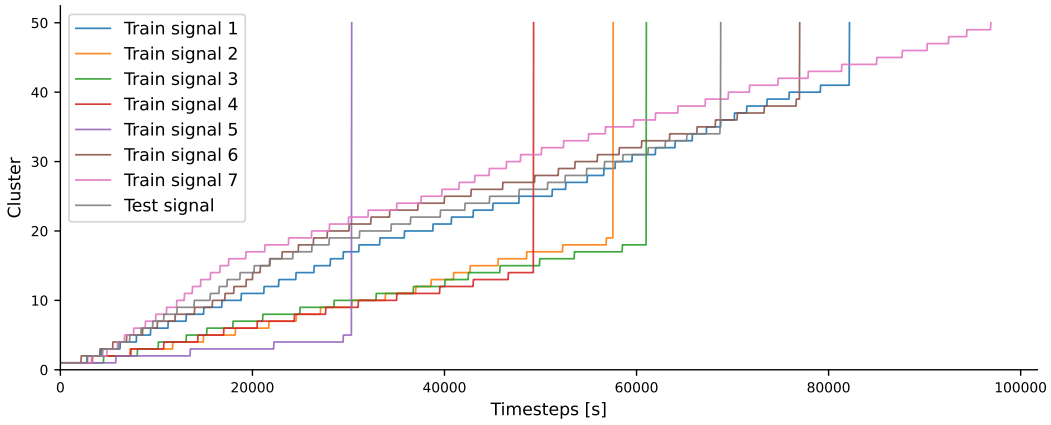
After the parameters are initialised, the parameter estimation can be performed as described in (Yu, 2010). When the optimal parameters have been estimated, they are utilised in order to predict the RUL of the asset, following the procedure in (Dong, He, Banerjee, & Keller, 2006)

4. RESULTS

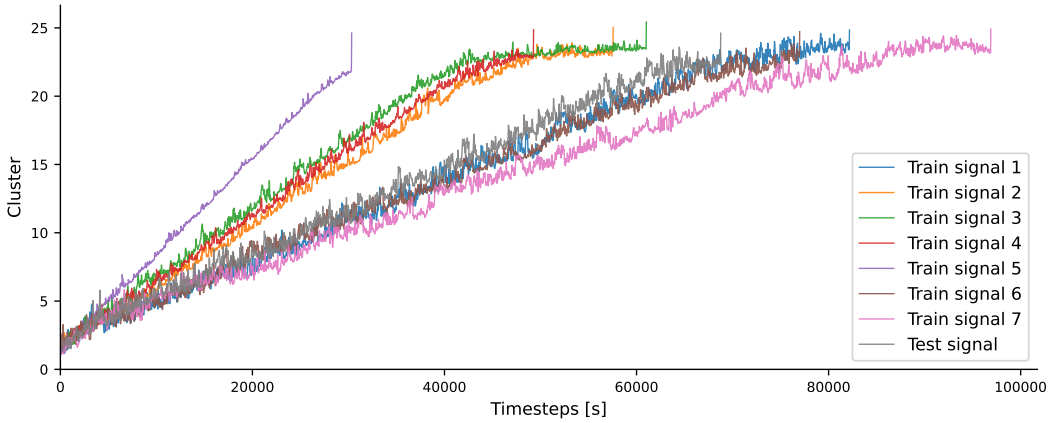
In the first part of the current section, the transformed data utilizing the proposed framework are presented and contrasted against the raw data and their cumulative transformation, highlighting the performance of the framework. Finally, the prognostic findings from the HSMM of the cumulative feature and the one obtained from our framework are contrasted.

4.1. FE results

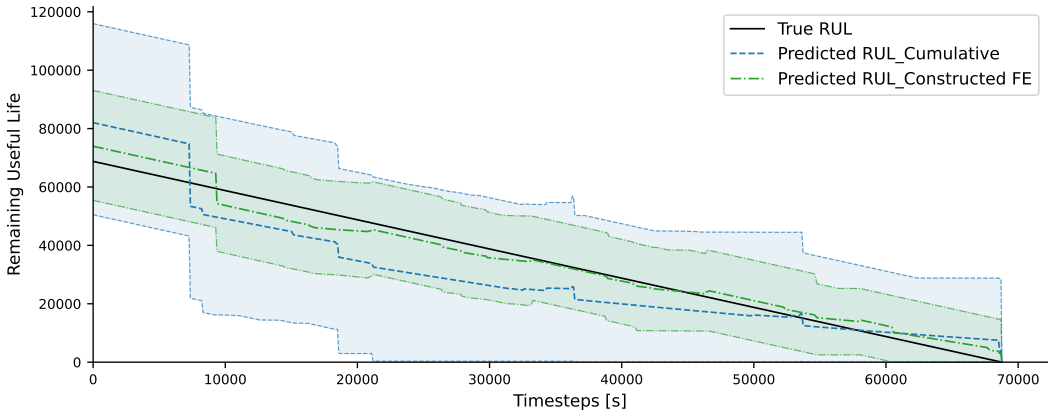
As a baseline for the proposed transformation, the cumulative transformation of the discretized raw data is calculated and presented in Figure 4a. This choice is justified as the authors consider it to be the most straightforward choice for transforming noisy and highly fluctuating data into monotonic ones. The necessity of transforming the data in the first place lies in the inability of prognostic algorithms to provide any meaningful results when applied to fluctuating data that present no monotonic behaviour. In Figure 4b, the transformed data utilizing the proposed framework are showcased. By comparing the two, it can be observed that even though the cumulative features present highly monotonic behaviour (as expected due to the cumulative summation function), there is a great uncertainty associated with the last value directly before failure (also known as prognostability). This is where an added contribution of the proposed transformation also lies. It can be seen (Figure 4b) that the transformed signals (both training and test) fail at values that are very close to each other. This is expected to, in turn, come with reduced uncertainty when it comes to the RUL prediction values, which remains to be seen in the following section.



(a) Cumulative feature



(b) Constructed feature with the proposed methodology



(c) Comparative plot for the test sample

Figure 4. Plots for the results of the proposed methodology

4.2. Prognostic results

In Figure 4c, the prognostic results of the test sample utilising both the cumulative feature and the proposed one are presented on the same plot for comparison reasons. We can see that not only the mean value predictions of the RUL using the constructed feature are closer to the true RUL, but also that the 90% confidence intervals are reduced. This is the manifestation of the main contribution of the constructed feature, which is the reduced uncertainty of the final values of the constructed feature compared to the cumulative one. Hence, the goal of a non-complex FE method that aids in the realization of accurate and highly confident PHM frameworks is achieved.

5. Conclusions

This research introduced a methodology integrating Monte Carlo simulated data with CNN to enhance prognostic performance in predicting system degradation by incorporating the stochastic nature of system deterioration and the noisy measurements in the labels for transforming raw data. Its theoretical viability has been demonstrated, as well as its practical applicability, particularly in its ability to operate online, making RUL predictions for CFRP specimens under fatigue loads, based on noisy AE measurements. It is worth noting that due to the simplicity of the proposed framework, given enough data and a proper HSMM initialization for the MCS (following the procedure showcased in Section 3.3), the applicability to more complex systems is a straightforward procedure. The main contribution of the proposed framework lies in its simplicity of deliberately combining well-established and non-complex components in a novel way that alleviates the deterministic labelling based on intuitively picked metrics in extracting suitable features for PHM applications. This led to the creation of a simple and efficient model that effectively transforms raw and noisy data for accurate and high-confidence prognostics. Our motivation was simple: We consider the labelling of signals that are by nature stochastic with deterministic labels to be ill-posed. Rather, we proposed the generation of labels by sampling a stochastic model (HSMM) in a framework that is independent of the prognostic algorithms and can be applied online. We aim to expand this framework to be able to fuse different CM features and compare its performance against numerous traditional FE methods for prognostic tasks.

ABSTRACT

The evolution towards "more electric" aircraft has seen a decisive push in the last decade, due to the growing environmental concerns and the development of new market segments (Urban Air Mobility). Such push interested both the propulsion components and the aircraft systems, with the latter seeing a progressive trend in replacing the traditional solutions based on hydraulic power with electrical or electro-mechanical devices. Electro-mechanical brakes, or E-Brakes hereby onwards, would present several advantages over their hydraulic counterparts, mainly related to the avoidance of leakage issues and the simplification of the system architecture. Moreover, although it is expected a weight increase of the brake, the elimination of the hydraulic lanes would still come with an overall weight reduction. Despite these advantages, it remains a new, relatively unproven technology within the civil aviation field. Within this context, the development of PHM solutions would align with the need for an on-line monitoring of a relatively unproven component. This paper deals with the preliminary stages of the development of such PHM system for the E-Brake of a future executive class aircraft, iterating on previously published material and presenting a particle filtering approach based on a new degradation model and data provided through a revised high-fidelity model. The paper opens with the introduction to the research project and the technological demonstrator, positioning the performed work within the available literature. PHM activities, performed on simulated data-set are then presented and the preliminary results discussed.

Keywords: PHM, EMAs, Brakes, Particle filter.

1. INTRODUCTION

Electro-mechanical brakes, or E-Brakes, are the next step in the evolution of aeronautical braking systems, and the natural consequence of the push for the electrification of civil aviation which is strongly affecting the development of future platforms. E-Brakes have already found applications in civil aviation, with different architectures already flying on the latest iterations of the Boeing 787 and the Airbus A-220 and have drawn interest in the aeronautic community thanks to the significant advantages over their hydraulic counterpart, including lower weight, the elimination of long hydraulic pipelines and a lower environmental imprint. Despite these success stories, they remain a relatively unproven and more complex technology with respect to the traditional hydraulic solution. The definition of a comprehensive PHM system, leveraging the higher number of sensors usually employed on electro-mechanical system, would provide additional confidence towards their application, lowering the risk of unanticipated failures, reducing the aircraft downtimes and giving access to strategic information useful to optimize the fleet management. Although literature on PHM activities for the most common components of electro-mechanical brakes is extensive, few papers have been published about the E-Brakes themselves. In (Ramesh et al., 2021) authors propose a Fault Detection and Identification (FDI) algorithm to observe and correctly assess the most probable failures occurring in a simple electro-mechanical brake for aeronautic applications. The analysis considers an aeronautical brake actuated by one Electro-mechanical actuator driven through a brushed DC-motor and is mainly focused on electrical failures. In (Oikonomou et al., 2022) authors investigate the prognosis of wear in aeronautical brakes through the analysis of historical series of brake pads thickness. Data-driven techniques are applied to perform the long-term prognosis, and the results of an interesting benchmarking activities comparing the performances of several algorithms are provided. Results are promising but assume the presence of

dedicated sensors to measure the thickness of the brake pads, which are not foreseen for the application under study in this paper. The E-LISA research project, performed within the Clean Sky 2/Clean Aviation framework, has the objective of developing an innovative iron bird dedicated to executing tests on the landing gear of a small aircraft equipped with an electro-mechanical landing gear and electrical brake. The E-LISA iron bird consists of a multi-functional intelligent test facility integrating hardware and software, allowing all the tests and analyses perceived as fundamental to be performed to demonstrate the maturity of an electro-mechanical landing gear, hence paving the way for its implementation in a small passenger aircraft. Such tests include the simulation of complete landing procedures under different operating conditions such as runway friction (wet/dry), presence of waving and irregularities along the runway, variable aircraft weight, and approach speed. At the same time, the rig will act as a technological demonstrator for PHM routines devoted to the analysis of the E-Brake health status. This paper opens with the description of the case study under analysis, a fully electrical landing gear leg for a new executive-class aircraft, detailing the system characteristics. Then the architecture of the technological demonstrator is presented, highlighting its most prominent features and the solutions required to meet its functional requirements. The focus is then shifted towards the definition of the PHM routines, where a possible scheme to detect and prognose the wear of the brake pads is proposed. A first-tentative approach to the problem was presented by authors in (De Martin, Jacazio, Parisi, et al., 2022), making use of a first-trial high-fidelity model and a simplified particle filtering approach. This study was used a basis: the model was further evolved to take into consideration the effects of different combination of environmental conditions and tires types, while the prognostic algorithm was substantially modified considering a physics-based representation of the fault progression. Early results are presented, alongside a test-plan to support the simulation findings through experimental activities, once the rig is operational.

2. CASE STUDY

The case study under analysis is an E-Brake system for an executive-class aircraft with an expected weight at take-off ranging between 5.5 and 6.1 tons, depending on the passengers' number and the amount of unspent fuel. Two E-Brake systems are integral with the Main Landing Gear system, one for the Left-Hand side, one for the Right-Side each. Depicted in Figure 1, each E-Brake is a multi-disk assembly actuated through four Electro-Mechanical Actuators (EMAs) controlled in force. Whenever the pilot acts on the brake pedals, a force command is sent towards the E-Brake system; such command signal is processed by the Brakes Control Unit (BCU), which can cut the force command signal through the touch-down protection routines, avoiding that the brakes are actuated before the aircraft rotation during landing has ended. The command signal can

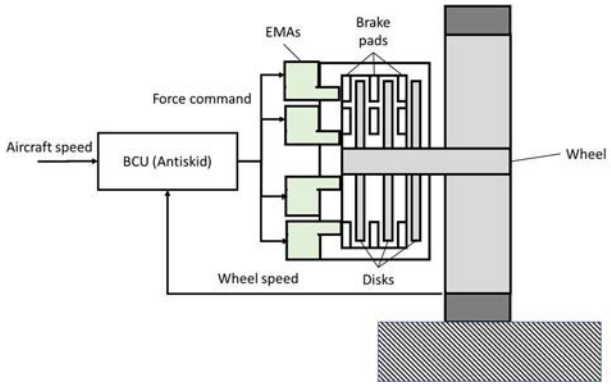

Figure 1. Case-study architecture.

be further modulated by the electronic anti-skid system, which decreases the force request depending on the runway conditions to avoid the occurrence of wheel blockage events and excessive slip according to a combination of pilot input and automatic recognition of the runway status. The electro-mechanical actuators are driven by one Brushless-DC motor with each, and act on the brake pads through a mechanical transmission made of a one-stage reducer and a ball-screw. Each actuator is equipped with a force sensor to measure the exerted action, while a resolver integral with the motor shaft is used to infer its position and realize the Field Oriented Control of its phase currents. The test-rig has being design to exchange information with the E-Brake during its operations interfacing with the BCU. As such all the signals provided by the sensors employed in each EMAs are acquired and can be used for PHM. Such signals include the angular position of the E-Brake motors shaft, the braking command issued by the pilot, the anti-skid and touch-down protection signals and the exerted force measurement for each EMA. The phase currents of each electric motor are acquired as well, along with the current request provided by the force control loops.

3. THE TECHNOLOGICAL DEMONSTRATOR

The main purposes of the technological demonstrator are to support the testing and certification of a novel E-Brake system and to foster the definition of dedicated prognostic logic. As such, the main functional requirements are twofold. On one side it is paramount to be able to conduct the tests prescribed by the normative, such as the on-ground start-stop test and the landing procedure. On the other side, it is important to recreate on the test bench the widest array of operating conditions to stress as much as possible the PHM routines and provide statistically representative datasets. To achieve this goal the test rig is designed to allow the arbitrary variation of several operating parameters, including the aircraft approach speed, the dynamic load applied on the landing gear leg, the friction coefficient between the aircraft wheels and the runway and the occurrence of a selected number of electrical failure or mechanical faults. The architecture of the test rig is depicted in Figure 2, while a

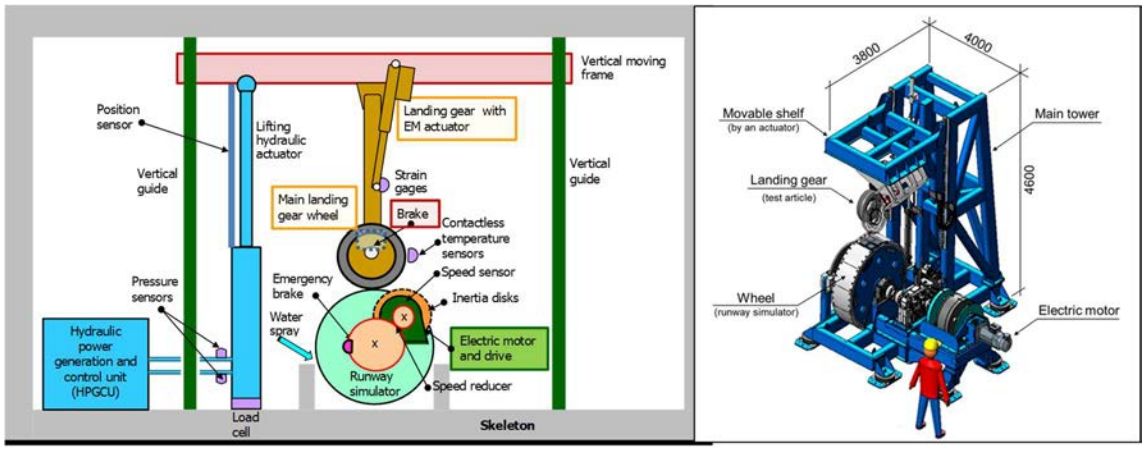

Figure 2. Iron bird schematics.

details of its mechanical structure can be retrieved in (Giannella et al., 2022). The mechanical structure can be divided between a fixed part and a moving platform integral with the landing gear leg, complete with a wheel and electrical brake. The moving platform can translate vertically along low friction guides according to the force provided by an electro-hydraulic servoactuator controlled through a 160 l/min servovalve. A calibrated by-pass orifice connects the two hydraulic lines serving the actuator to improve the dynamic response of the force-controlled system. The test-rig behavior is continuously monitored through one linear variable differential transformer (LVDT) sensor measuring the hydraulic actuator travel, a load cell measuring the force exchanged between the actuator and the moving platform and a differential pressure transducer sensing the pressure drop across the two actuator's chambers. The hydraulic power available for the test-rig operation is that of the facilities in which the rig will be installed and is limited at 207 bar. The contact between the landing gear wheel and the runway is represented through a runway simulator, a rotating disk, connected to a selected number of inertia disks, representative of the aircraft inertia, through a gearbox. A different solution, based on a novel hydraulic system, was considered in (De Martin, Jacazio, Ruffinatto, et al., 2022) but discarded due to budget constraints. The diameter of the rotating cylinder is such to be representative of the expected linear speed of the aircraft along the runway during the landing procedure and must be higher than the wheel diameter to reduce at a minimum the differences between the wheel/runway simulator contact and the wheel/real runway contact. A gearbox is interposed to significantly reduce the mass and the encumbrance of the flywheels, the number of which can be increased or decreased to scale-up or scale-down the weight of the simulated aircraft. The runway simulator was designed with the possibility to change the external coating. To achieve the variation of the friction forces between the wheel and the runway and allow the verification of the anti-skid logic behavior in different operating conditions, while a sprinkler can be activated to reproduce the wet-runway conditions. An electric motor is used to accelerate the runway simulator up to the angular frequency corresponding to the aircraft horizontal speed given the diameter of the rotating disk, while an emergency brake is installed in-line with the rotating cylinder, allowing to bring the full system to a complete stop in less than 60 s. The technological demonstrator is controlled through an engineering test station (ETS), which accepts the inputs from a central control unit (CCU) that in turn receives the commands from an operator via a user interface. The input signals are then sent together with rig measurements to a dedicated computer running a real-time (RT) representation of the aircraft dynamics during landing. Such real-time model is then used, along with a model of the runway and a model of the landing gear dynamics, to compute in real-time the load that must be applied to the test-article. The ETS also include the rig control logic, which is designed to manage both the position of the moving platform and the force exerted by the hydraulic actuator and include a safety routine check to limit the damages to the rig and to the test article in case of a failure of the anti-skid system during the execution of a test. The structure of the control system is depicted in Figure 3, where three main modules can be identified. The Simulation Module involves the real-time representation of the landing dynamics, including a real-time representation of the aircraft dynamics, a runway model, which allows to describe the presence of periodical or localized runway irregularities, and the model of the landing gear legs, each modelled as a two-degrees of freedom vibrating systems, where the mechanical

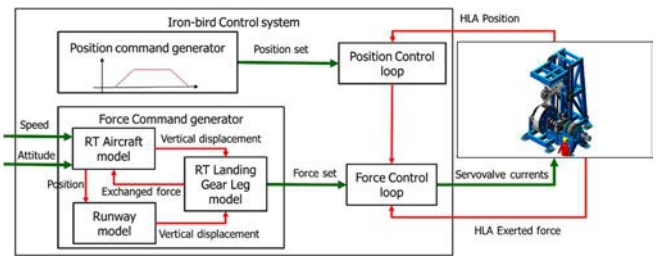

Figure 3. Control system structure.

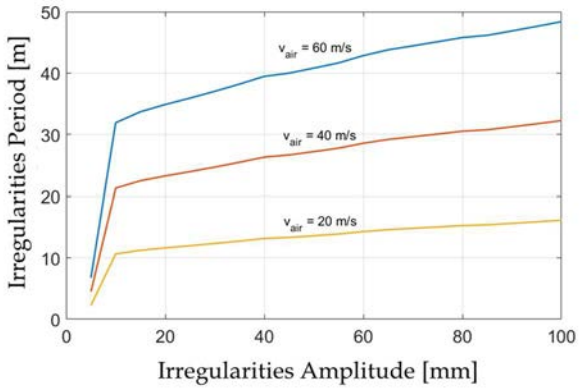

Figure 4. Projected limits on the representation of the periodical runway irregularities on the test-rig.

characteristics of the shock-absorber, of the tires and of the mechanical structure are provided by the industrial partners of the project. The control system is based on two control loops, one operating in position and the other on force, alternatively active before and after the contact between the landing gear wheel and the runway simulator. The control system, best described in (Bertolino et al., 2023) is designed to achieve bandwidth higher than 10 Hz in both force and position control loops. As shown in Figure 4, the control system, combined with the Real-Time simulation of the aircraft behavior during landing, it allows to reproduce on the test-rig the effects of periodical runway irregularities up to 100 mm depending on their period, the aircraft mass and its expected approach speed (De Martin, Jacazio, & Sorli, 2022).

4. Simulation Activities

To achieve the definition of a PHM scheme for the entire E-Brake assembly a number of tasks are required. In order, there is the need to orderly assess which failure modes or which cause of service disruption to investigate, to prepare a high-fidelity model of the system representative of its operational performances and finally proceed to support such activities through experimental tests and validation. As stated in the introduction the technological demonstrator is not yet in function, thus the analysis is so far limited to simulation results. The failure modes being investigated includes the occurrence of several types of short circuits within the windings of the electro-mechanical actuators and wear of the mechanical transmission. Such failure modes, although important, are fairly common in electro-mechanical actuators independently from their function. As such, priority was given to the detection and prognosis of the wear of the brake pads. Although not a failure-mode per se, the reduction of the brake pad thickness is accompanied with a lower dynamic response of the brake and requires periodical maintenance operations. Currently wear of the brake pads is detected through dedicated sensors or through periodical inspection of visual indicator on top of the brake itself. Making the monitor of the brake pads wear part of the PHM system would allow to limit or avoid the necessity of periodical inspections, anticipate the maintenance action and avoid unpredicted aircraft-on-ground situations. Authors started analyzing the possibility of such a system in (De Martin, Jacazio, Parisi, et al., 2022) through a simple particle filtering routine based on data coming from streamlined landing simulations. As more data were made available the analysis was improved through the definition of a higher-fidelity simulation model and a more realistic operational scenario. The prognostic routine was similarly revised and will be presented in the next sections of the paper.

4.1. System modelling

The high-fidelity simulation model includes a two-dimensional representation of the aircraft dynamics during landing, a three degrees-of-freedom multi-body model of the landing gear legs and of their interaction with the runway, and an in-detail representation of the E-Brake dynamics. Parts of such model, with particular reference to the aircraft dynamics and the vertical displacement of the landing gear leg were already described in (De Martin, Jacazio, & Sorli, 2022; De Martin, Jacazio, Parisi, et al., 2022) and won't be reported here, limiting the description to the component interested by modifications. Starting with the rotational dynamics of the wheel and addressing with $F_n = k_t(x_w - x_{rw}) + c_t(\dot{x}_w - \dot{x}_{rw})$ the vertical force exchanged between the wheel and the runway it is possible to express the wheel angular acceleration $\ddot{\vartheta}_w$ as a function of the rolling friction coefficient u_{rw}, expressed as a function of the wheel angular frequency and of the tire pressure (Carbone & Putignano, 2013), of the the moment of inertia of the wheel assembly I_w, the wheel diameter D_w and the viscous friction coefficient roughly representative of the dissipation in the wheel supports c_w.

$$F_n\mu\left[\frac{D_w}{2} - \left(x_{leg} - x_{rw}\right)\right]\text{sign}(\lambda) - F_n u_{rw}\tanh\dot{\vartheta}_w - c_w\dot{\vartheta}_w - T_{brk} = I_w\ddot{\vartheta}_w \quad (1)$$

The friction coefficient μ is evaluated according to a modified version of the Burckhardt model (M. Burckhardt, 1993), as a function of the slip factor λ between wheel and runway simulator and of the experimental parameters β_1, β_2 function of the tires temperature, thread type and runway conditions.

$$\mu(\lambda) = \left[\beta_1\left(1 - e^{-\beta_2\lambda}\right) - \beta_3\lambda\right]\mu_{max}(p_{tire}, v_{air}) \quad (2)$$

The parameter $\mu_{max}(p_{tire}, v_{air})$ is function of the tires pressure and of the aircraft speed and was fitted on experimental dataset provided for different combination of thread type and runway conditions for an aircraft of similar size to the target platform. An example of the fitter profiles is shown in Figure 5, where data for smooth tires on dry-runway

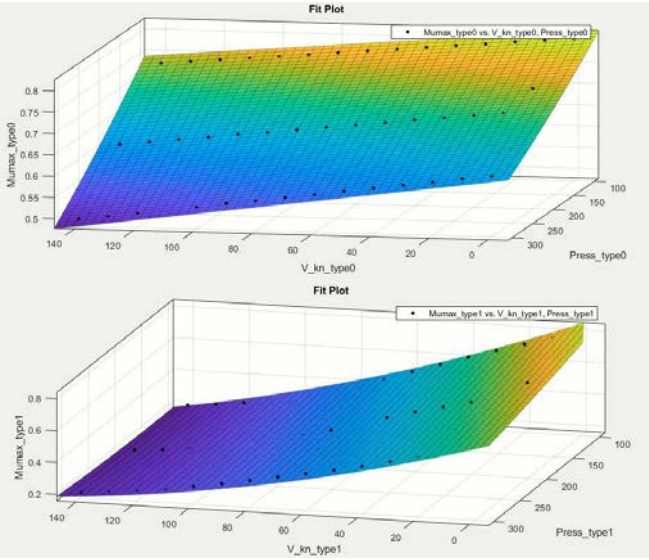

Figure 5. μ_{max} values for dry (above) and wet (below) runway conditions.

conditions are compared against data for threaded tires on a wet runway. The four Electro-Mechanical Actuators (EMAs) responsible for the braking action are controlled in force and act in parallel on the multi-disk brake. The control system is described as a two-nested control loops, where a sequence of Proportional-Integrative controllers operates on the force control loop and on the current control loop of each brushless motor. The sensors are modelled through second order transfer functions replicating the expected dynamics of the load cell and of the Hall-effect sensors employed to monitor the angular position of the Brushless-DC rotor. The simulation of the measure chain is complete with the model of the employed A/D converters. The dynamic model of each EMA features a functional description of the Electronic Power Converter derived from (Mohan et al., 2005) for a three-phase inverter controlled through Pulse Width Modulation (PWM). The electrical dynamics of the motor is described according to a streamlined three-phase model of the system, where $V_{a,b,c}$ and $i_{a,b,c}$ are the phase voltages and currents.

$$[V_{a,b,c}] = [\boldsymbol{R_{a,b,c}}(T_w)][i_{a,b,c}] + [\boldsymbol{L}(T_w)]\frac{d}{dt}[i_{a,b,c}] + \frac{d}{dt}[\phi_{a,b,c}(\vartheta_{el})] \quad (3)$$

$[\mathbf{R_{a,b,c}}]$ is the electric resistance matrix, which elements depends on the windings' temperature (T_w). The diagonal elements of the matrix represent the single-phase resistance, while the non-diagonal terms represent the electrical resistance provided by the insulating material separating the coils of different phases, addressed as phase-to-phase resistances hereafter. Such values can be degraded to simulate the effects of a turn-to-turn or phase-to-phase short respectively. [**L**] is the inductance matrix, accounting for self-induction and mutual induction phenomena along with the effect of magnetic flux dispersion. Finally, $[\phi_{a,b,c}]$ is the concatenated magnetic flux provided by the permanent magnets, function of the electrical angle (ϑ_{el}). The torque at the motor shaft can then be computed, leading to the dynamic equilibrium of the rotor

$$\sum_{a,b,c}\frac{d\phi}{dt}i_{a,b,c} - c\dot{\vartheta}_m - k_m(\vartheta_m - \vartheta_{gb}) - c_m(\dot{\vartheta}_m - \dot{\vartheta}_{gb}) = I_m\ddot{\vartheta}_m \quad (4)$$

where ϑ_m and ϑ_{gb} are the angular position of the motor shaft and of the gears. I_m is the moment of inertia of the rotor, while k_m and c_m address the torsional stiffness of the motor shaft and its associated damping. The gear pair is described as a rotational mass-spring-damper system, thus leading to the following equation,

$$k_m(\vartheta_m - \vartheta_{gb}) + c_m(\dot{\vartheta}_m - \dot{\vartheta}_{gb}) - \frac{1}{\tau}[k_{gb}(\vartheta_{gb} - \vartheta_{rs}) + c_{gb}(\dot{\vartheta}_{gb} - \dot{\vartheta}_{rs})] - T_{fr,gb} = I_{gb}\ddot{\vartheta}_{gb} \quad (5)$$

where τ is the transmission ratio, $T_{fr,gb}$ the friction torque, while ϑ_{rs} is the angular position of the rotating part of the screw. The friction torque is computed as the sum of three components, one dependent on the acting load, one related to the viscous friction and a drag torque component. The power-screw is modelled as a two-degrees of freedom elements, where the rotating part is connected to the translating element through a viscoelastic element. Defining with $x_{rs,i}$ the position of the translating portion of the screw pertaining to the i-th actuator, it becomes possible to describe the brake dynamics, and thus that of the pads. Addressing with k_{eb} the stiffness, it is possible to evaluate the braking torque acting on the landing gear wheel as a function of the translating mass of the brake pads m_{eb}, its translation x_{eb} and the angular speed of the wheel $\dot{\vartheta}_w$ as,

$$\begin{cases} T_{brk} = 0 \leftrightarrow x_{eb} < x_{thr} \\ T_{brk} = R_{eb}f_{eb}[k_{eb}(x_{eb} - x_{thr}) - c_{eb}(\dot{x}_{eb})]x_{eb} \geq x_{thr} \end{cases} \quad (6)$$

where $f_{eb} = f_{eb}(\dot{\vartheta}_w)$ is the friction coefficient between the brake pads and disk, function of the wheel angular frequency. Knowing the braking torque and the wheel angular frequency it is possible to compute the mechanical power transformed into heat by the braking process. Such power is used within a simplified thermal model of the E-Brake assembly to estimate at each time step the temperature of the pads and the temperature of the electric motor windings considering both the thermal power generated by the motor themselves and that transmitted to the external environment. Since the pads contact the brake disks only when their translation x_{eb} overcomes a predefined stroke equal to x_{thr}, it is possible to model the effects of the pads wear by properly increasing such threshold value under the assumption that the brake pads return in the original position once the braking procedure is

finished. According to (Olesiak et al., 1997; Yevtushenko et al., 2017) , wear progression in brake pads can be described as dependent on an experimental coefficient f_{wear} and k_{wear}, function of the local absolute temperature T, the sliding velocity between disks and pads v, and the contact pressure p. The dependency of the friction and wear coefficient on temperature is due to how the interaction between the disc and the brake pads occurs at a microscopic level. The brake performance (and its wear) depends on how the material of the pads bonds with the material of the disk and with the particles of the pads material which have remained bonded with the disc due to the run-in process and previous usage. This process is temperature dependent: at very-low temperature (-40°C) friction tends to increase in mechanical systems. Similar effects occurs at very high temperatures, where the bonding effects can be favored by localized fusion processes, accelerating the wear rate.

$$\Delta x_{thr} = \int_t f_{wear}(T) K_{wear}(T) v(t) p(t) dt \tag{7}$$

Expressing the sliding velocity as a function of the wheel angular frequency $\dot{\vartheta}_w$ and the radial coordinate of the pads with respect to the wheel axis R_{pad}, we have

$$v = \dot{\vartheta}_w R_{pad} \tag{8}$$

The average pressure within the pads/disks contact area can be computed as a function of the braking force exerted by the four actuators and the pad contact area.

$$p = \frac{k_{eb}(x_{eb} - x_{thr}) - c_{eb}(\dot{x}_{eb})}{A_{pad}} \tag{9}$$

An example of the model response is provided in Figure 6, where the system behavior in response to an emergency brake in presence of a wet runway and smooth tires is presented.

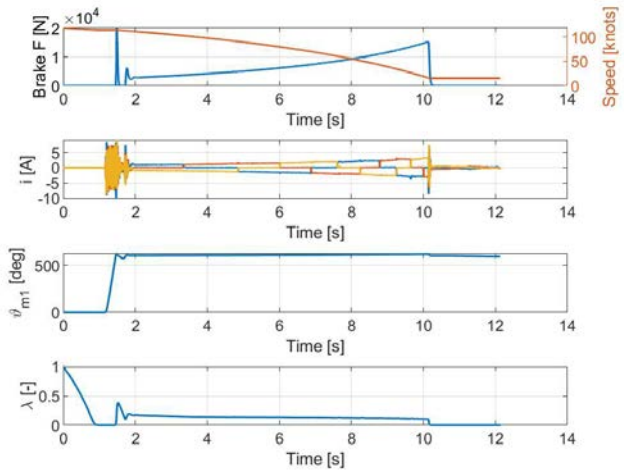

Figure 6. Example of the model response.

The figures depict the behavior of the total braking force expressed by the four EMAs, the aircraft speed along the runway, the three phase currents of the BLDC motor belonging to one of the EMAs (i [A]), the correspondent angular rotation of the motor shaft ϑ_{m1} and the slip factor λ between the wheel and the runway.

4.2. Operational scenario and data-base building

The simulation model is built for two main reasons: to generate a data-base to train and stress the PHM routines and to help in characterizing the system and provide additional information that could be useful to the PHM system itself. The first task in generating a reliable operational scenario is to characterize all possible sources of uncertainty of the system behavior. For the case study under analysis the following sources were identified and addressed.

- Aircraft mass at landing
- Runway temperature and conditions
- Tires type (smooth, threaded) and pressure
- Aircraft horizontal approach speed
- Type of braking procedure (emergency, normal)
- Production tolerances in the E-Brake system
- Pilot reaction time
- Sensors noise, deviations

The aircraft mass at landing is drawn randomly at each simulation from a uniform distribution ranging between 5.5 and 6.1 tons approximately, which is considered the expected variance depending on the passengers number, payload presence and type, and the remaining fuel. Runway temperature and conditions were taken into account by considering the temperature and rainfall distribution of three distinct area, each representative of a prevalently cold (Vancouver), hot (Dubai) and temperate (Rome) operating conditions. Data were obtained through public access data-base and randomly drawn at each simulation. Tires type is chosen at each simulation between threaded and smooth, while their pressure is randomly chosen from a normal distribution with mean 200 psi and variance 30 psi. The aircraft horizontal approach speed is randomly drawn from a normal distribution with mean equal to 110 knots and standard distribution equal to 5 knots. The type of braking procedure (whether emergency or normal) is decided before launching the simulation: during emergency stops, the pilot commands the E-Brake to supply its maximum force, while the anti-skid routine modulates such request to achieve the slip factor associated with the maximum friction coefficient between wheel and runway. On the contrary, during normal operations, the pilot modulates the braking force command trying to mimic a sequence of aircraft horizontal speed drawn from a pool of experimental results provided by the industrial partners of the project for an aircraft of similar size. An example of the difference between the two braking procedures is provided in Figure 7.

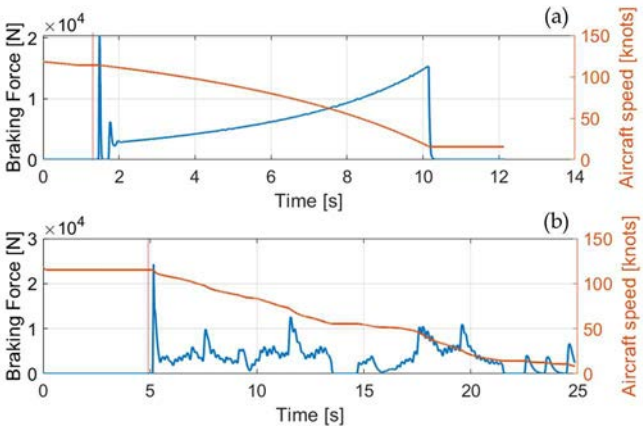

Figure 7. Comparison between emergency stop (a) and normal braking (b).

In this comparison, both aircrafts are decelerated down to 16 knots, which is the limit taxing speed on most civil runways. Another uncertainty source related to the brakes performances is the pilot reaction time, which is modelled as a simple transport delay with time constant variable between 0.1 and 0.5 s.

These first uncertainty sources are expected to be the most significant for the E-Brake performances.

The aircraft speed and its mass at landing affects the overall kinetic energy to be dissipated through the brakes, while the operating conditions, tires type and inflating pressure affects the efficiency with which the braking torque produced by the electro-mechanical device is transferred to the ground.

Additional uncertainty sources, affecting the signals pertaining the E-Brake that can potentially be used for PHM includes the production tolerances, which were over imposed onto the main electrical and mechanical parameters of the EMAs, and sensors noise, modelled according to the indication provided in the manufacturer catalogues.

5. PHM ALGORITHM

The PHM algorithm for the wear of the brake pads is based upon the scheme presented in Figure 8, designed to leverage the physical knowledge of the system and employ the past knowledge of the E-Brake operations to better characterize the uncertainty distribution.

Prognosis is achieved through a Bayesian estimation method using a particle filtering approach, which provides after each landing an estimate of the current level of wear in the brake pads leveraging the indirect knowledge of the terms employed in the wear function provided in Equation 7. This step, functionally part of the fault identification process, is necessary to achieve the long term prognosis through physics-driven equations by supplying the particle filter with pdfs of future usage of the brake based on previous information retrieved and stored after each landing. Particle filters, firstly introduced in PHM by (Orchard & Vachtsevanos, 2009), take advantage of a nonlinear process (fault / degradation) model to describe the expected dynamics of the fault progression and a measure model derived from the feature/wear progression dependence observed during the feature selection phase. The particle filtering approach was chosen over other considered options (LSTMs in particular, were considered following previous works on a different application (Grosso et al., 2020)) for several reasons. The main one is that this process enables the estimation of the fault size through physics-based equations; since activities have been performed over simulated data-set, the adoption of a physics-driven approach was preferred to mitigate the risk of not operating on experimental datasets. The second reason is that brake pads wear is only one of the many failure modes that can occur in electro-mechanical brakes. Other failure modes, such as the brake rotors wear, faults in the EMAs mechanical and electrical components or issues in the EMAs sensors can occur, and have a direct effect on the progression of other failure modes. Looking ahead, the authors have planned to pursue the definition of a PHM scheme able to

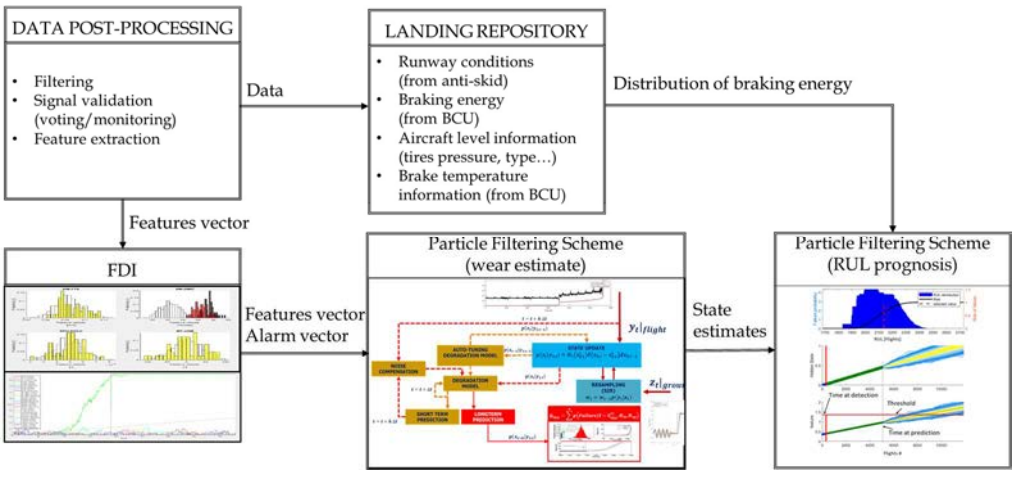

Figure 8. PHM Scheme.

define the expected RUL of the system including the possible cross-dependence between different failure modes. Particle-filtering techniques naturally lend themselves to this step, since their results are well-suited to data-fusion algorithms (Vachtsevanos et al., 2006). Moreover, being based on a physics-based description of the failure mode, the outcome of PF algorithms can be more easily interpreted from an engineering perspective and more easily included in digital-twin representations of the system under analysis.

Prognosis through particle filtering is achieved by performing two sequential steps, prediction and filtering. Prediction uses both the knowledge of the previous state estimate and the process model to generate the a priori estimate of the state probability density functions (pdfs) for the next time instant,

$$p(x_{0:t}|y_{1:t-1}) = \int p(x_t|y_{t-1})p(x_{0:t-1}|y_{1:t-1})\,dx_{0:t-1} \quad (10)$$

This expression usually does not have an analytical solution, requiring Sequential Monte Carlo algorithms to be solved in real-time with efficient sampling strategies (Roemer et al., 2011). Particle filtering approximates the state pdf using samples or "particles" having associated discrete probability masses (often called "weights") as,

$$p(x_t|y_{1:t}) \approx \tilde{w}_t(x_{0:t}^i)\delta(x_{0:t} - x_{0:t}^i)dx_{0:t-1} \quad (11)$$

where $x_{0:t}^i$ is the state trajectory and $y_{1:t}$ are the measurements up to time t. The simplest implementation of this algorithm, the Sequential Importance Re-sampling (SIR) particle filter (Arulampalam et al., 2009), updates the weights using the likelihood of y_t as:

$$w_t = w_{t-1}p(y_t|x_t) \quad (12)$$

Although this traditional particle filtering technique has limitations, in particular with regards to the description of the distributions tails, and more advanced resampling schemes have been proposed (Acuña & Orchard, 2017), this technique was still deemed valid for a purely preliminary analysis. Long-term prediction of the fault evolution can be obtained by iterating the "prediction" stage, and are used to estimate the probability of failure in a system given a hazard zone that is defined via a probability density function with lower and upper bounds for the domain of the random variable, denoted as H_{lb} and H_{up}, respectively. Given the probability of failure, the RUL distribution for any given prediction can be computed along with the risk function (Acuña & Orchard, 2018). The declination of the particle filter employed in this paper is based on a physics-based degradation model and a process model describing the dependency between the worn-out thickness x of the brake pads and the selected features.

$$\begin{cases} x_{N+1} = K_{wear}(E_{brake_N}) + x_N + \omega(N) \\ y_{N+1} = f(x_{N+1}, \nu(N)) \end{cases} \quad (13)$$

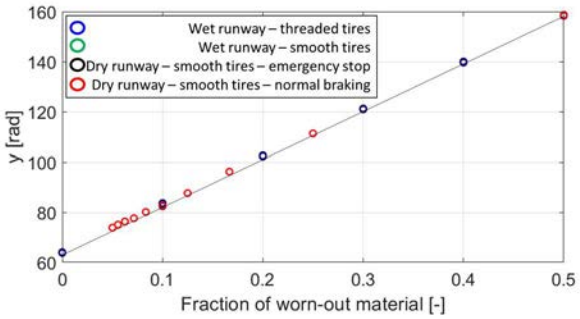

Figure 9. Dependency of the proposed feature on external factors and on degradation progression.

where K_{wear} is the wear constant, y is the feature and E_{brake_N} is the gross energy produced during the N^{th} landing. $\omega(N)$ and $\nu(N)$ are noises, estimated at each time step considering the probability distributions of the parameter and the accuracy of the process model through a certain number of previous steps.

The gross energy E_{brake_N} is estimated as follows, and provides an indication of an energy proportional to the terms of the modified Archard's Equation provided in Equation 7, following the expression:

$$E_{brake_N} = r_{ebrake} \int_{t_0}^{t_{end}} \sum_{i=1}^{4} F_i\,\omega_w dt \quad (14)$$

where F_i is the force exerted by each actuator and ω_w is the wheel angular frequency. The feature y is defined as the average angular position of the EMAs motor for which the measured force signal is significantly different from zero at the beginning of the braking procedure. Such data point is identified computing the rolling variance of the force signal and searching for the first point which rolling variance exceed 0.1. Such feature was successfully identified as the most promising in (De Martin, Jacazio, Parisi, et al., 2022) due to its high correlation with the degradation process. As shown in Figure 9, such feature is also not affected by variations in the operating conditions, nor by the braking procedure (emergency or normal). For each landing, the quantity E_{brake} is computed and memorized in a "landing repository", where it is stored along with related aircraft-level information, such as the aircraft weight at landing, for future usage.

During the long-term prognosis, the "landing repository" data-base is used to build an array of possible future landings through random sampling. If an indication or prevision of the area in which the aircraft is going to typically operate is available, a planned feature is to further refine the sampling procedure to account for the most probable weather conditions. The prognostic algorithm is tested against 40 simulated fault-to-failure processes, where the wear of the brake pads evolves dynamically as a function of the system behavior and operating conditions (temperature, dynamic load, fluid pressure), with increasing number of particles N_p

(from 50 to 5000) and evaluated according to the traditional metrics provided by (Saxena et al., 2008), namely the Prognostic Horizon, evaluated as the first real RUL value for which the prognosis falls within a $\pm$ 20% threshold of the real RUL, and the Relative Accuracy RA, defined as a function of the ground-truth value of the RUL (RUL_r) and its expected value RUL.

$$RA = 1 - \frac{|RUL_r - RUL|}{RUL_r} \quad (15)$$

An example of the prognostic output for the case of a is provided in Figure 10, where the system behavior is plotted against the number of simulated landing procedures N_L.

The behaviour of the particle filtering algorithm is investigated in two steps. At first considering the "filtering" performances, thus evaluating whether the system is able to correctly assess the severity of the on-going degradation, and secondly considering the long-term prognostic capabilities. Figure 11 depicts the behavior of the particle filter algorithm with respect to the simulated ground truth for the landing sequence already used for Figure 10, evidencing the particles distribution considering the estimated values assumed by the hidden state (the linear measure of the brake pad wear progression) and the selected feature. This information is given considering four equidistant prediction instances, with indication of the considered simulated landing.

It can be observed that the results of the particle-filtering routine are compatible with the simulated ground-truth in all of the shown cases, highlighting that the algorithm is able to coherently track the fault growth from the fault detection until imminent failure conditions. Figure 12 and Figure 13 describe the algorithm behavior against the simulated ground truth from a prognostic perspective. The estimated RUL distribution are coherent with the ground truth, and achieve convergence towards the simulated end-of-life.

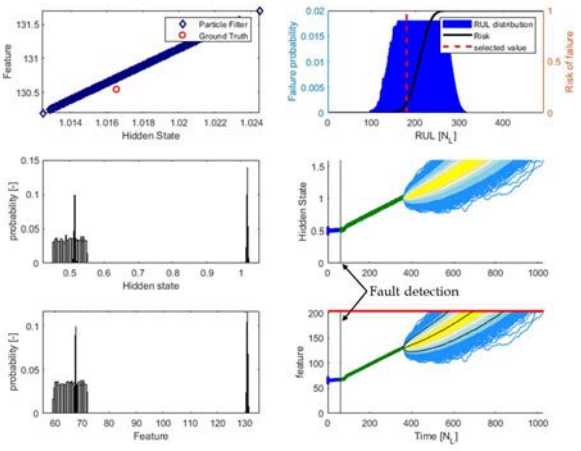

Figure 10. Prognostic performance against simulated data-set ($N_P = 5000$)

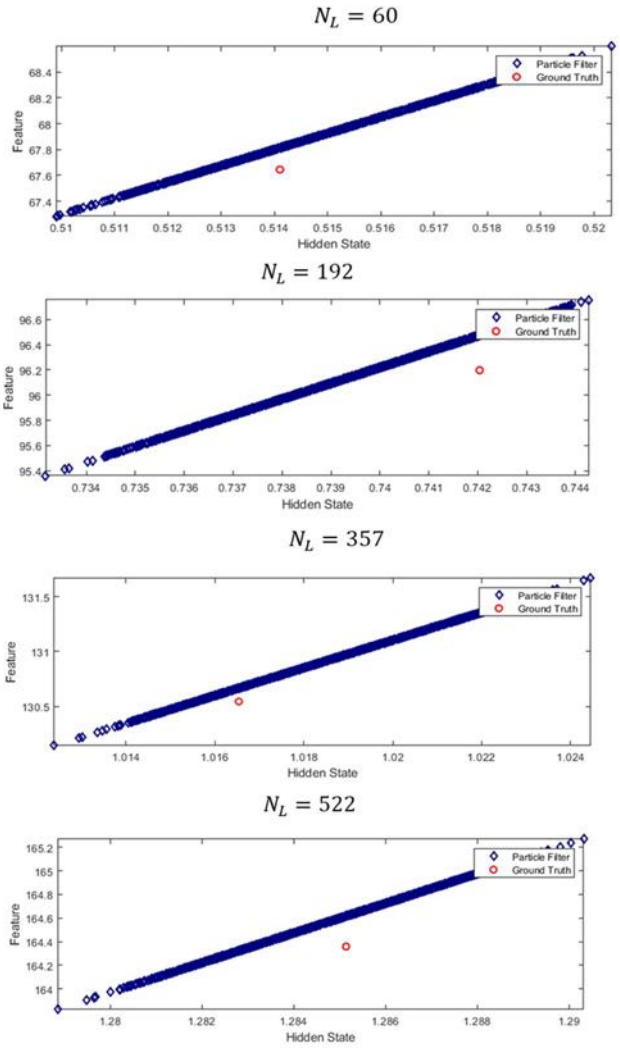

Figure 11. Comparison between PF and simulated ground-truth during the filtering stage ($N_P = 5000$)

In Figure 12, the RUL distribution at each considered prediction step is depicted along the selected value, corresponding to the RUL estimate with the highest probability of occurrence according to the algorithm. The "ground-truth" EOL, coming from simulation data set, is also provided. Results shows that the real EOL always falls within the prediction distribution, in the near proximity of values of risk of failure equal to 1. Although providing only anecdotal evidence – a more rigorous approach would be to compare the predicted RUL distribution against a real RUL distribution – this figure attests that the algorithm converges to the EOL in the analyzed case, providing then promising results.

This observation is confirmed by the $\alpha - \lambda$ diagram in Figure 13. The small deviation of the expected RUL with respect to the simulated ground-truth close to the EOL is expected to the prediction uncertainty increasing relatively to the RUL estimate.

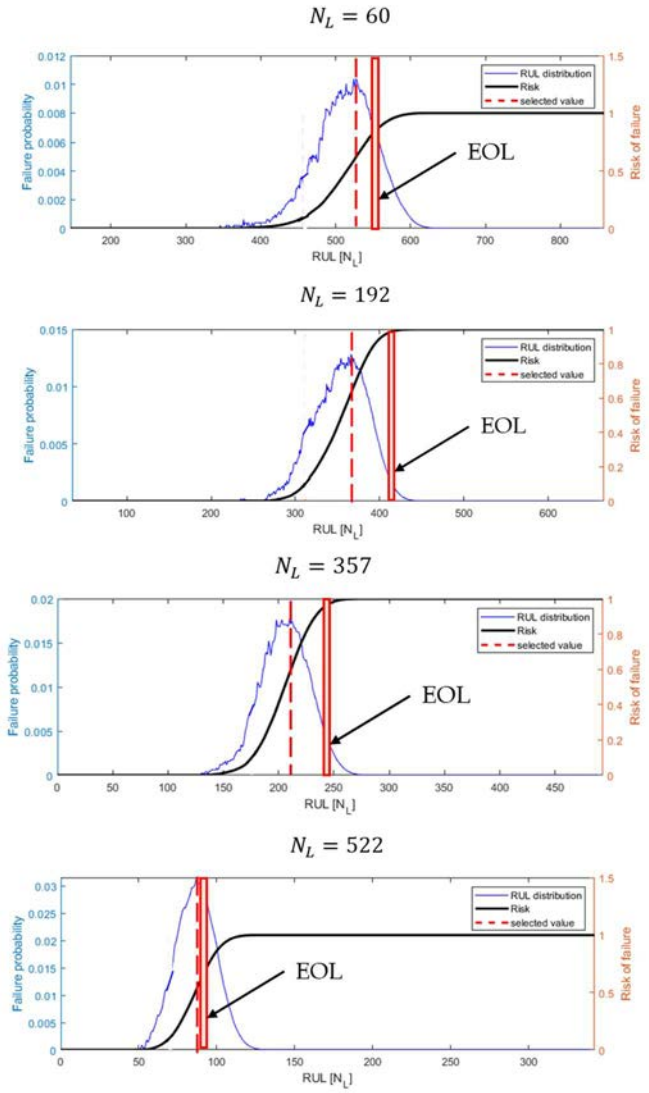

Figure 12. Comparison between estimated RULs at different prediction steps ($N_P = 5000$, $EOL = 600$ landings)

The prognostic performances of the algorithm are presented in terms of Relative Accuracy and Cumulative Relative Accuracy in Figure 14, where the results averaged over the 40 simulated landing sequences. It can be observed that the average Relative Accuracy remains well above the 80% threshold, while scoring high marks in CRA as well.

Finally, the algorithm is evaluated considering its elapsed time, to verify whether it is suitable for on-board or on-line deployment. Results were obtained on a DELL Precision 3660 workstation with *IntelCore i9-4.2 GHz* and *64GB* of DDR-4 RAM. Results are coherent with a possible real-time usage of the algorithm, although out of scope for the current project.

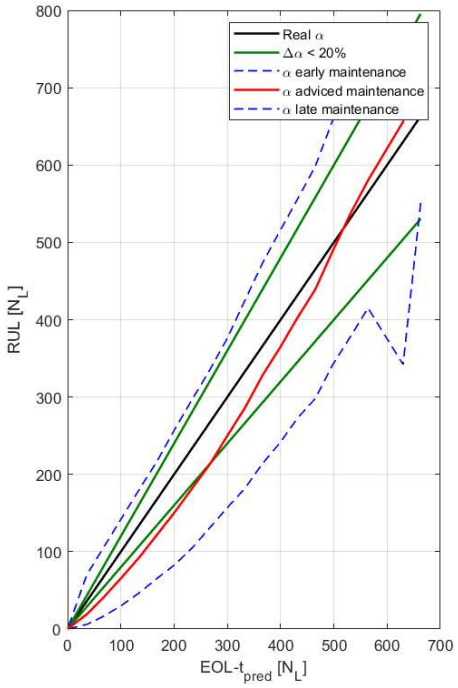

Figure 13. Dimensional $\alpha - \lambda$ diagram

6. PHM Implementation and Test Plan

Given the intermittent nature of the E-Brake operations, PHM algorithms are expected to be run offline, without the need to suffice restrictive computational constraints to achieve a real-time identification of the fault occurrence or progression. After each landing data are collected and analyzed. These same considerations are carried to the technological demonstrator, which is thought to monitor the E-Brake health status considering the results coming after each test.

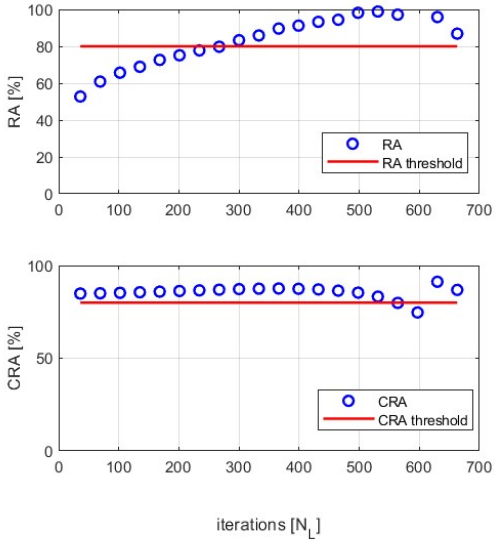

Figure 14. Prognostic performances (RA, CRA)

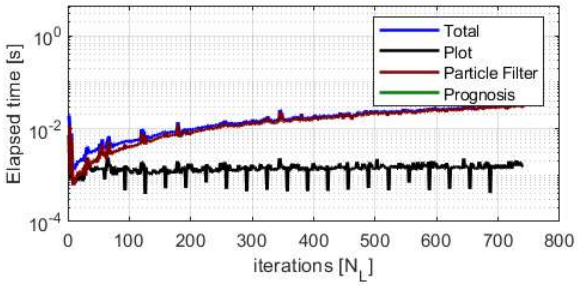

Figure 15. Algorithm elapsed time

The test plan is designed to verify and validate the most critical aspects of the presented work, namely the high-fidelity model employed to generate the synthetic database used to prepare the PHM activities and the wear model itself. Similarly, it is necessary to stress the PHM algorithm to check for false alarms and evaluate the performance of the prognostic output.

For these reasons the test plan includes:

- Registration of the qualification tests, including the simulated landing and the aborted take-off to evaluate the model behavior, considering different aircraft mass as detailed in Section 4.2.
- A number of consecutive landing simulations (at least 100), considering different aircraft weight and braking operation type (emergency, normal).
- The visual evaluation, after each landing, of the amount of worn thickness from the brake pads.

Since the test rig is not yet operational authors are not able to present the results of these activities, that will be hopefully the subject of further dissemination once the experimental steps are completed.

7. CONCLUSIONS

This paper presents the design of a novel technological demonstrator for PHM activities on a fully electrical landing gear and the preliminary design of a prognostic routine to forecast the wear in the pads of an electro-mechanical brake for a short-range aircraft. Since the test-rig is not yet operational, PHM activities have been tentatively proposed through a high-fidelity simulation model, iterating on the results of a previously published study. Such model, presented in the paper, is based on well-known equations, and translated into a state-of-the-art dynamic simulation engine. The PHM scheme is based on equations strictly correlated with the physics of the investigated degradation, and leverages the previous knowledge of the system usage to forecast the long-term estimate of the brake pads RUL. Early results are encouraging, but experimental support is needed to validate the findings of the simulation activities.

Further work will include the description and analysis of the effects of disks wear and the definition of health monitoring schemes to detect and prognose other prominent failure modes potentially affecting electrical brakes.

ABSTRACT

This study delves into the creation of anomaly detection technology applicable to a range of equipment groups within smart factories. This advanced technology uses high-performance MEMS vibration sensors, edge CMS devices, and PHM platforms to tackle issues such as data imbalance, learning model limitations, complex equipment operating patterns, and real-time processing. It also addresses central server concentration, data cycling problem, various equipment classification, and algorithm operation problems that can arise when implementing systems in the field. Using AI-based vibration detection algorithms, data can be collected at high sampling rates and analyzed in real-time through edge computing, minimizing latency and mitigating server capacity issues compared to cloud-based analytics. The system continually monitors and learns standard performance data from equipment to provide practical solutions that minimize equipment failures and downtimes. The results of this study are impressive, as it has successfully developed anomaly detection framework and PHM systems that are expected to enhance the efficiency and sustainability of smart factories. Furthermore, the study aims to showcase and improve the effectiveness of predictive maintenance in both domestic and international automotive factory production lines. This revolutionary technology will be a key component in smart and software-defined factories and help companies achieve intelligent automation.

1. INTRODUCTION

The rise of smart factories has recently led to an increase in production line automation equipment. As a result, maintenance activities have become crucial, and the need for predictive maintenance technology that can foresee equipment failures has emerged. Many companies are exploring ways to perform predictive maintenance, from installing additional sensors to analyzing controller data. Currently, predictive maintenance technology is limited to equipment that moves at a constant speed, like large turbines and fan motors.

We have developed a PHM (Prognostics and Health Management) system and an AI-based vibration detection algorithm capable of predicting anomalies in constant and variable-speed equipment to meet this need. Our technology stands out as it can collect vibration data at a high sampling rate, perform AI learning, and make decisions at the edge.

The PHM system consists of two primary components: the CMS (Condition Monitoring System) module and the PHM platform. The CMS module is a device equipped with edge computing functions, data collection capabilities, and decision-making algorithms. The PHM platform, on the other hand, monitors mining data from the CMS module, manages its operations, and deploys registered algorithms as a service for each CMS. Additionally, the platform is responsible for deploying the optimal algorithm as a module. The algorithm used in the PHM platform is developed through deep learning AI modeling and is registered and deployed as a CMS module [1].

Four-stage research was undertaken to create an AI-powered anomaly detection algorithm that relies on vibration data. Initially, a PoC (Proof of Concept) scenario was devised that focused on identifying the target equipment (robot reducer, automation equipment drive motor, etc.), the operating type (constant/variable speed, part/finished product), and the target defect type (robot reducer defect, motor bearing damage, etc.). Next, data was collected based on specific criteria for data type (vibration, current, speed, etc.) and collection method (CMS module, PLC, Cloud, etc.). In the third stage, signal feature extraction methods were defined through feature-based analysis, which uses domain knowledge to determine data analysis. An anomaly detection method was also developed to check abnormal scores by learning the normal group to suit the data imbalance situation where it is challenging to secure abnormal data compared to normal. The AI model used an Auto-Encoder structure and an unsupervised learning method, and an optimal model was developed through hyper-parameter adjustment to define the anomaly score [2]. The algorithm was verified through PoC activities by matching the score of the normal/abnormal state

of equipment with the actual motor defect phenomenon.

The PHM system and AI anomaly detection algorithm operate within the production line to learn and monitor the equipment's standard performance data. An alarm prompts maintenance activities when a score falls outside the normal range [3]. This approach minimizes equipment failure and ultimately aims to reduce non-operation rates. By leveraging data analysis to inform condition-based maintenance activities, our system establishes highly efficient maintenance and production plans that surpass traditional time and usage-based approaches. As a result, we can lower costs associated with non-operation rates within the production line [4].

2. BACKGROUND

Current predictive maintenance systems have typically utilized centralized models to analyze and predict facility-level data gathered from a central server. This approach has allowed rule-based algorithms to successfully extract key characteristics and implement predictive maintenance, even in low data sample rate environments where the facility operates at a constant speed.

However, operation patterns have become more complex with the rise of smart factories and diverse automation equipment. As the number of transmission equipment containing acceleration and deceleration patterns increases and the data types become more varied, data quality and accuracy have become increasingly important. A high data sample rate is required to analyze these transmission facilities effectively, and the utilization of AI algorithms has become crucial.

As a solution, we have developed a cutting-edge PHM system that seamlessly integrates an edge device and platform. With the power of edge computing technology, this system can efficiently process data near the facility, thereby reducing the volume of data transmitted to the central server. This not only lessens network load but also alleviates server burden. Furthermore, the system's real-time processing capabilities have been enhanced, resulting in a faster response time for our predictive maintenance system.

A framework for detecting anomalies that utilize advanced AI algorithms has been crafted to manage high data sample rates and identify significant features for precise anomaly detection. This framework has been customized for different kinds of facilities and effectively fulfills the requirements of smart factories.

Adopting smart manufacturing has necessitated a departure from conventional, centralized PHM systems towards decentralized, intelligent, and adaptive solutions. Incorporating edge computing and robust AI analytics is a forward-looking measure that promotes operational efficiency and dependability in contemporary automated facilities. Such innovations react to the evolving industrial landscape and a deliberate strategy to harness sophisticated technologies for more accurate fault prediction and prevention.

3. CHALLENGES

3.1. Challenges with PHM system developments

3.1.1. Data imbalance

Smart factories primarily collect steady-state data, which poses a challenge in detecting anomalies. The lack of abnormal data makes developing effective anomaly detection models difficult, as supervised learning models require sufficient labeled abnormal data. However, intentionally creating abnormal states in real environments is not feasible [5]. As a solution, an experimental test bench can be created to simulate normal and abnormal conditions to ensure a continuous supply of abnormal data. This data can be used to perform PoC verification. By conducting PoC, we can collect normal/abnormal data based on test conditions and create labeled data for each facility. This enables the use of highly accurate supervised learning models.

Unsupervised or semi-supervised learning methods are commonly used to solve the data imbalance in in-line. Unsupervised learning uncovers hidden patterns without labels, while semi-supervised learning enhances model performance by utilizing limited labeled data. This approach leverages smart factory inline data, primarily normal data, to establish normal distribution benchmarks for monitoring status. We can monitor anomaly score set up the lines divided warning and fault. By configuring and implementing the system on the production line, we can effectively address issues related to data imbalances.

3.1.2. Challenges with learning models

While unsupervised or semi-supervised learning methods can effectively identify anomalies, they do have a drawback because it can be challenging to pinpoint the exact cause of the anomaly. For instance, if a model detects an abnormality, it does not necessarily reveal whether the sensor responsible for the anomaly is faulty. To address this issue, it is necessary to conduct a thorough re-analysis of the facility's data after an anomaly is detected. Data from sensors must be separated and examined individually for each moving part or component location in the equipment, and specific patterns or characteristics contributing to the anomalies must be identified. To accurately determine the characteristic frequency based on the rotational speed of each component and identify any unusual fluctuations, we utilize domain knowledge to collect statistical data on gear frequency bands prior to the learning process. This stored information can be easily accessed through our platform for thorough analysis. This approach can be incredibly helpful in taking practical measures to resolve the issue.

3.1.3. Equipment challenges with complex patterns of robots

Sophisticated machinery, such as robots, can be challenging to monitor for irregularities due to their frequent acceleration, deceleration, and complex patterns. Additionally, the lengthy cycle times and diverse movements of robots make it difficult to identify patterns using traditional methods. However, advanced algorithms, including cycling techniques and signal processing methods such as time-frequency transformation (STFT) [6], can be applied to more accurately detect abnormal changes. These techniques make it possible to detect abnormalities with a higher degree of accuracy, even in facilities with complex patterns.

3.2. Challenges when applying PHM in the field

3.2.1. Challenges with the central server concentration method

In a cutting-edge factory setting, copious amounts of data are produced from diverse facilities. Specifically, intricate automation facilities generate significant quantities of data, including high sample rate vibration data. However, the conventional approach of transmitting this data to a central server for processing results in heightened network load and latency [7]. A practical solution to this challenge is to create an 'edge + platform system' leveraging edge computing technology to analyze data in real-time near the facility, extract critical information, and transmit it to the central server. This approach can expedite data processing while minimizing communication costs and central server storage management cost.

3.2.2. Challenges with cycling

In order to analyze data, it is necessary to cycle the data for a certain period, and PLC data is often used for this purpose. PLC typically utilizes line start/end process signals to timestamp data accurately. While low sample rate data is easily timestamped, high sample rate data like vibration presents a challenge. While the existing method to set timestamps was straightforward given the low data sample rate, more intricate equipment necessitates using high-sample rate vibration data to prevent information loss through down-sampling. However, this presents a challenge when attempting to set timestamps with PLC due to its limitation of about ten samples per second to avoid taxing the controller. As vibration sample rates can reach up to 16 k Samples/second, the resulting difference of approximately 1600 times is sufficient for information loss. A cycling or robust delay learning method is needed to address this issue.

3.2.3. Challenges with algorithm operation

Given the dynamic nature of smart factory environments, ensuring that AI algorithms remain up-to-date is crucial. To achieve this, an MLOps must be implemented, enabling periodic retraining and redeployment of algorithms [8]. Moreover, a collaborative approach between operating departments and maintenance organizations must be established to adapt swiftly and effectively, with a mechanism in place for rapid feedback and adaptation.

The upkeep and enhancement of AI algorithms demand consistent attention and a well-structured approach. To achieve this, the operations, conservation, and AI development departments must collaborate closely. Through monitoring data, identifying areas that require retraining, and leveraging real-time operational feedback, they can optimize the predictive conservation system's performance, leading to heightened efficiency.

3.2.4. Challenges with directing maintenance workers

In the early stage of system implementation, maintenance workers may face challenges in responding promptly to fault alarms. To enhance their response effectiveness, it is imperative to set up a system that showcases the blueprint of each facility on the platform and highlights the precise location of the alarm. The platform clearly presents the factory layout, indicating the location of all facilities. Every moving part of the facility has sensors and edge devices placed in precise locations, making it easy for maintenance workers to identify maintenance work locations through alarms displayed on the screen. Achieving this level of efficiency should be effortless. This approach will significantly boost the speed and precision of maintenance work.

4. METHODS

4.1. PHM System

4.1.1. Vibration sensor

Smart factory transmission equipment requires more precise and accurate data analysis. For this purpose, we used a vibration sensor with a sensitivity of 160 mV/g and a sampling rate of more than 8 k Samples/second to obtain high-quality data. These high-performance wired vibration sensors have the disadvantage of incurring additional installation costs. Still, applying a cost-effective, inexpensive vibration sensor of the MEMS type has compensated for this disadvantage. This makes it possible to collect high-quality vibration data economically.

Table 1. Vibration sensor

Vibration Sensor	Type	MEMS
	Axis	Z (mono)
	Sensitivity	160mV/g

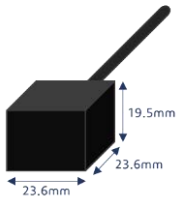

Figure 1. Vibration sensor

4.1.2. Edge CMS (Continuous Monitoring System)

As the amount of data increases exponentially, concentrating data on a central server for analysis becomes difficult due to storage capacity management and data latency issues. In particular, high sampling rate data processing is essential in facilities with complex patterns, which makes centralized analysis more difficult. To respond to this, we developed Edge CMS with edge computing capabilities, processing high-sample rate vibration data in real-time at the edge, extracting features, and calculating AI scores. The system supports 24-bit resolution and a sampling rate of 16kS/s, allowing processing without data loss. AI algorithms are mounted on these Edge CMSs and can make decisions immediately near the facility.

Table 2. Edge CMS module

CMS Module	Max. Sampling Rate	16 k sample/sec
	Channel	8 channel
	Bit Resolution	24 bit

Figure 2. Edge CMS module

4.1.3. PHM Platform

The PHM platform is located on the central server and manages each Edge CMS device applied to each facility. The AI algorithm is registered in the platform as learned and then distributed to the CMS, which requires updates when necessary to optimize and manage abnormality detection. For example, if the line situation changes and the operating pattern teaching is modified, two weeks' worth of raw data is relearned, and the learned model is redistributed to the CMS located in the relevant process facility for operational management. In other words, the MLOps cycle that allows re-learning/re-distribution was implemented. Key features and AI scores calculated from the CMS located at each facility are transmitted to the platform and displayed to check trends by date. If the appropriate standard value is exceeded, a warning and fault alarm is given to notify the operator, and it displays which equipment and location on the layout shows signs of abnormality, helping to instruct maintenance workers on maintenance work. The platform layout was modeled after each factory line, and the web screen was designed so that if an error occurs, the area is marked in red to be visually checked immediately.

4.2. Anomaly detection framework

4.2.1. Cycling Techniques

'Cycling' is 'Extracting one cycle in operating data patterns of equipment'. Our data must be 'cut off' in the equipment operation cycle. Usually, cutting is done with PLC signals, but down-sampling is necessary to match the start / end signal timestamps to the data. However, the simple down-sampling method may be ineffective when collecting vibration ineffective when collecting vibration data at 8kS/s

Figure 3. PHM platform monitoring screen composition

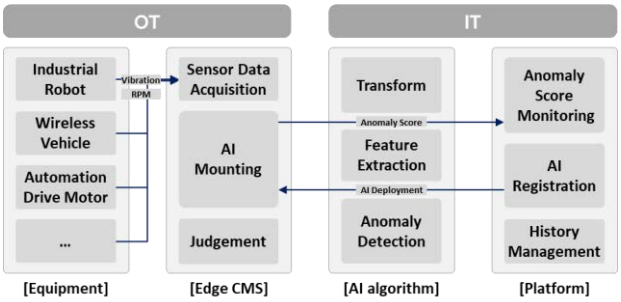

Figure 4. A configuration block diagram of the PHM platform and Edge CMS module connection with AI algorithm in the OT/IT range

to analyze transmission equipment that repeats acceleration/deceleration. To overcome this, we utilized an auto-cycling technique to divide the acceleration, constant speed, and deceleration sections. We obtained the specific frequency by determining the rotational frequency based on the equipment motor's RPM. We then counted the peaks of the acceleration/deceleration in both time and frequency and set a vibration magnitude threshold to divide the acceleration/constant speed/deceleration sections. This technique can be applied to various equipment motors, including lifts, conveyors, and stackers/destackers for transporting logistics boxes or vehicles. Regardless of the distance traveled, the acceleration/constant speed/deceleration types can be learned and utilized separately.

Advanced gear-shifting equipment, such as robots, faces a challenge when splitting acceleration and deceleration using auto-cycling techniques. As a result, the entire one cycle must be used for learning. The process signals receive start and end bits, which are then used to set the cycling point. To ensure robust learning despite delays caused by different sample rates, features are imaged at a later point. The frequency distortion caused by converting the entire cycle is resolved through STFT conversion, allowing for the utilization of all time-frequency information.

4.2.2. Preprocessing and Conversion

Data value can vary depending on the unique conditions of each facility. To refine normal data, checking its distribution, applying DC offset, and filtering where necessary is essential. Since most equipment comprises motors and gears, confirming rotation frequency in the frequency spectrum based on speed is possible. Features are extracted to ensure accurate expression of rotational frequency and harmonic components based on gear mesh theory [9], and window size is set to perform FFT spectrum conversion up to the 4kHz band [10], [11]. After conversion, RMS statistics are calculated for each harmonic frequency band and basic statistics like Min, Max, Average, Kurtosis, and Skewness [12]. This data is stored on a server to enable detailed analysis and monitoring. The magnitude of the FFT spectrum converted to a 1D shape is fed into the AI algorithm for further study. The spectrum is transformed with a window size of 3 seconds, and data is extracted through window sliding with a duration of 0.25 seconds [13]. In the

slow-speed equipment, the spectrum is reduced to 1.5 kHz, and the conversion values for each channel are concatenated and studied in the form of a wave set. This process has led to the development of an optimized anomaly detection framework that applies different conversion techniques to suit the specific characteristics of each facility.

Robots utilize STFT transformation to extract features, which involves cycling in the manner described above. The output of STFT is a 2D shape from a colormap image, which serves as input to the AI algorithm. When features are extracted using 1D Conv, some degree of conversion freedom allows for flattening and use within the algorithm. The STFT value is also stored separately and used for detailed feature analysis. The robot stores features in separate channels for each axis to allow for more accurate analysis. This approach enables the identification of any anomaly score increase in a specific channel, which can then be used to issue maintenance instructions for the affected axis. The FFT spectrum is re-extracted for the robot's statistics, using a window size of 3 seconds within one cycle. The extracted features are stored similarly to the driving motor of general equipment and are not separately learned by the AI model. They are stored on the server for monitoring during detailed analysis.

4.2.3. AI algorithm

The most effective method for confirming data classification is Dimensional Reduction Visualization. This involves reducing the extracted features' dimensions and representing them on a 2D graph's x and y axes. Doing so can ascertain how the feature distribution is formed by date and whether it is clustered. LDA (Linear Discriminant Analysis) is utilized for dimensionality reduction [14]. The average feature value for each date is represented as a single point, and each month is color-coded to show how the features change visually from one month to the next.

Supervised learning struggles to classify typical smart factory data due to the difficulty of obtaining abnormal data. However, clear labeling can ensure the accuracy of this method. To address this issue, we developed an algorithm to collect abnormal data and classify the collected abnormal data so that it can be distinguished from normal data in various scenarios, such as motor misalignment, bearing failure, bearing cage damage, robot reducer failure, and lubricant shortage. We utilized deep learning, specifically a convolution method, to capture features easily using spatial information of image data. The 1D CNN layer consisted of 3 layers, utilizing the relu activation function [15], a model was created to classify into normal/abnormal through the dense layer. After verification, over 97% of the classifications were confirmed. The classification model was saved in the system, and data on diverse types of defects were collected and attributed to the system for future classification purposes.

In cases where there is insufficiently abnormal data, Anomaly Detection can be achieved by establishing a baseline of what constitutes "normal" data and monitoring any deviations from that baseline through a scoring system. An AI algorithm utilizing an auto-encoder structure must be introduced to employ this method [16]. Before training the model, extracted features are inputted as the model's input values. When dealing with robots, input values take the form of images, for which a convolution layer is created to facilitate image analysis. This layer consists of three layers with a relu activation function, and instead of pooling, it utilizes the stride technique to employ all pixel information [17]. The decoder comprises three Conv2DTranspose layers reconstructing the extracted features. Learning uses the Adam optimizer, mae loss, and appropriate batch_size and learning_rate parameters. The trained model predicts new data with the same feature shape, calculates the loss difference from the normal group learning value, and generates an anomaly score. Anomaly detection is achieved by monitoring this score over time and checking the platform display for gradual increases.

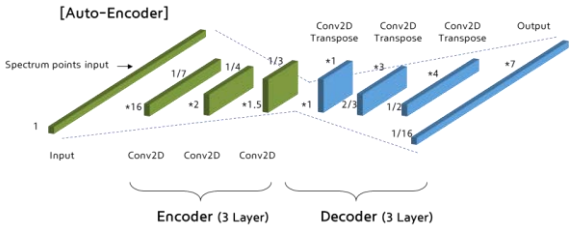

Figure 5. Configuration of vibration-based AI model (Auto-Encoder) for Anomaly detection

5. Verification

5.1 Verification of PoC

5.1.1 Construction of Test-bench and data collection environment through PoC

We set up an external test bench and conducted a PoC test to gather information on the target equipment. In the case of industrial robots, we installed vibration sensors on each axis of the reducer part for manufacturers such as Hyundai, ABB, Yaskawa, and Kawasaki. We repeatedly drove the machine by teaching it a complex, 6-axis movement that could withstand heavy use. To collect vibration data from the reducer part, we used a motor with the same capacity as the logistics line conveyor and lift equipment and connected a load system to apply a constant speed drive. We monitored and verified the target type by selecting equipment with a high non-operation rate in-line, such as when replacing a reducer due to mechanical defects.

5.1.2 Development of Motor PHM diagnosis algorithm and Verification in Test-bench

A dynamometer was installed on the motor and reducer (manufactured by SEW) to confirm the PoC, which drives the automation equipment utilized in actual mass production. A load was applied, and critical parts were equipped with a vibration sensor to collect data. The system was run at a constant speed of 1800rpm with load currents ranging from 2.5 to 0.1A.

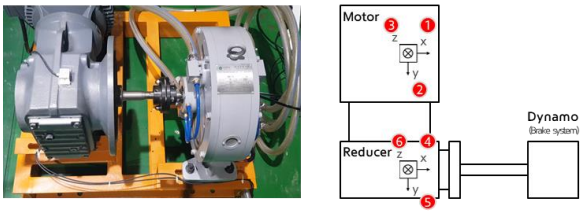

Figure 6. Real and dynamometer configuration diagram of Motor and Reducer

In our analysis, we compared normal and abnormal data. Specifically, we examined changes in vibration magnitude on the time axis and alterations in specific frequency values, band ranges, and harmonics of the rotating body on the frequency axis. Using this information, we conducted a date-wise assessment to determine if there was a gradual change.

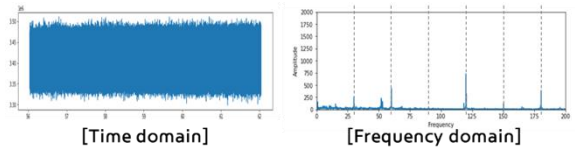

Figure 7. Normal data pattern by time/frequency domain

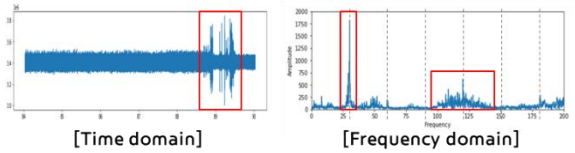

Figure 8. Abnormal data pattern by time/frequency domain

Our process involves extracting feature vectors from acquired data using FFT spectral transformation. These vectors are then input into an autoencoder model, which returns an output vector. The model first learns the vector of the normal group, compares it with the vector of new data, and returns the error value as the final score using MAE. To test this, we selected ten days of motor operation data with the same conditions and the occurrence time of an abnormality. We trained the model using the first three days and predicted the next seven days. Finally, we analyzed the predictions to identify any changes in the data.

Figure 9 displays vibration RMS values over time, indicating that the RMS only increased at the time of failure, making it challenging to predict through rule-based measurement value monitoring. However, in Figure 10, the Anomaly score gradually increases over time. Figure 11 displays the average value per date, revealing an increasing score from January 28th. As the anomaly score rises, data that differs from the standard norm is being collected, making it feasible to operate a PHM system that anticipates failure and notifies the time of failure via an anomaly score baseline of 0.2 to 0.3.

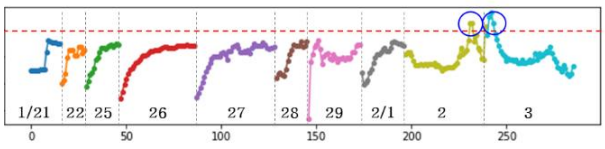

Figure 9. Comparison of vibration RMS values by date

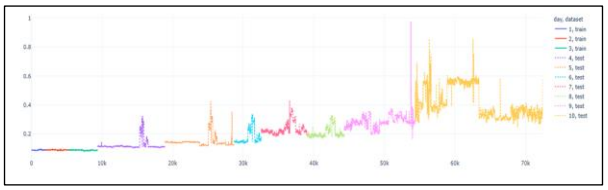

Figure 10. Comparison of Anomaly scores by date

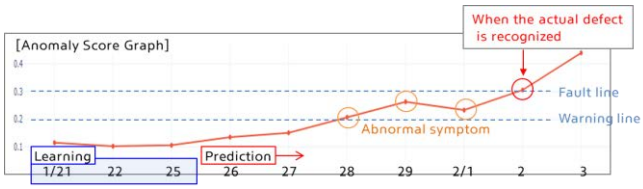

Figure 11. Comparison of Anomaly scores average

After the actual abnormal data was acquired, the operation stopped due to motor failure after continued operation for two months, and a motor disassembly analysis was performed to confirm the phenomenon.

The cause is damage to the reducer and internal bearing due to dynamometer misalignment. Damage to the bearing cage and excessive tooth surface wear can be seen in Figure 12. As a result, a prediction model for motor failure was developed, and it was confirmed that the algorithm could be applied and operated by matching the failure phenomenon.

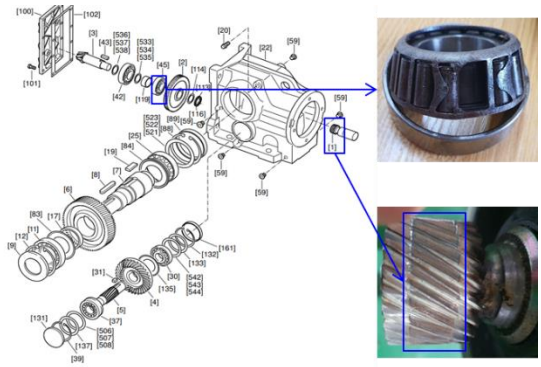

Figure 12. Result of disassembling bearing of faulty reducer

5.2 Verification of Production factory in-line

5.2.1 Inline data analysis process

An aging robot was selected from the in-line welding robots used for car body production to verify the development algorithm. A vibration sensor was installed, and data was collected. The robot was significantly aged after operating for 11 years without a reducer replacement. Upon analysis of the iron concentration in the reducer grease, it was found to be approaching the replacement criterion. The data was monitored for an additional four months, and the reducer was replaced with a new product. The change in Anomaly score was checked to verify the replacement. This verification process aims to determine whether the aging pattern is distinguishable from normal, even if it is not a failure, and whether the score can increase gradually and eventually lead to a failure.

Figure 13. Appearance of aging robot reducer in-line

The anomaly detection process utilized the Auto-Encoder model through AI technology. Upon replacement, the data was swiftly learned and compared to the data not learned before replacement using the AE model for score evaluation by date. Below is the comprehensive data analysis procedure that is verified based on what is described in Chapter 4.

Using raw vibration data, we extracted one-cycle data by analyzing the similarity or the on/off signals of a PLC. The data collected includes six channels and spans 51 seconds, with sensors installed on each axis of a 6-axis robot. However, the window size was too large to analyze one-cycle data in the frequency spectrum. To address this, we used partial data corresponding 1~3 seconds to transform to FFT spectrum or performed an STFT transformation using total cycled data to extract features in both time and frequency bands. This is a

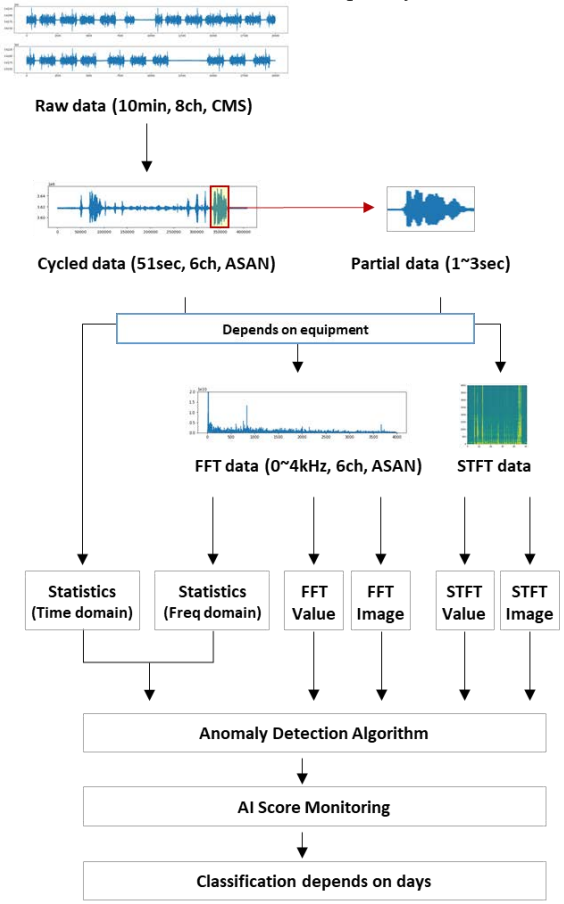

Figure 14. In-line data analysis process

key method for extracting features based on the equipment and operation pattern. The converted STFT was then shaped into an image with the following input dimensions.

Abnormal dataset: (580, 385, 387, 3)
Normal dataset: (185, 385, 387, 3)

To ensure accurate and reliable results, we split 60% of the data set into a training dataset of 459 samples and a test dataset of 306 samples. This allowed us to effectively organize and analyze the data before proceeding with the learning process.

5.2.2 Visualization of data distribution

To visually represent the distribution of data, we employed dimensionality reduction using the LDA (Linear Discriminant Analysis) technique. This involved breaking it down into two-dimensional components and displaying it on a 2D graph. M5 to M10 in the graph represent months. After the reducer was replaced, October was expressed in brown, and the months from May to September before the replacement were expressed in a different color. Upon observation, we concluded that the data's distribution clusters were formed differently before and after the reducer replacement.

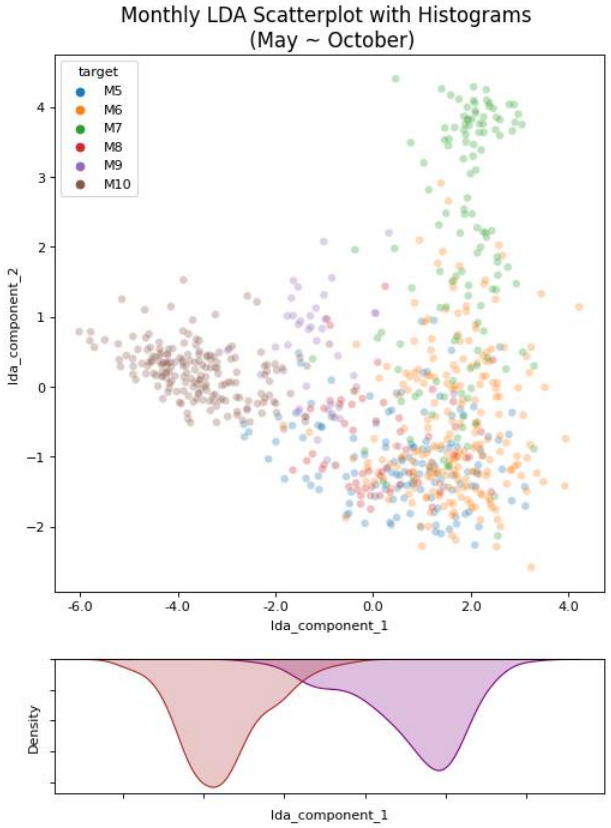

Figure 15. Monthly scatter plots and histograms were separated using Linear Discriminant Analysis – Abnormal (M5~9_purple) and Normal (M10_brown).

5.2.3 Results of Anomaly Detection Analysis

We use STFT colormap image as the characteristic feature. Utilizing colormap images demonstrated superior feature extraction through a convolution layer [18]. This led to a highly effective anomaly detection model, which relied on an Auto-Encoder structure as its foundation. Specifically, we constructed an encoder consisting of three convolutio

and a decoder featuring a convolution transpose layer.

50% of the normal dataset was used for learning, and the remaining abnormal and normal datasets were used as a test set to check the anomaly score.

A discernible visual difference was observed in the scatter plot after comparing the reconstruction error before and after replacement with a new product. The distribution graph distinguishes the abnormal state in orange color and normal state in blue color before and after the replacement time point. (Figure 17). Subsequently, upon setting the error threshold, the distinction in distribution between the normal state, which is represented in dark blue and the abnormal state, which is represented in orange, was confirmed through the histogram. These findings suggest that the replacement product had a significant impact on the reconstruction error and, thus, could enhance the overall performance of the system. (Figure 18)

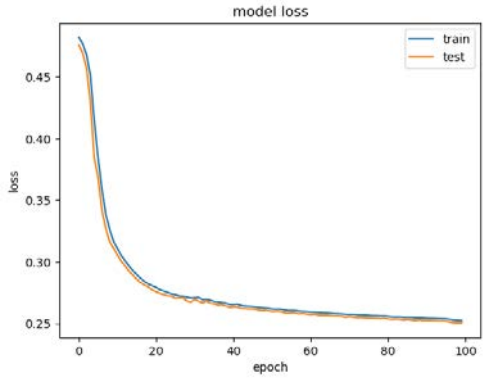

Figure 16. Auto-Encoder Model learning loss graph

Learning was performed by repeating epochs to minimize loss.

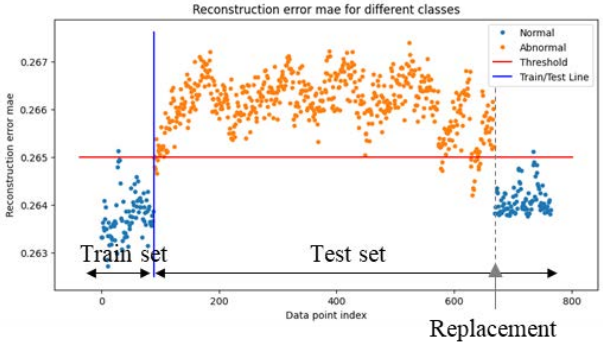

Figure 17. Reconstruction error scatter plot by Train/Test set

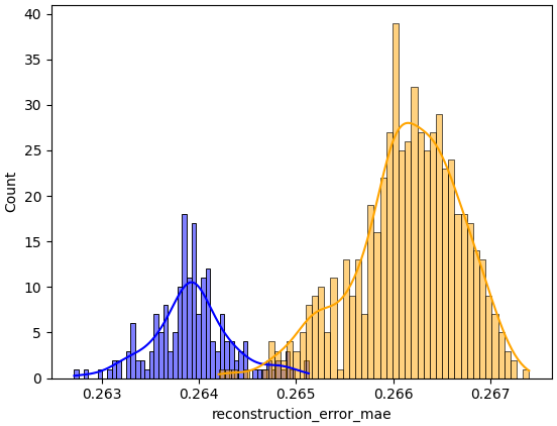

Figure 18. Reconstruction error distribution histogram

It was determined through predictive analysis of the test dataset that significant differences in reconstruction error exist between the normal and abnormal datasets. The formation of distinct clusters in the reconstruction error distribution further confirmed these differences. By setting the appropriate threshold value and checking the classification accuracy, it was ascertained that the classification was highly accurate, exceeding 97%. Additionally, by monitoring the anomaly score through unsupervised learning, variations in data patterns in aging equipment were identified as indicative of potential breakdowns.

Table 3. Test set classification results depending on metrics

Accuracy	Precision	Recall	F1	ROC_AUC
97.04%	99.82%	96.72%	98.25%	97.84%

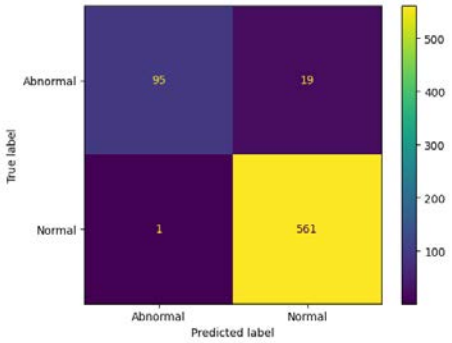

Figure 19. Ab/Normal state confusion matrix of the Test set

6. Smart Factory Application

Our new smart factory's assembly and logistics lines currently utilize the PHM system. It's applied to both constant-speed equipment like fan motors and variable-speed equipment like robots, lifters, and wireless mobile vehicles. Through our research and development, we've been able to internalize our technology and significantly reduce construction investment costs compared to external products. Moving forward, we plan to constantly monitor data and enhance our algorithm by identifying and addressing specific facility defects. Our ultimate goal is to expand horizontally, proving and verifying the effectiveness of predictive maintenance on domestic and overseas automobile factory

production line facilities.

6.1. Classification of Smart Factory Equipment Group

6.1.1 Constant speed equipment

When it comes to equipment that operates at a consistent speed, the relevant data values are monitored and analyzed, or specific window sizes are set to monitor the score obtained from learning features within the frequency spectrum. This applies to equipment like painting fan motors, supply/exhaust fans, and air blow pumps.

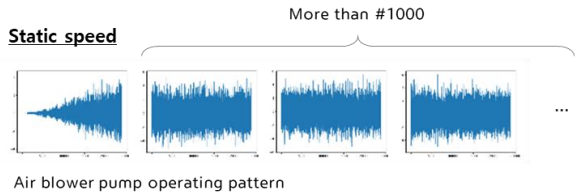

Figure 20. Operation pattern of constant speed equipment

6.1.2 Monotonic acceleration/deceleration pattern equipment

Regarding in-line equipment, movement automation equipment may follow a repetitive pattern of acceleration, deceleration, and constant speed. This is evident in stacker/de-stacker equipment that moves BIW between floors in an automobile manufacturing line and conveyor belt drives for movement between processes. Despite having variable-speed capabilities, the acceleration/constant speed/deceleration pattern remains constant, allowing for the extraction and utilization of features across the frequency spectrum by dividing the pattern accordingly.

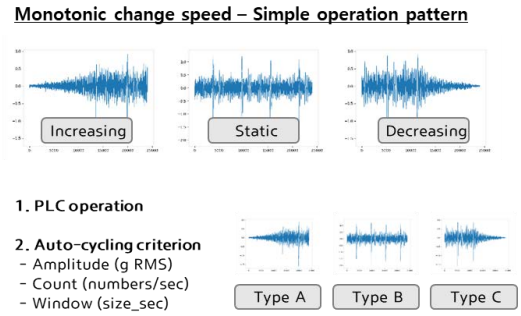

Figure 21. Operation pattern of acceleration/deceleration equipment

6.1.3 Monotonic acceleration/deceleration and various pattern equipment

In logistics box warehouses, repetitive acceleration and deceleration patterns are common, but the locations of the logistics boxes can vary greatly. This is particularly true with equipment such as the MSC (Multi Stacker Crane) and the SC (Stacker Crane). Given the vast number of possible box positions, it is not practical to learn the patterns of each position individually. Instead, the deceleration, constant speed, and acceleration patterns are divided, and learning is conducted by selecting features through the frequency spectrum.

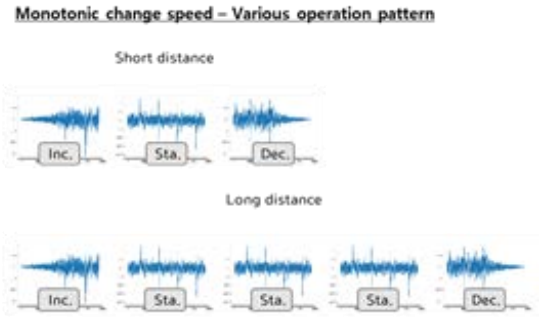

Figure 22. Operation pattern of wireless mobile device

6.1.4 Complex acceleration/deceleration pattern equipment

With the rise of smart factories, 6-axis industrial robots have become the primary choice for automation. However, due to the complexity of their multi-jointed structure, obtaining features for each movement can be challenging. To overcome this, the one-cycle pattern for each process is cropped and transformed into STFT to extract features using both time and frequency. The resulting colormap image is then learned and configured to predict one pattern for a new cycle.

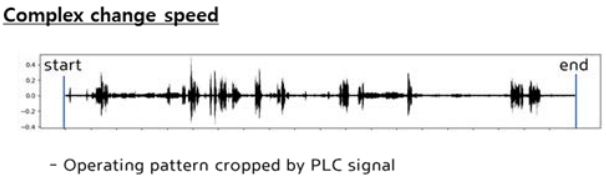

Figure 23. Operation pattern of industrial robot

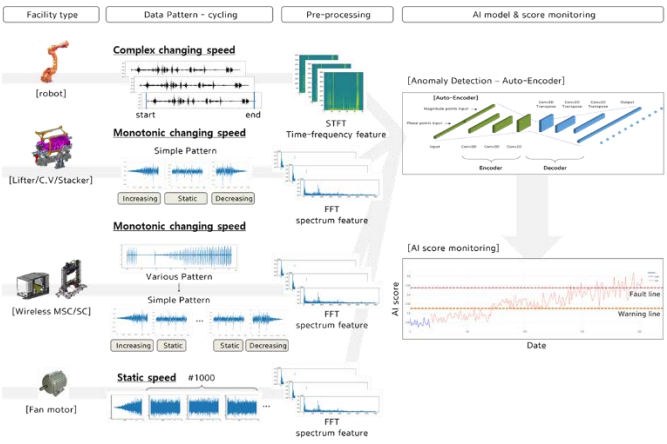

Figure 24. Feature extraction method and anomaly score calculation/monitoring process for various smart factory equipment

The final process is outlined above. When dealing with a fan motor that runs at a constant speed, the frequency spectrum of the continuous speed pattern is used as an input feature. For an engine that drives a stacker/conveyor or wireless mobile device with repetitive acceleration/deceleration, the cycle's acceleration/constant speed/deceleration pattern is separated by the driving part motor and configured through frequency spectrum conversion. For industrial robots with intricate patterns, both time-frequency features are utilized by imaging and

organizing STFT features. An auto-encoder structure defines an input shape for each piece of equipment. The model is saved by learning the data of the normal group. When new data is received, the reconstruction error is calculated and compared against the learned features to determine how much it differs. Finally, an anomaly score is calculated, and the smart factory is monitored by date for anomaly detection.

6.2 Smart Factory operation screen

They are displayed below, as Figure 25 shows the smart factory's configuration screen. The process locations that have undergone PHM algorithm application are marked, allowing for confirmation of AI-predicted vibration data anomalies through Anomaly score monitoring. The score's baseline is partitioned into warning and fault lines. Crossing the warning line triggers a yellow alarm while crossing the fault line triggers a red alarm. Workers can observe the red

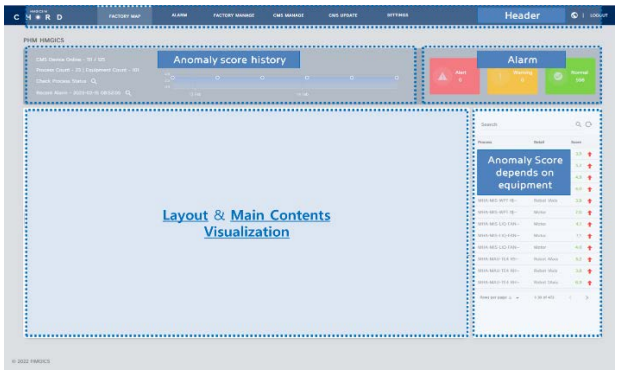

Figure 25. Monitoring screen of the factor layout displayed in the PHM system and each facility's anomaly score

indicator at the factory at the relevant facility location and conduct equipment maintenance activities. The score can be historically tracked by date/time, and a system utilizing MLops has been implemented to enable optimized algorithm re-learning and re-deployment. This system aids in optimizing the anomaly score baseline while operating the factory and conducting intelligent maintenance activities accordingly.

7. Open Problems

Thus far, we have elaborated on developing a PHM system and an abnormality detection framework to effectively address the challenges that may arise when performing predictive maintenance on various facilities within a smart factory. However, there are still some outstanding issues that require attention. Rest assured, we intend to leverage further work to tackle these challenges with precision and efficiency.

7.1. Storage space problem

Despite utilizing edge computing and storing only feature extraction results to address some challenges, many issues still need to be solved. With the emergence of intelligent factories that automate more processes and gather vast amounts of data for analysis, the issue of storage capacity remains a pressing concern.

7.2. The problem of wired sensor installation costs

Vibration data with a high sample rate is ideal for more precise analysis. However, the drawback is that it requires the installation of vibration sensors and the laying of wired cabling. To optimize the return on investment, it is vital to classify equipment based on whether it requires high sample rate data analysis, like vibration.

Installing vibration sensors on every axis would provide valuable data when analyzing robots, but the associated costs would be significant. To mitigate this, it's essential to develop technology that relies on multivariate time series data, such as current, torque, and speed, collected from the robot controller while leveraging multimodal techniques and correlational analysis with vibration to ensure optimal analysis performance without excessive wiring [19], [20].

7.3. Problems classifying various types of defects by line equipment

Efficiently identifying different kinds of defects in manufacturing plants can be challenging. Establishing a seamless collaboration between the operation, analysis, and maintenance departments is crucial. Gathering data on each defect type during factory operations requires meticulous attention to detail and careful feedback collection.

7.4. Problems predicting RUL and lifespan for each line facility

To make precise predictions about facility lifespan [21], data must be collected throughout the entire cycle from the initial operation to the eventual failure. This data can only be obtained once the factory and predictive maintenance system have matured, and the technology can only be developed when the organization and system are well-equipped and consistently engage in seamlessly integrated predictive maintenance activities. With these measures in place, accurate facility lifespan predictions can be confidently made.

7.5. MLOps automation level needs to be increased

The systemization process has been completed; however, users need to re-learn and redistribute the system to utilize its full potential. Once this is done, the system will need further development to enable Continuous Integration and Deployment and subsequently automate MLOps.

7.6. Existing smart factory applications are applied to new facilities.

Due to the implementation of predictive maintenance technology in smart factories, it is anticipated that the emergence of breakdowns caused by aging will be delayed in newly established facilities. As a result, tangible outcomes may take longer to manifest. Given the challenges of collecting defective data in this complex environment, it is imperative to undertake individualized efforts to advance the algorithm.

7.7. Abnormal signal problems, such as simple line failure

In practice, numerous irregular signals may be present alongside the established patterns. These signal

include something as basic as a line fault interruption and can be leveraged in detecting abnormalities due to their distinct data format. In instances with misleading performance data, it is crucial to classify it in a manner that recognizes it as one of the typical states rather than categorizing it as an anomaly.

7.8. Types of failure problems that do not tend to increase gradually

Our team oversees an algorithm designed to identify anomalies by monitoring gradual increases in their score compared to a standard value. However, we recognize that certain types of failures may not exhibit gradual increases, requiring a distinct model for prediction. While we can currently diagnose failures that have already occurred, we strive to advance our technology to enable predictive foresight and prevent these failures altogether.

8. Conclusion

As the demand for predictive maintenance in automated facilities grows alongside the expansion of smart factories, a new study introduces a necessary PHM (Prognostics and Health Management) system and abnormality detection framework method. The system includes a MEMS vibration sensor, Edge CMS device, and PHM platform, while the anomaly detection framework addresses various challenges such as cycling techniques, preprocessing, and AI algorithm development. This methodology effectively addresses data imbalances, learning model limitations, complex equipment patterns, and real-time processing issues commonly faced in manufacturing plants. It also improves upon the problems that arise when deploying such systems in the field, including central server concentration, cycling, classification of various equipment, and algorithm operation problems.

Cutting-edge anomaly detection technology employs an AI-based vibration detection algorithm to collect data at a high sampling rate. It uses edge computing to analyze this data and make real-time decisions. This approach minimizes latency compared to cloud-based analysis and eliminates server capacity issues. The system monitors standard performance data of equipment, learns from it, and provides practical solutions to mitigate issues, ultimately reducing equipment failure and minimizing downtime.

The study has yielded an impressive outcome with the development of abnormality detection technology and PHM systems that are anticipated to enhance the efficiency and sustainability of smart factories. The new smart factory has already achieved mass production, and the challenge of data imbalance in algorithm development has been overcome through data verification. By replacing the reducer of an aging robot in a domestic factory, the technology has proven to be effective. Additionally, the domestic production of these systems can significantly reduce technology investment costs compared to foreign products while allowing for the internalization of HMG's technology. The technology's potential is not limited to smart factories and can be deployed in new facilities such as wireless logistics carriers.

Moving forward, we aim to demonstrate and enhance the efficiency of predictive maintenance in domestic and international automobile factory production line facilities. This vital technology is the backbone of smart and software-defined factories and is poised to assist numerous companies in their pursuit of intelligent automation. Our strategy involves ongoing data monitoring and algorithmic refinement, paving the way for an optimal production line experience.

ABSTRACT

The maintenance paradigm based on PHM (Prognostics and Health Management) technology, utilizing big data to predict process conditions through manufacturing intelligence, is rising. However, in most industries, there is lack of accurate labeling of sensor data, posing challenges in data utilization due to the significant cost of labeling tasks. Consequently, recent research has focused on semi-supervised learning methodologies, which are applicable in label-absent scenarios. Especially, there is a growing emphasis on semi-supervised autoencoder, which learns both labeled and unlabeled data simultaneously. Also, there is a demand for the development of fault diagnosis models for essential components, such as bearings in most mechanical systems. Vibrational data is actively being integrated with artificial intelligence for application in bearing fault diagnosis frameworks. Nonetheless, diagnosing the condition of bearings inside machine systems, especially within the machine tool spindle, remains challenging, as the labeling of collected data causes significant costs. Therefore, this paper aims to develop a fault diagnosis model for unlabeled bearings in machine tool spindle using a semi-supervised autoencoder. Initially, a monitoring system of bearing simulator that imitates a machine tool spindle bearing was constructed, and vibration signals from both normal and fault bearings were collected based on this system. Subsequently, a semi-supervised autoencoder model was developed to construct a fault diagnosis model using labeled simulator data and unlabeled machine tool spindle bearing data. To evaluate the model, additional data of normal and fault bearings in machine tool spindle were collected, and the performance of the model was compared with a conventional fault diagnosis model based on 1D-CNN.

1. INTRODUCTION

In manufacturing, machine system faults not only degrade the quality of the products but also lead to downtime, resulting in significant costs. Therefore, Prognostics and Health Management (PHM) techniques utilizing sensor data and artificial intelligence are widely used to monitor equipment and diagnose failures. In particular, deep learning methods, such as Convolutional Neural Networks (CNNs) and Recurrent Neural Networks (RNNs), are used to enhance the reliability of failure diagnosis (Wen, Li, Gao & Zhang, 2017; Ince, Kiranyaz, Eren, Askar & Gabbouj, 2016; Cabrera, Guamán, Zhang, Cerrada, Sanchez, Cevallos, Long & Li, 2020; Abed, Sharma, Sutton & Motwani, 2015). However, acquiring a large amount of high-quality data for deep learning training is challenging in industries. While data are collected in various processes, almost data lack labels due to the high cost of labeling. Therefore, although data are abundant, distinguishing between normal and faulty states is difficult, posing challenges for developing failure diagnosis models. Particularly bearings, the core components of machine tools such as spindles, disturb the stable operation of the spindle when they break down because real-time confirmation and labeling of bearing failure are difficult.

Therefore, this paper proposes the utilization of data from a similar domain system and a semi-supervised autoencoder model to diagnose faults in unlabeled bearings of machining spindle bearings. First, a testbed capable of simulating the rotational motion of machining spindle bearings is constructed to create an environment for collecting enough labeled bearing data. Then a semi-supervised autoencoder

structure, which can learn unlabeled real-world data and labeled testbed data, is used for fault diagnosis model. By learning unlabeled data, domain difference between the actual equipment and the testbed is reduced, allowing for the extraction of generalized features and thus the development of a fault diagnosis model applicable to actual equipment. To verify its effectiveness, the performance of the proposed model is compared with that of a conventional model trained only on testbed data.

This paper introduces the proposed model and its applications in Chapter 2. Chapter 3 describes the data collection process for machining spindle bearings and the testbed. Modeling is performed in Chapter 4, and a comparison of the performance between the conventional model and the proposed model is also conducted.

2. METHODS

2.1. Autoencoder

Autoencoder is one of the unsupervised learning algorithms, that has an Encoder neural network that reduces the dimension of input data, and a Decoder neural network that reconstructs the input data from the reduced dimensions. Both networks are connected through the latent space, to reconstruct the original data from the latent space where features of the data are preserved. Typically, the Mean Squared Error (MSE) is used as the loss function to minimize the difference between the input data and the reconstructed data. Hinton and Salakhutdinov (2006) confirmed Autoencoder is available for data dimensionality reduction, and Kingma and Welling (2013) proposed the Variational Autoencoder structure, which combined with probabilistic models, for data generation applications. Additionally, Sakurada and Yairi (2014) confirmed its usability in anomaly detection.

2.2. Semi-supervised Autoencoder

Semi-supervised learning is a method of training model where one part of the input data is labeled (Reddy, Viswanath & Reddy, 2018). This approach is typically used in situations where labeled and unlabeled data are mixed. Semi-supervised learning uses labeled data to train the model and unlabeled data to improve the model's generalization performance. This offers the advantage that utilizing data efficiently and building models with a shortage of labeled data.

Semi-supervised Autoencoder is the conventional Autoencoder structure with a separate Fully-Connected layer(FC layer) to enable learning from labeled data. For the task of classification, a Classifier can be added to the Encoder and Decoder structure as shown in Figure 1. In this structure, labeled data is used to train the Classifier to perform well in classification from the reduced dimensions by the Encoder. Also, with the unlabeled data the Autoencoder is trained to extract generalized features. Additionally, the loss function is defined as a joint loss combined with the cross-entropy for classification and the Mean Squared Error(MSE) for reconstruction, as shown in Eq. (1). Each weight is one of the hyperparameters that need to be optimized during the training process. As a result, by using both labeled and unlabeled data in training, an Encoder that extracts generalized features and a Classifier that has high classification performance can be obtained.

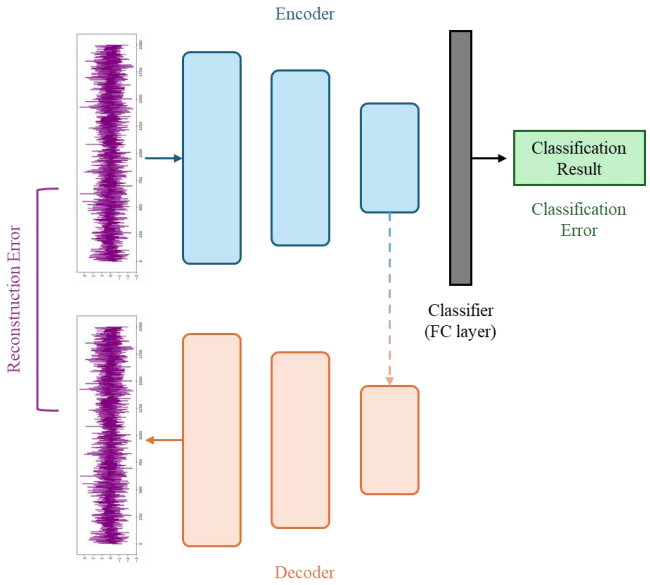

Figure 1. Semi-supervised Autoencoder structure

$$L_J = w_R L_R + w_C L_C \quad (1)$$

2.3. Proposed Method

In this paper, labeled bearing simulator(source) data, which is similar to an unlabeled machining spindle bearing(target) data, is used for fault diagnosis using the Semi-supervised Autoencoder, as shown in Figure 2. Initially, both labeled source data and unlabeled target data are used to train a feature extractor(Encoder) and reconstructor(Decoder). This allows the feature extractor to extract generalized features that reduce domain difference between target and source. Furthermore, the labeled source data is additionally used to train the feature extractor and classifier, making the classifier determine a decision boundary that can classify normal and fault conditions from generalized features. Through this structure and method, it can diagnose normal and fault conditions of the unlabeled target data.

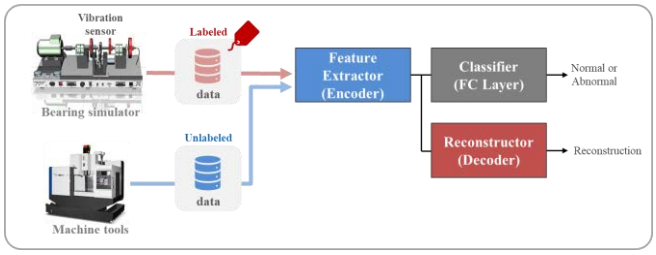

Figure 2. Diagram of proposed method

3. Experiment and Data Acquisition

3.1. Machining spindle bearing

The machining spindle bearing, which is the target domain for fault diagnosis, has a 6204 ball bearing inside the spindle, as illustrated in Figure 3. An accelerometer is attached to the spindle for data acquisition. While the spindle was rotating at 2,000 RPM, 200 data were collected every 0.1 seconds with 20,000Hz sampling frequency without overlapping, so each data had 2,000 points. However, this data was collected without labels, lacking information about normal or fault conditions. Therefore, to develop a fault diagnosis model, it is necessary to use a source domain that is similar to the machining spindle bearing, but with information on the condition.

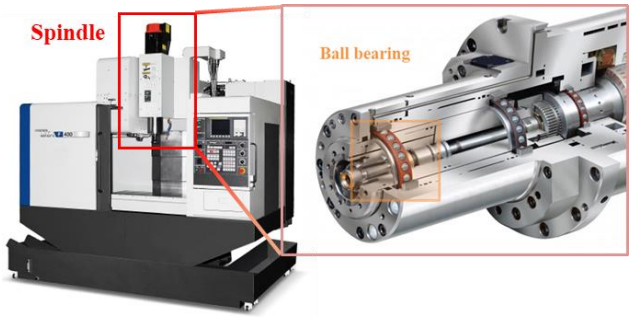

Figure 3. Image of machining spindle bearing

3.2. Bearing Simulator

The bearing simulator is a source domain to imitate the operation of a machining spindle bearing, as shown in Figure 4. It connects the motor on the left and the bearing on the right by the shaft to allow rotation. The attached bearing is the 6204 ball bearing used in the machining spindle, and an accelerometer is installed in the Y direction to collect data during rotation. The way of data acquisition was identical to those for the machining spindle bearing, and 400 data are each collected using both normal and fault bearings.

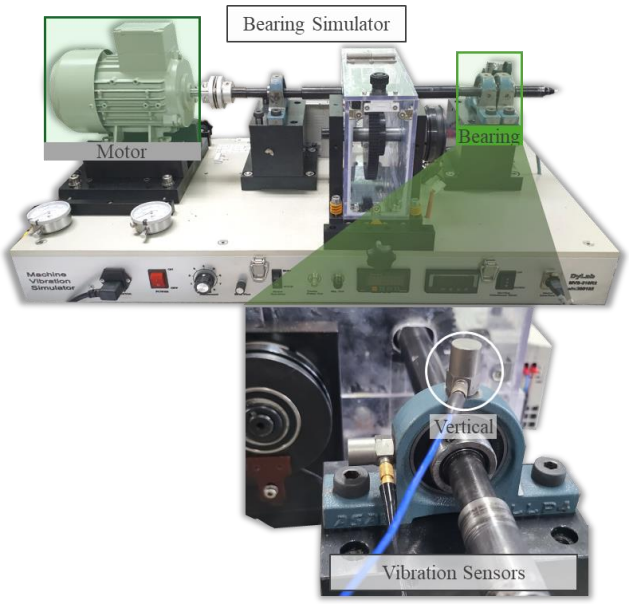

Figure 4. Image of bearing simulator

4. Modeling

4.1. Model Architecture

The architecture of the proposed model is explained in Table 1. The Feature Extractor and Reconstructor were composed of 1D convolutional layers and transposed 1D convolutional layers, and the hidden layer of the classifier was set as one, as shown in Figure 5. A 1D convolutional layer is a network that replaces vertical and horizontal convolution with unidirectional convolution to apply convolution operation in vector data. Through this layer, time-series data can be used in training without converting into a matrix.

Table 1. Description of proposed model architecture

Network	Layer type
Feature Extractor (Encoder)	Conv. layer 1
	Conv. layer 2
	Max Pooling layer
	Conv. layer 3
	Conv. layer 4
Reconstructor (Decoder)	Transposed Conv. layer 1
	Transposed Conv. layer 2
	Up sampling
	Transposed Conv. layer 3
	Transposed Conv. layer 4
Classifier (FC)	Hidden layer
	Output layer

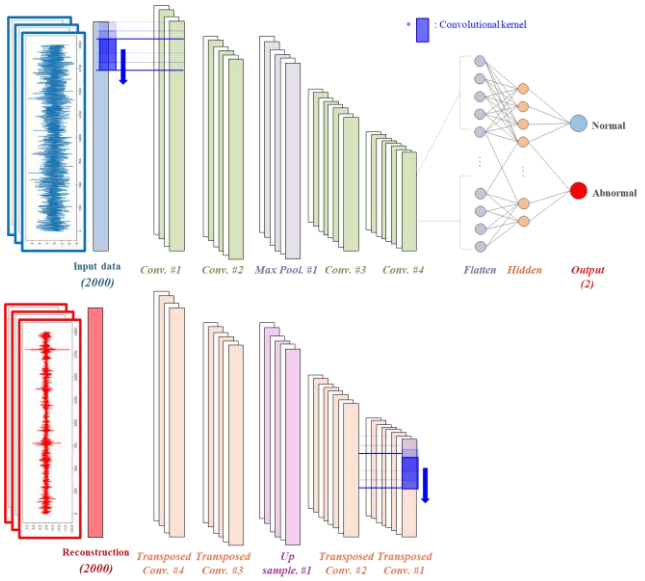

Figure 5. Proposed model architecture

4.2. Model Training

While training the model, the hyperparameters were set as follows. The number of filters in all convolutional layers was 16, the neuron of the hidden layer was set to 16, kernel size was set to 7, and stride was set to 5. ReLU was used for the activation function for all layers, except the output layer, which was set to softmax. The optimizer was Adam, with a learning rate of 0.0001, the weights for classification error (w_C) and reconstruction error (w_R) in the joint loss were set to 0.5 arbitrarily. A total of 700 iterations were done for training with a mix of 200 unlabeled target domain data and 800 labeled source domain data.

To evaluate the performance of the proposed model, a conventional fault diagnosis model was additionally trained. It had only a feature extractor and classifier as shown in Figure 6, with the same model structure and hyperparameters as the proposed model. Since this model can only be trained with labeled data, it is trained with only 800 labeled source domain data.

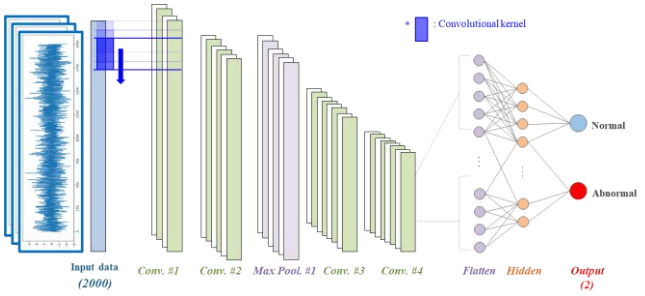

Figure 6. Conventional model architecture

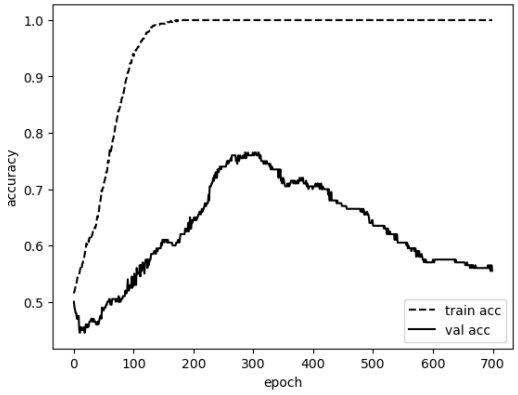
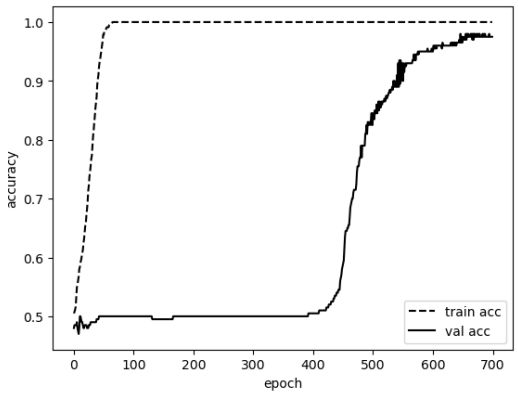
4.3. Result

Model performance comparison was done using additional validation data, collected by machining spindle bearing. Normal and fault data were collected by operating the machining spindle at 2,000 RPM, with normal bearings and bearings damaged by impacts. Under the same setting as the training data acquisition, 100 data for each normal and fault condition were collected. Using these data, the accuracy of the proposed model and conventional model were evaluated to compare the performance of the models. The final accuracy was 76.5% for the conventional model and 97.5% for the proposed model which the proposed model has higher performance. Figure 7 shows the accuracy of both train and validation data at each epoch for both models. Both models reached 100% accuracy on the train data. However, the validation accuracy of the conventional model initially shows an increase, but the accuracy decreases in the end part because of the overfitting problem caused by domain differences. In contrast, the proposed model's validation accuracy did not increase significantly at the beginning but reached high accuracy at the end. This happens due to the delay in optimizing the autoencoder's error compared to the classifier, which can be improved by changing the weight ratio.



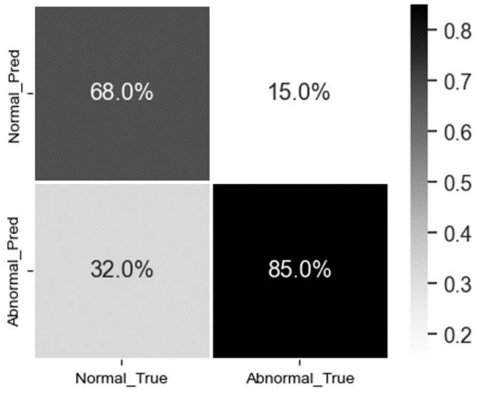
(a) Conventional model



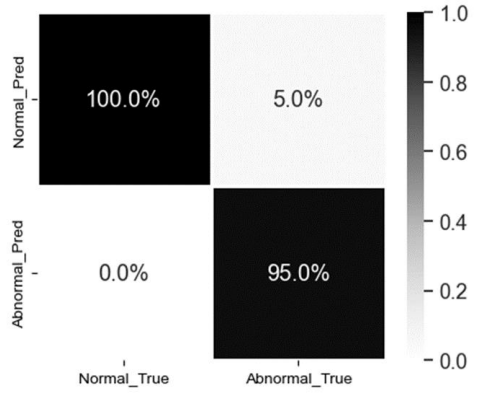
(b) Proposed model

Figure 7. Training and validation accuracy at each epoch

Figure 8 is a confusion matrix that compares the accuracy of the proposed and conventional models with validation data. Only 5% of the fault data are misdiagnosed by the proposed model, whereas 15% of fault data are misdiagnosed by the conventional model. Also, the conventional model misdiagnoses 32% of normal data, resulting in low performance.



(a) Conventional model



(b) Proposed model

Figure 8. Confusion matrix of final accuracy

Figure 9 visualizes features extracted by the feature extractor from the source domain data used for training and the target domain data used for validation, using t-distributed Stochastic Neighbor Embedding (t-SNE). Unlike the conventional model, which makes it hard to define a decision boundary due to the domain differences, the proposed model can make a clear decision boundary, showing reduced domain differences.

5. CONCLUSION

This paper proposes a fault diagnosis methodology with multi-domain data using a semi-supervised autoencoder to solve the problem of developing fault diagnosis models with the lack of label data in the real-world industry. A testbed, similar to the domain of actual equipment, was constructed to train the proposed model with sufficient labeled data and unlabeled equipment data. From this approach, a feature extractor that extracts generalized features by reducing the influence of domain information, and a classifier that can diagnose conditions based on generalized features were developed. The model was validated with additional machining spindle bearing data, resulting in the development of a high-performance fault diagnosis model. This approach enables the practical utilization of unlabeled data collected

from industrial machines. Furthermore, it has been demonstrated that a high-performance fault diagnosis model can be developed with unlabeled data. This can be applied to many manufacturing, contributing to the reduction of labeling costs across various industries.

However, this study conducted a fault diagnosis model from the perspective of deep learning without considering physical method. In case of bearings, the amplitude of certain fault frequency increase depending on fault characteristics of bearings. The reason for not applying this method is that the value at the fault frequency does not appear clearly, because of the various signals of the machine tool. Therefore, just monitoring the value in the fault frequency is not appropriate for bearing fault diagnosis of the machine tool. However, by considering both data-driven model and physical method, a hybrid model with higher performance can be developed.

And this study did not include the uncertainty caused by various operating conditions of bearings, as it focused on a diagnostic model under fixed operating conditions. Also, the comparison with other models, that can use the unlabeled data, was insufficient. Therefore, the development of a fault diagnosis model that can robustly operate under changing bearing operating conditions and validation of the effectiveness of the proposed methodology through comparison with other semi-supervised learning, synthetic data generation techniques, and domain adaptation technologies are planned for future works.

BIOGRAPHIES

Yongjae Jeon is now Ph.D. candidate in the Sustainable Design and Manufacturing Laboratory, Department of Mechanical Engineering, Sungkyunkwan University. He obtained his bachelor's degree (System Management Engineering) from Sungkyunkwan University in 2020. His research interest is AI-based prognostics and health management for smart manufacturing.

Kyumin Kim is now master candidate in the Sustainable Design and Manufacturing Laboratory, Department of Mechanical Engineering, Sungkyunkwan University. He obtained his bachelor's degree (Mechanical Engineering) from Sungkyunkwan University in 2023. His research interest is AI-based prognostics and health management for smart manufacturing.

Yelim Lee is now master candidate in the Sustainable Design and Manufacturing Laboratory, Department of Mechanical Engineering, Sungkyunkwan University. She obtained her bachelor's degree (Mechanical Engineering) from Sungkyunkwan University in 2023. Her research interest is AI-based prognostics and health management for smart manufacturing.

Byeong Kwon Kang has a master's degree in the Sustainable Design and Manufacturing Laboratory, Department of Mechanical Engineering, Sungkyunkwan University. He obtained his bachelor's degree (Mechanical Engineering) from Sungkyunkwan University in 2022 and completed his master's degree in 2024. His research interest is AI-based prognostics and health management for smart manufacturing.

Sang Won Lee is now professor in the school of Mechanical Engineering, Sungkyunkwan University. He obtained his bachelor's degree in 1995 and master's degree in 1997 (Mechanical Design and Production Engineering) from Seoul National University. He obtained his Ph.D. degree (Mechanical Engineering) from University of Michigan in 2004. His research interest includes prognostics and health management (PHM), cyber-physical system (CPS), additive manufacturing, and data-driven design.

DiffPhysiNet: A Bearing Diagnostic Framework Based on Physics-Driven Diffusion Network for Unseen Working Conditions

ABSTRACT

Fault diagnosis is essential to ensure bearing safety in industrial applications. Many existing diagnostic methods require large scales of data from a full range of working conditions. However, the structure and working conditions differences between machines lead to significant variation in data distribution, making it difficult to diagnostic with unseen samples. To handle this situation, an unknown condition diagnosis Framework (UCDF) based on physics-driven diffusion network (DiffPhysiNet) is proposed, effectively integrating the generation capability of the diffusion model and learning from the working conditional encoding (WCE). Specifically, signals under limited working conditions are gradually convert to noise through a forward noising process. Then, DiffPhysiNet reconstructs signals from the noise by a reverse denoising process. In addition, a physics-driven UNet (Physi-UNet) structure is designed to extract WCE for noise level prediction during the reverse process. Moreover, an Unsupervised Clustering Filter (UCFilter) is constructed to select signals with high quality after generation. Signals under unknown working condition can be generated with certain WCE. Ultimately, extensive experiments on two bearing datasets (SDUST and PU) validate the effectiveness of our method compared with the state-of-the-art baselines and the ablution test confirms the significant role of Physi-UNet and UCFilter.

1. INTRODUCTION

Rotating machinery is crucial in modern industry, highlighting the need for effective condition monitoring and fault diagnosis technology to ensure its security and reliability (Kordestani et al. 2021). Deep learning-based approaches have gained significant attention in machine condition monitoring as a data-driven fault diagnosis method(Zio 2022).

For deep learning to effectively diagnose faults in rotating machinery, it requires consistency in the data distribution between training and testing sets. However, practical industrial applications often present challenges that hinder the applicability of deep learning methods, which can be concluded as follows: **(1)** Rotating components often operate under varied conditions, such as changes in rotational speed and load (Chen and Li 2017). **(2)** Obtaining sufficient labeled data with precise health information across all operating conditions can be impractical. **(3)** Domain shift issues arise when attempting to compensate for information gaps by utilizing labeled data from multiple machines or different working conditions. Also, due to discrepancies in data (Ben-David et al. 2010).

In recent years, various advanced techniques have been developed to tackle the aforementioned challenges. One of these techniques is domain adaptation (DA), which aims to reduce the distribution discrepancy between the source and target domains during model training (Wang et al. 2020). DA allows the transfer of knowledge acquired from large source datasets to construct diagnostic models for smaller target datasets with similar characteristics. Wang et al. proposed the use of intra-class maximum mean discrepancy (MMD) in conjunction with multi-scale ResNet architectures to reduce the conditional distribution discrepancy of vibration signals (Wang et al. 2020). Hu et al. introduced tensor-aligned invariant subspace learning, which enables the discovery of a shared tensor representation for cross-domain diagnosis cases (Hu, Wang, and Gu 2020). Inspired by adversarial learning principles, Li et al. developed a method to map knowledge from target to source working conditions using generative adversarial networks (Li et al. 2021). Domain adaptation techniques can improve the robustness and generalization capabilities of fault diagnosis models. However, these methods are limited by the closed-set assumption, meaning that the source and

target domains have feature distributions that cannot be crossed (Si et al. 2021).

Under this premise, it is necessary to develop a technique that takes the out-of-distributed (OOD) fault classification into account (Michau and Fink 2019). Generative Adversarial Networks (GANs) nowadays adopts an unsupervised learning method and automatically learns from the source data. In the applications of PHM, conditional GANs have been used to control the generation process to generate desired distinct classes. Wang et al. introduced an enhanced version of Least-Square Generative Adversarial Networks (LSGANs) which notably retain more signal details compared to traditional methods and exhibit significant robustness (Wang et al. 2019). However, these methods are only suitable for generating data from previously observed conditions and not for generating previously unseen conditions in a specific domain (Rombach, Michau, and Fink 2023). The latter is the focus of our research. For the issue of the diagnostic works under unseen working conditions, propose a new framework for Open-Partial DA based on generating distinct fault signatures with a Wasserstein GAN, which enables a better transferability between two different domains (Li et al. 2022). However, the main drawback of GANs is that they are unstable during the training process and it is hard to embed diagnostic knowledge during the process of generation(Cui et al. 2023). Nowadays, same as a generative model, diffusion model does not suffer from GANs-like problems of training non-convergence and pattern collapse.

To achieve the stable and effective diagnostic framework for unseen working conditions based on feature embedding, we first propose a Physics-Driven Diffusion Network (DiffPhysiNet) for unknown condition diagnosis, which can generate a complete bearing sample of industrial environments and maintain the real-world working conditions through physics-informed methods. DiffPhysiNet effectively integrates the generation capability of the diffusion model and embeds working conditional encoding (WCE). Essentially, the forged signals generated by DiffPhysiNet guarantee the generation accuracy while retaining the utility. To summarize, the primary contributions of this work are concluded as follows:

- A denoising diffusion-based generative model DiffPhysiNet is proposed, which can generate high-quality signal data.
- A novel neural network structure called Physi-UNet, which integrates the residual block and attention mechanism to model signal features of bearings.
- UCFilter is constructed based on K-means clustering method to select the valuable signals after generation.

The remainder of the paper is structured as follows: In Section 2, we provide background information relevant to our research and in Section 3, we formally introduce the proposed diagnostic framework and its components in detail. Section 4 outlines the dataset utilized and presents the experimental results and in Section 6, we summary our work and proposes some research directions for the future.

2. PRELIMINARY

In this section, we first briefly introduce the basic knowledge of Denoising Diffusion Probabilistic Models (DDPM) (Shu, Li, and Farimani 2023) and Fourier Neural Operator (FNO)(Rafiq, Rafiq, and Choi 2022), which are the fundamentals of the proposed DiffPhyisNet.

2.1. Diffusion model

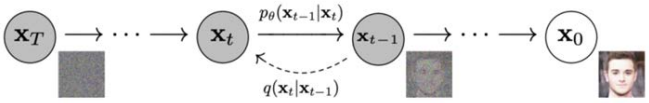

Figure 1. Two processes in Denoising Diffusion Probabilistic Models

As shown in Figure **1**, the diffusion model that typically contains two processes: forward process and reverse process. In this setting, a sample from the data distribution $x_0 \sim q(x)$ is gradually noised into a standard Gaussian noise $x_T \sim \mathcal{N}(0, I)$ by the forward process, where the transition is parameterized by $q(x_t \mid x_{t-1}) = \mathcal{N}\left(x_t; \sqrt{1-\beta_t}x_{t-1}, \beta_t \mathbf{I}\right)$ with $\beta_t \in (0,1)$ as the amount of noise added at diffusion step t.

A neural network learns the reverse process of gradually denoising the sample via reverse transition $p_\theta(x_{t-1}|x_t) = \mathcal{N}(x_{t-1};\, \mu_\theta(x_t,t), \sum \theta(x_t,t))$ .Learning to clean x_T through the reversed diffusion process can be reduced to learning to build a surrogate approximator to parameterize $\mu_\theta(x_t,t)$ for all t. The denoising model $\mu_\theta(x_t,t)$ can be trained by using a weighted mean squared error loss which we will refer to as:

$$\mathcal{L}(x_0) = \sum_{t=1}^{T} \mathbb{E}_{q(x_t|x_0)} \|\mu(x_t,x_0) - \mu_\theta(x_t,t)\|^2 \qquad (1)$$

where $\mu(x_t,x_0)$ is the mean of the posterior $q(x_t \mid x_{t-1})$. This objective can be justified as optimizing a weighted variational lower bound on the data log likelihood. Also note that the original parameterization of $\mu_\theta(x_t,t)$ can be modified in favor of $\hat{x}_0(x_t,t,\theta)$or$\epsilon_\theta(x_t,t)$.

2.2. Fourier neural operator

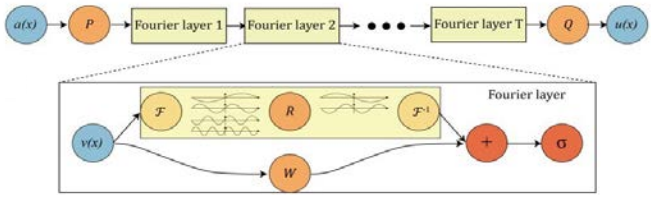

Figure 2. The full architecture of neural operator

The main idea of FNO is to use Fourier transform to map high-dimensional data into the frequency domain and approximate nonlinear operators by learning the relationships between Fourier coefficients through neural networks. The FNO architecture is shown in **Figure 2**, which consists of three main steps:

a) The input $a(x)$ is lifted to a higher dimensional representation $v_0(x) = P\big(a(x)\big)$ by the local transformation P, which is commonly parameterized by a shallow fully connected neural network.

b) The higher dimensional representation $v_0(x)$ is updated iteratively by:

$$v_{t+1}(x) = \sigma\big(W v_t(x) + (\mathcal{K}(a;\phi)v_t)(x)\big) \qquad (2)$$

where $(\mathcal{K}(a;\phi)v_t)(x)$ is a linear transform on the frequency domain of the amplitude and the phase of $v_t(x)$, W: is a linear transform on the high-dimension of the time domain. σ: is the non-linear activation function.

c) The output $u(x)$ is obtained by $u(x) = Q\big(v_T(x)\big)$, where Q : is the projection of v_T , and it is parameterized by a fully connected layer.

$\mathcal{F}$ and $\mathcal{F}^{-1}$are denoted as Fourier transform and its inverse transform of a function, allowing the operations on the frequency domain of the high-dimension. The Fourier neural operator (FNO)(Lehmann et al. 2024) aims to map between two infinite-dimensional spaces by training on a finite set of input–output pairs. It has been demonstrated that the FNO can serve as a universal approximator capable of accurately representing any continuous operator.

3. PROPOSED METHOD

In this section, we elaborate on the proposed DiffPhysiNet framework as shown in Figure 3. We start by presenting the diagnostic principles and steps of the proposed method under unseen working conditions. Then, we introduce the details of the denoising model, i.e., Physi-UNet. Furthermore, UCFiler utilize K-means to cluster some generated sample to prove the generation quality is also introduced.

3.1. Diagnostic principles of DiffPhysiNet

As illustrated in **Figure 3**, aiming at the diagnostic under unseen working conditions, 4 parts (a-d) are involved in the framework.

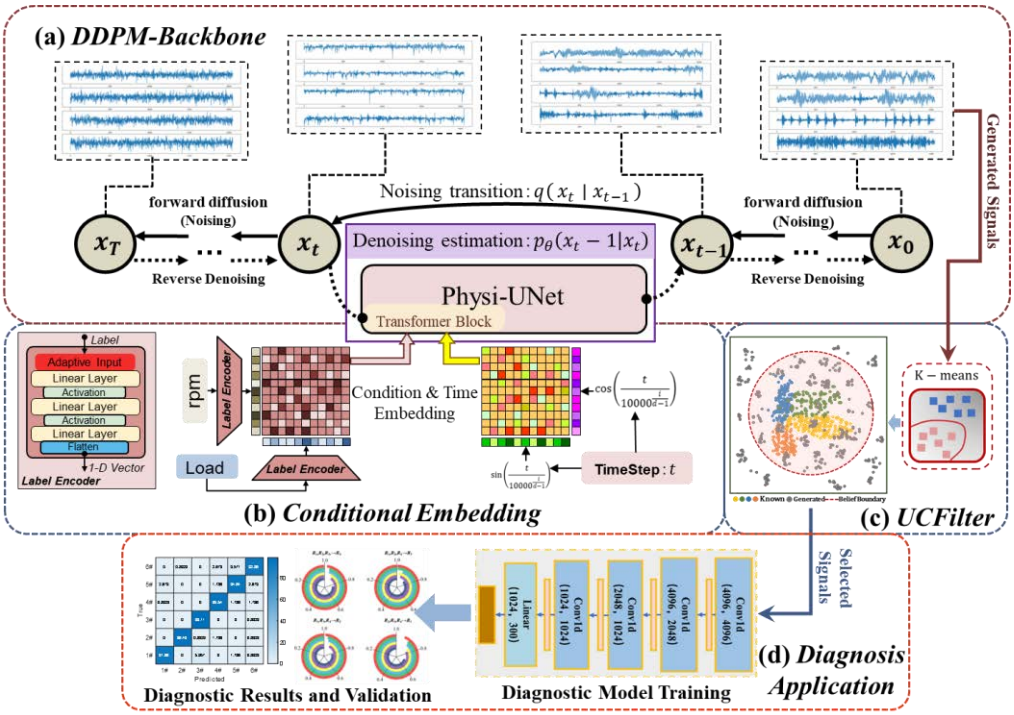

Figure 3. The diagram of proposed DiffPhysiNet framework

(a) The first part is based on the diffusion model which is introduced in **2.1**, utilizing this generative model rather than other generative methods mainly attribute to the style embedding convenience which ensures that generated fault signatures contain physics-driven features. (b) The second part aims to construct a latent space with conditional

encoding methods, making sure of that the projection space of working conditions are continuous. (c) The third part utilizes an unsupervised clustering method to select qualified generated signals guaranteeing the effectiveness of the training datasets. (d) The last part is the application stage of this proposed method, utilizing the selection of generated signals for the diagnostic model training. Then the validated diagnostic model can be applied for online fault diagnosis.

3.2. Structure of Physi-UNet

As aforementioned, the diffusion model (DDPM), A neural network learns the reverse process of gradually denoising the sample via reverse transition $p_\theta(x_{t-1}|x_t) = \mathcal{N}(x_{t-1};\ \mu_\theta(x_t,t), \sum\theta(x_t,t))$ .Learning to clean x_T through the reversed diffusion process can be reduced to learning to build a surrogate approximator to parameterize $\mu_\theta(x_t,t)$ for all t. In our proposed framework, Physi-UNet is utilized for the process of denoising estimation, of which the structure is shown in **Figure 4**. As illustrated in the figure, an implicit U-Net is introduced to enhance Fourier neural operator. The denoised signal after $(T-t)$ steps is utilized as the input, which is then converted into a high-dimensional representation via the lifting layer P, and finally the output is obtained through the projection of Q, converting the vectors from a high-dimensional space to 1D vibration signal (Benitez et al. 2023) .

The structural design of the Physi-UNet is based on the hypothesis that the Fourier spectrum of fault data can be expressed as the sum of (1) domain-specific components (the spectrum of a signal from normal operation) and (2) of fault-specific components representing the specific fault characteristics. In other words, this hypothesis allows us to express Fourier coefficients (Dang and Ishii 2022) of the fault data of a certain class c from a specific domain $\mathbb{X}$ ($x^{c,FFT}_{fault,\mathbb{X}}$) as a sum of domain-specific characteristics that are represented by the domain features $x^{FFT}_{\mathbb{S}}$ and the fault class specific characteristics that are domain-independent $x^{c,FFT}_{fault}$ $fault$ and scaled by a factor w, which can be expressed by:

$$x^{c,FFT}_{fault,\mathbb{X}} = x^{FFT}_{\mathbb{X}} + w * x^{c,FFT}_{fault} \tag{3}$$

The physics-driven fault component and the domain specific features are demodulated based on the embedding of Times Step t and the continuous working conditional encoding (WCE), which is of great importance on the guidance of feature decomposition. As shown in **Eq. (4)**.

$$\begin{cases} Attention(Q,K,V) = softma\,\boldsymbol{x_t}\left(\dfrac{QK^\top}{\sqrt{d}}\right)\cdot V \\ x^{c,FFT}_{fault,\mathbb{X}} = \boldsymbol{x_t} + Attention(Q,K,V) \\ Q = W_Q\cdot x_t, K = W_K\cdot x_t, V = W_V\cdot x_t \end{cases} \tag{4}$$

where $\boldsymbol{x_t} \in \mathbb{R}^{c\times n}$ (c and n represent the dimensions and length of the signal) is the given input, W_Q, W_K, and W_V are learnable parameter matrices from the embedded Timestep t and the encoded working condition.

Hence, the fault components of the vibration signals are captured in using Fourier bases:

$$A^{(k)}_{i,t} = \left|\mathcal{F}(x^{c,FFT}_{fault,\mathbb{X}})_k\right|, \Phi^{(k)}_{i,t} = \phi\left(\mathcal{F}(x^{c,FFT}_{fault,\mathbb{X}})_k\right), \tag{5}$$

$$\kappa_{i,t}{}^{(1)},\cdots,\kappa^{(K)}_{i,t} = \underset{k\in\left\{1,\cdots,\left\lfloor\frac{\tau}{2}\right\rfloor+1\right\}}{arg\ TopK}\left\{A^{(k)}_{i,t}\right\}, \tag{6}$$

$$P_{i,t}(x) = \sum_{k=1}^{K} A^{\kappa^{(k)}_{i,t}}_{i,t}\ cos\left(2\pi f_{\kappa^{(k)}_{i,t}}\tau c + \Phi^{\kappa^{(k)}_{i,t}}_{i,t}\right), \tag{7}$$

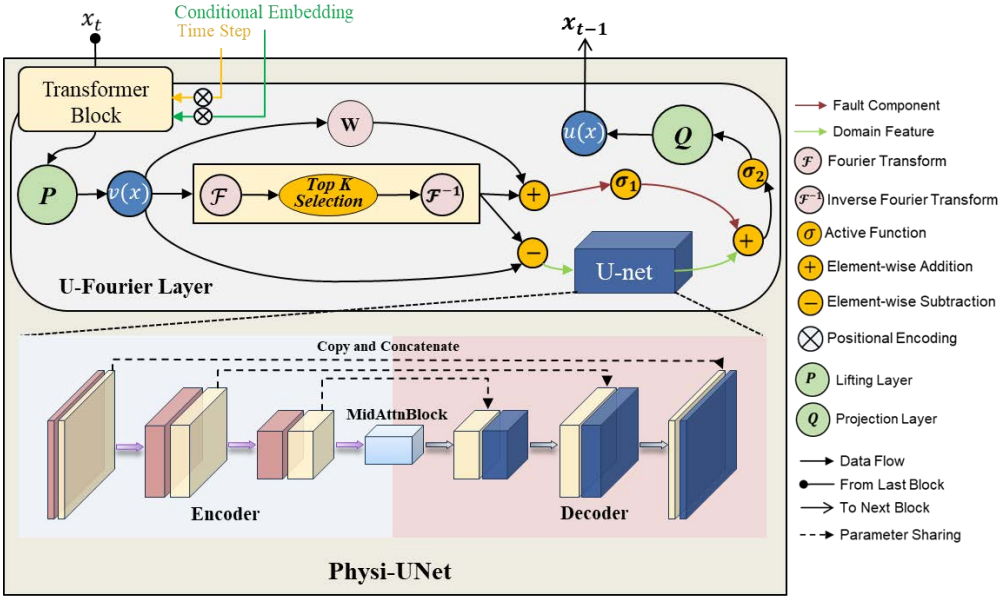

Figure 4. The structure of proposed Physi-UNet enhanced with FNO and U-Net component

where arg TopK is to get the top K amplitudes and K is a hyperparameter. $A_{i,t}^{(k)}$, $\Phi_{i,t}^{(k)}$ are the phase, amplitude of the k-th frequency after the discrete Fourier transform $\mathcal{F}$ respectively. f_k represents the Fourier frequency of the corresponding index k. In fact, the Fourier layer selects bases with the most significant amplitudes in the frequency domain, and then returns to the time domain through an inverse transform to model the physics-driven fault features.

The U-Net structure is utilized to synthesis the corresponding domain features according to the residue component after removing the fault frequencies.

$$D_{i,t}(x) = UNet(v_0(x) - P_{i,t}(x)) \tag{8}$$

where the $P_{i,t}$ is selected fault component and the $D_{i,t}$ is the obtained domain features.

$D_{i,t}$ and $P_{i,t}$ are then reweighted and activated in the following process, the summation and projection combine the physic-driven and domain feature components, which can be expressed as:

$$C_{i,t}(x) = \sigma_2\left[UNet(v_0(x) - P_{i,t}) + \sigma_1[W(P_{i,t})]\right] \tag{9}$$

$$x_{t-1} = Q\left(C_{i,t}(x)\right) \tag{10}$$

where $\sigma_1[\cdot]$ and $\sigma_2[\cdot]$ are the activation function, $W(\cdot)$is the reweight layer, $Q(\cdot)$ is the projection layer aforementioned, $x_{t-1}$is the out put of this diffusion step.

3.3. Unsupervised Clustering Filter

Once the DDPM in the DiffPhysiNet training is completed, the working conditions of signal generation is controlled by the WCE. As shown in Figure **5**. the generated signal clustered by K-means algorithm, which is an unsupervised clustering method. The top of n samples nearest to the signal sample center selected as valuable signals.

The distances between inter-class samples are measured by distribution probability based on Kullback-Leibler divergence between the joint probabilities R_{ij} in the high-dimensional space and the joint probabilities T_{ij} in the low-dimensional space. The values of R_{ij} are defined to be the symmetrized conditional probabilities, whereas the values of T_{ij} are obtained by means of the Student's t-distribution with one degree of freedom. The calculation is summarized as follows:

$$r_{ij} = \frac{r_{i|j} + r_{j|i}}{2n} \tag{11}$$

$$t_{ij} = \frac{\left(1 + |y_i - y_j|^2\right)^{-1}}{\sum_{k \neq l}(1 + |y_k - y_l|^2)^{-1}} \tag{12}$$

where $r_{i|j}$ is the distribution probability of sample point j when the sample point i is given. y is the generated samples. The values of r_{ii} and t_{ii} are set to zero. The calculation of the Kullback–Leibler divergence C_d between the two joint probability distributions R and T is given as follows:

$$C_d = KL(R\,||T) = \sum_i \sum_j r_{ij} \log r_{ij} - r_{ij} \log t_{ij} \tag{12}$$

After calculated the Kullback–Leibler divergence C_d of every sample in generated signals, the selection boundaries are decided according to the expectation numbers of acceptable samples n, and k value of the ***Boundary Decision*** indicates the portion of selected samples (k=n/N).

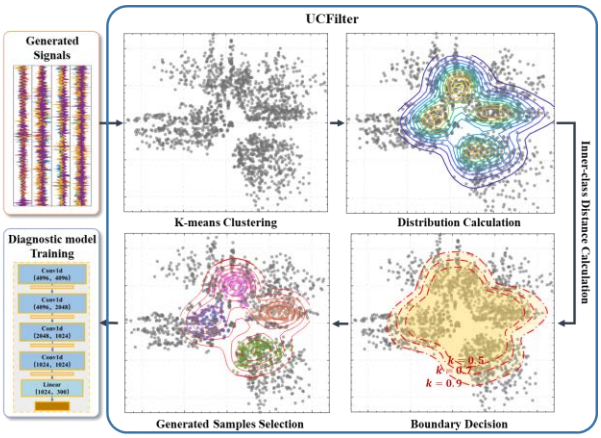

Figure 5. The steps of unsupervised clustering filter method

4. Experimental Validation

4.1. Experiments Setting

To assess the diagnostic model's performance in unfamiliar conditions, we conducted two experimental case studies using test rigs from SDUST (Jia et al. 2020) and the Paderborn University bearing dataset (PU dataset) for bearing fault diagnosis. The first case involves a constant domain shift with the rig operating at various constant speeds, while the second case examines a constant domain shift with the rig operating under multiple conditions of variable rotational speeds and loads. These experiments confirm the effectiveness of the DiffPhysiNet method, which utilizes diffusion models, for complex industrial applications.

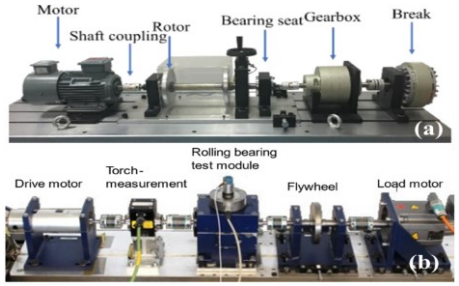

Figure 6. Experimental platform of SDUST dataset (a) and PU dataset (b).

4.1.1. Description of SDUST dataset and Case1

Figure **6** (a) shows the experimental platform of SDUST, which includes a motor, a shaft coupling, a rotor, a testing bearing, a gearbox, and a break.The bearing type utilized is N205EU, with data collected across four health conditions: normal (NOR), inner ring fault (I), rolling element fault (B), and outer ring fault (O). Four distinct working conditions were tested at speeds of 1000, 1500, 2000, and 2500r/min. The experiment sets four diagnostic cases for unseen working conditions across domains: T1000, T1500, T2000, and T2500 as shown in Table 1.

Table 1. **Case1:** Diagnostic cases of SDUST dataset.

Diagnostic cases	Seen Domain	Unseen Domain
T1	1500r/min,2000r/min,2500r/min	1000r/min
T2	1000r/min,2000r/min,2500r/min	1500r/min
T3	1000r/min,1500r/min,2500r/min	2000r/min
T4	1000r/min,1500r/min,2000r/min	2500r/min

4.1.2. Description of PU dataset and Case2

The test rig of PU dataset is shown in Figure **6** (b), which is mainly composed of a motor, a torque measurement shaft, a bearing test module, a flywheel, and a load motor. There are 7 health conditions, normal (N), inner-race fault (IF) with three damage levels (IF1, IF2, and IF3), outer-race fault (OF) with two damage levels (OF1 and OF2), and compound fault (CF) containing IF and OF.

Faulty bearings with real damage were acquired from an accelerated lifetime test. Vibration data was collected under four distinct working conditions, involving rotational frequency (Hz), load torque (Nm), and radial force (N), at a sampling frequency of 64 kHz. These conditions create four domains: P1, P2, P3, and P4, leading to four diagnosis cases, as outlined in Table 2. Each category in unseen working conditions comprises 2000 samples.

Table 2. **Case2:** Diagnostic cases of PU dataset.

Domain	Rotational frequency	Load	Diagnostic Cases	Seen Domain	Unseen Domain
p1	25Hz	1000N	**R1**	*p2, p3, p4*	*p1*
p2	15Hz	400N	**R2**	*p1, p3, p4*	*p2*
p3	15Hz	1000N	**R3**	*p1, p2, p4*	*p3*
p4	25Hz	400N	**R4**	*p1, p2, p3*	*p4*

4.1.3. Compared methods

Some typical or up-to-date technologies were utilized as a set of compared methods to validated the effectiveness of the DiffPhysiNet framework with the idea of Physi-UNet and UCFilter and all the methods used the same preprocessing and network back-bone for a fair comparison. As shown in Table 3, M1-M6 series are competitive related methods, M1 means the Domain Adaption (DA) method based on empirical risk minimization (ERM) principle using multi-domain data based on the general cross-entropy loss of DA method. M2-M4 follow the same setting in (Jiao et al. 2020; Huang et al. 2022; Han, Li, and Qian 2021) by adding a distance metric or distribution alignment as a loss term, such as MMD, JMMD, and CORAL. M5 (Li et al. 2020) is a start-of-the-art method DG that uses adversarial training with normalization strategies and a strategy of multi-case training and M6 (Chen et al. 2022) is a competitive method for cross-domain diagnosis under unseen domain through triplet loss and data augmentation with Gaussian noise.

Table 3. Related methods for comparation

Methods	Description
M1	DA
M2	DA with MMD
M3	DA with JMMD
M4	DA with CORAL
M5	ADIG (Li et al. 2020)
M6	IEDGNet (Chen et al. 2022)

4.2. Experimental results and analysis

4.2.1. Generated signal and analysis

To assess the effectiveness of the proposed diagnostic framework, we illustrate the generated signals in Figure **7**. Notably, there were no fault samples with a 1000N load and an rpm of 40Hz in the training set, yet similar fault samples were generated. Thus, DiffPhysiNet can generate fault signals for unseen combinations of rpm and load.

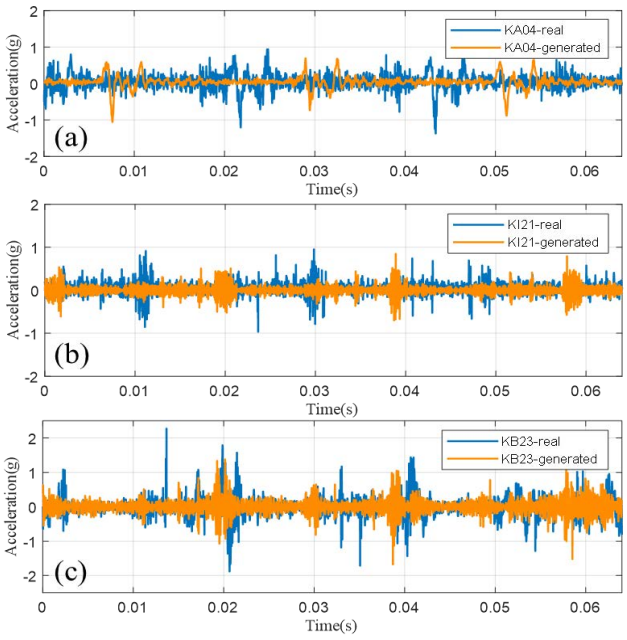

Figure 7. Generated signals comparison of time-domain on Set *R1* of *PU dataset* and real signals (a)Inner ring fault (b) Outer ring fault (c) Cage fault.

Comparing the time-domain of the generated signals with real signals reveals a high degree of similarity, confirming the ability of the proposed method to generate signals under unseen working conditions that closely resemble real signals. This verifies the effectiveness and practicality of the generative model. On the frequency-spectrum comparison between the generated signals and the real signals is shown in **Figure 8**. The frequency spectrum of the generated signal and the real signal has a high degree of coincidence, especially in the low-frequency band where contains most damage features according to the vibration theory of bearing fault.

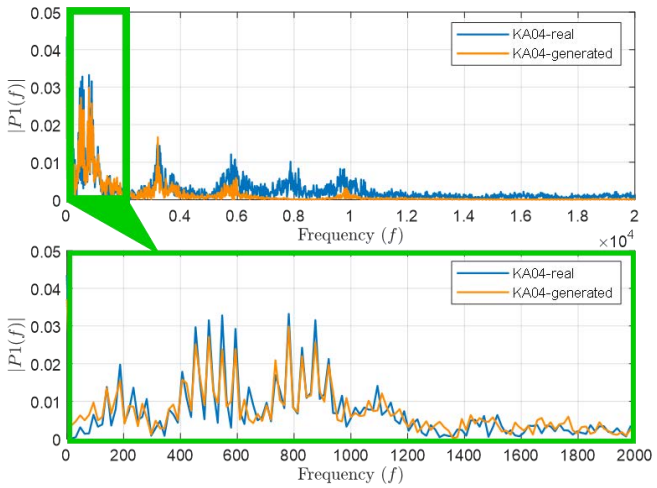

Figure 8. Generated signals comparison of frequency-domain on Set *R1* of *PU dataset* and real signals (a)Inner ring fault (b) Outer ring fault (c) Cage fault.

4.2.2. Experimental results and analysis

Table 4. presents the diagnostic results for the proposed method and comparison methods in Case 1 (SDUST dataset) and Case 2 (PU dataset). Several conclusions can be drawn. Firstly, the basic DA method achieves notably lower average test accuracies of 76.46% and 80.63% in the two cases respectively, indicating interference among data distributions during training, affecting model generalization. Secondly, DA methods using MMD, JMMD, and CORAL exhibit improvements over basic ERM, with average accuracy gains of 1.57%, 12.06%, and 10.05% respectively in Case 1, and 4.04%, 5.27%, and 3.49% in Case 2. These methods aim to eliminate distributional discrepancies between source domains and learn domain-invariant representations. Finally, the proposed method achieves the best diagnostic performance in almost all DA cases, with the highest average accuracy of 94.15% and 93.27% in both experimental cases. Furthermore, it demonstrates superior stability compared to com-parison methods in most cases. **Figure 9.** illustrates the classification accuracy of different diagnostic cases for Case 1 and Case 2, aiding in the comparison of diagnostic results.

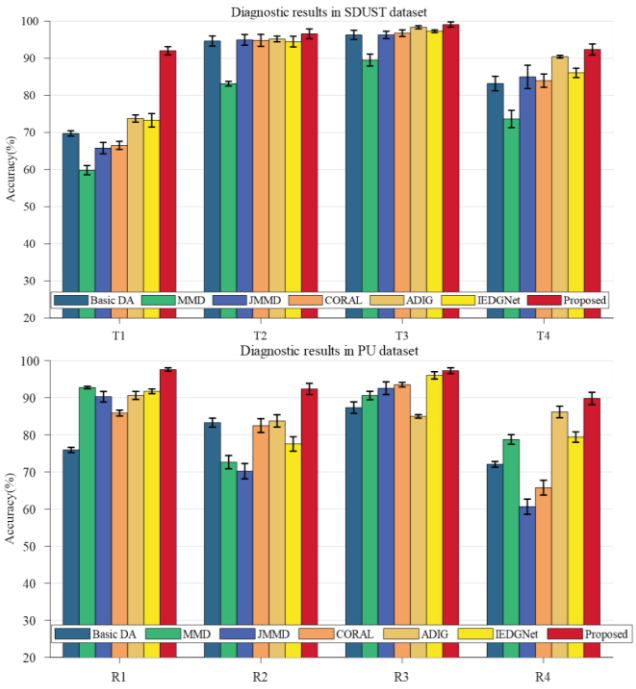

Figure 9. Classification accuracy of the different diagnostic cases of case 1 and case 2.

4.2.3. Feature visualization and analysis

Compared methods based on domain adaptation (DA) aim to learn domain-invariant features, while our diagnosis seeks to generate physic-embedded signals to cover unseen distributions. we employ feature visualization to validate these conclusions. To illustrate the distribution of fault features from seen and unseen domains corresponding to seen and unseen working conditions, we present 2-D features from the second layer of the fault classifier using T-SNE (van der Maaten and Hinton 2008). For clarity, we plot the feature vectors of the SDUST dataset (Case 1) from four health conditions under case T1and four colors represent four domains, with gray points indicating features extracted from unseen domains, while other colors denote features from available source do-mains.

The domain adaptation (DA) based method aims to extract generalized features that are consistent across different domains, including unseen domains. However, as illustrated in **Figure 10**, the features learned by methods M1-M3 fail to capture the generalized representation of the I02 fault due to significant domain discrepancies between seen and unseen working conditions. Although method M4 may learn more robust features compared to M1-M3, it struggles to cluster effectively in the seen domains of I02.

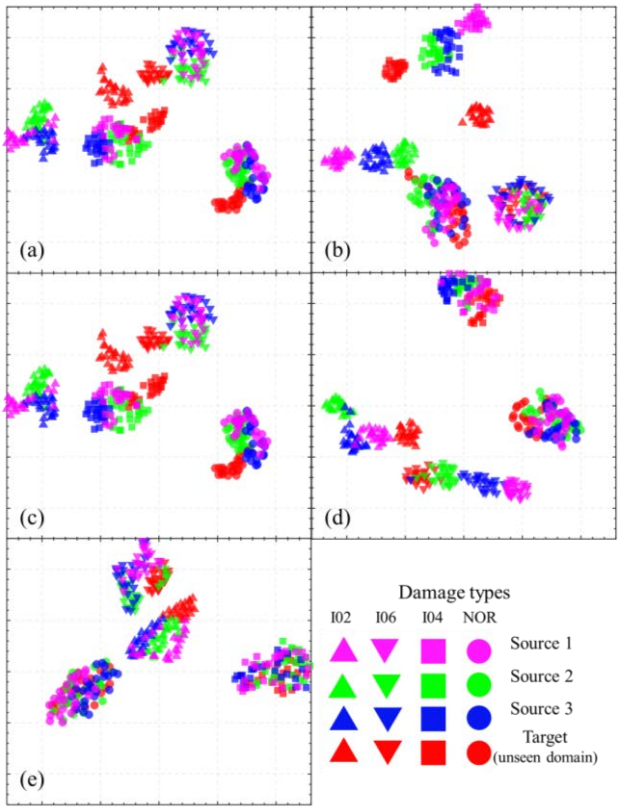

Figure 10. Results of feature-dimension reduction via T-SNE under unseen target working condition:M1, (b) M2, (c) M3, (d) M4, (e) Proposed.

In contrast, the proposed DiffPhysiNet method, leveraging the feature embedding capability of Physi-UNet, can generate signals with more domain-invariant features. This leads to improved classifier training and reaffirms that the Physi-UNet structure enables the model to fit not only the source data distribution but also data from unseen working conditions.

4.2.4. Parameter sensitivity analysis

Adjustable parameters are involved in the construction and training of the proposed method and considering their impact on the model performance, parameter sensitivity analyses are performed on all case.

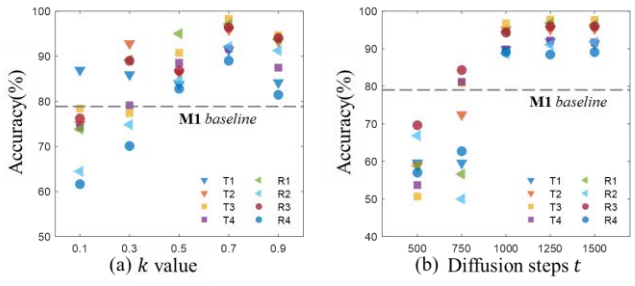

Figure 11. Parameter sensitivity analysis (a) k value: the portion of selected nearest generated samples. (b) Diffusion steps t: the iteration steps of generation progress.

k value represents the proportion of selected samples ($k = n / N$), where N is the total number of generated samples and n is the number of selected samples among them. These selected samples undergo the nearest distribution process in the K-means clustering algorithm, as depicted in **Figure 5**, where the Boundary Decision is determined by the k value. Figure **11**(a) illustrates the diagnostic accuracy for each case under different k values ranging from 0.1 to 0.9. The graph indicates that when k is below 0.5, meaning less than half of the total generated samples are selected, the performance is inferior to the baseline M1 method. This could be attributed to the reduced generation capability resulting from a smaller set of selected samples, causing offsets in the feature distribution from the real distribution. Conversely, if k is too large, the model's performance declines, likely due to the utilization of too many substandard generated signals for diagnostic model training. Hence, selecting a value of k around 0.7 is recommended.

t is the parameter of diffusion steps, the larger the value of diffusion steps the more detailed the signal generation process will be, as well as the larger the model training time and the computational resources it will consume. As shown in Figure **11** (b), it can be concluded that the performance of DiffPhysiNet framework becomes better and more stable as t is bigger than 1000 steps. Regarding the performance of M1 method as the baseline, the diffusion steps should not be less than 1000. As t increased from 1000 to 1500, the

performance of the model stabilizes and does not improve significantly.

5. CONCLUSION

In conclusion, we propose the DiffPhysiNet framework for diagnosing bearing faults under unseen working conditions for safety-critical equipment. Leveraging a generative diffusion model and working conditional encoding (WCE), this framework effectively embeds signal features, and the UCFilter method ensures signal quality using principles from K-means clustering. Experimental validation on real-world bearing datasets demonstrates the superiority of Physi-UNet over existing approaches, particularly in diagnostic accuracy. Feature visualization confirms the framework's ability to capture generalized signal features under unknown conditions, highlighting the generative model's efficacy in signal generation.

BIOGRAPHIES

Zhibin Guo was born in Zhengzhou, Henan, China, in 2001. He is currently pursuing the D.E. degree in transportation engineering with Central South University, Changsha, China. His current research interests include rotating machine diagnosis, PHM for railway infrastructure, health management of highspeed train bogie, and deep learning.

Jingsong Xie was born in Anren, Hunan, China, in 1989. He received the B.S. degree from the School of Mechanical Engineering, Northwestern Polytechnical University, Xi'an, China, in 2013, and the Ph.D. degree in mechanical engineering from Xi'an Jiaotong University, Xi'an, in 2018. He joined the School of Traffic and Transportation Engineering, Central South University, Changsha, China, as a Lecturer. His research interests include fault diagnosis, machine learning, vibration analysis, and crack diagnosis.

Tongyang Pan was born in Shaanxi, China, in 1994. He received the B.S. and Ph.D. degrees in mechanical engineering from Xi'an Jiaotong University, Xi'an, China, in 2017 and 2022 respectively. He is currently a lecturer with Central South University, Changsha, China. His research interests include mechanical signal processing, intelligent fault diagnosis, and machinery condition monitoring

Tiantian Wang received the bachelor's and Ph.D. degrees from Beihang University, Beijing, China, in 2012 and 2018, respectively. He is currently a Professor with Central South University, Changsha, China, and Hunan University, Changsha. His current research interests include vehicle aerodynamics and vehicle structure, especially train/tunnel aerodynamics, and prognostics and health management (PHM) for trains.

Domain Adaptation for Fault Detection in Civil Nuclear Plants

ABSTRACT

Recent domain adaptation approaches have been shown to generalise well between distant data domains achieving high performance in machine fault detection through time series classification. An interesting aspect of this transfer-learning inspired approach, is that the algorithm need not be exposed to fault data from the target domain during training. This promotes the application of these methods to environments in which fault data is unfeasible to obtain, such as the detection of loss-of-coolant accidents (LOCA) in nuclear power plants (NPPs).

A LOCA is a failure mode of a nuclear reactor in which coolant is lost due to a physical break in the primary coolant circuit. If undetected, or not managed effectively, a LOCA can result in reactor core damage.

Three high-fidelity physics based models were created with divergent behaviour that represent different data domains. The first model is used to generate source domain data by simulating labelled training data under both nominal and LOCA conditions. The second and third models act as surrogates of real plants and are used to generate target domain data, i.e. to simulate nominal data for training and LOCA condition data for validation.

Several deep-learning feature encoders (with varying levels of connectivity) were applied to this LOCA detection problem. Among these, a 'Baseline' encoder was used to quantify the improvement that domain adaptation techniques make to LOCA detection performance under large domain divergences.

Classification accuracy for each model is explored within the context of LOCA break size and location within each plant model.

The proposed method for LOCA detection demonstrates how the dependence upon sparse accident-specific data can be alleviated through the use of domain adaptation. Detection capability of the LOCA condition is maintained even when no data examples are available in the target domain.

1. INTRODUCTION

There is an opportunity in the nuclear industry to adopt data-driven methods to help maintain the safe operation of critical systems, both as a result of the improved availability of sensing instrumentation and the rapid evolution of network architectures for fault detection (Gomez-Fernandez et al., 2020). A plethora of approaches for identifying abnormal transient behaviour, such as a LOCA, exist with foundations in probabilistic methods (Aldemir, 2013), complex fluid-structure interaction models (Mahmoodi et al., 2011) and Markov modelling (Sakurahara et al., 2019). Although effective in finite environs, conventional methods suffer when attempting to compensate for the lack of available labelled fault data in the nuclear domain.

A LOCA occurs when a physical break in the reactor coolant system releases coolant faster than recovery systems can replenish it. This increases the temperature of the core, which can damage the plant and potentially release reactivity. Detection of this transient behaviour is paramount to the safe operation of pressurised water reactors (PWRs).

Time series classification through deep learning methods has seen increased attention (Ismail Fawaz et al., 2019) in previous years, with myriad techniques being derived to tackle a spectrum of fault detection problems (Wei & Keogh, 2006). The nuclear industry has received its share of attention in this regard, with neural network based methodologies tasked with

aiding the monitoring of numerous aspects of NPPs, including diagnosing the source of abnormalities in operation data (Lee et al., 2021) and tuning a digital twin to provide supplementary NPP data (Wang et al., 2021).

Existing examples of these methods simultaneously identify and characterise transients whilst making remaining useful life predictions (Rivas et al., 2024). Typically, though, these approaches rely upon the assumptions that similar quantities of nominal and faulty data exist, and that data gathered from differing NPP sources (physical plants and simulations alike) will share a similar data distribution.

One branch of deep-learning research aims at tackling this manner of problem through Transfer Learning. Current works in industrial contexts display impressive results regarding fault diagnosis with minimal labelled training data under diverse application domains (Y. Zhang et al., 2023), as well as combinations of global and local models providing more robust remaining useful life predictions (J. Zhang et al., 2023). Domain adaptation (a subset of Transfer learning where data sources share the same input space) can simultaneously make data gathered from multiple sources appear more similar, whilst separating sub-classes within those sources, eg. 'Normal' and 'Faulty' data (Qian et al., 2023).

Existing LOCA detection procedures that attempt to overcome the issue of the lack of available NPP accident data perform well in a limited range of operating conditions (Farber & Cole, 2020). The generalised knowledge available through leveraging transfer-learning from attainable model data has not yet been fully exploited in the context of LOCA detection. Domain adaptation allows the transfer of the knowledge contained in such a classifier on to a new domain containing previously unseen behaviour.

In this work, we introduce adaptations to current transfer learning based fault detection methods with application to the detection of the LOCA condition. The model design process was guided by system experts in order to construct data 'features' that well represent the NPP behaviour in both nominal and LOCA conditions. Results show how domain adaptation is able to retain the fault detection performance that is achievable for the labelled training data when it is applied to the surrogate models data domain.

2. PROBLEM FORMULATION

2.1. Domain adaptation overview

Consider data sampled from two distinct domains, Source (S) and Target (T). The data from each domain (x_S and x_T, respectively) posses different distributions. Additionally, suppose that class labels for the data sampled from the Target domain, y_T, are unavailable. Given the data is drawn from disparate distributions, conventional supervised methods cannot infer knowledge about the Target domain using data from the Source domain.

Domain adaptation provides methods for prediction of target domain labels y_T from target domain data x_T using the information present in source domain data and labels x_S and y_S. In this work, we will describe a feature extractor as an encoder: a network designed to construct a feature space Z using the distributions of x_S and x_T. The aim of the encoder is to provide a transformation through which the distributions of x_S and x_T appear similar to each other in the feature space Z.

The generalised feature space Z is used to aid classification for samples from the target domain, since the encoded representations of x_S and x_T are similar, and we have access to class labels for the source domain data, y_S. There exist many well documented methods by which the encoder can construct Z, with two of the most commonly used domain-adaptation specific measures being Mutual Information (MI) and Maximum Mean Discrepancy (MMD).

2.1.1. Mutual Information

MI is a statistical quantity that describes how much information one variable conveys about another. If we consider these variables in terms of the feature space representations of the input domain data, i.e: z_S and z_T (obtained from passing x_S and x_T respectively into the transformative encoder), then maximising the MI between the Target domain feature space representation (z_T) and the entire feature space (Z) will encourage the encoder to generate features that are generalised between the two input domains.

The MI between these specific variables can be expressed as a linear combination of the Shannon Entropy of each feature space representation (Chen et al., 2021). The Shannon Entropy for a distribution A is given by

$$H(A) = -\sum_{a \in A} P(a) \ln P(a). \tag{1}$$

If we state that Z_S and Z_T are the distributions of the feature space representations z_S and z_T respectively, then the MI becomes

$$\text{MI}(Z_T; Z) = -\sum_{z_S \in Z_S} P(z_S) \ln P(z_S) - \sum_{z_T \in Z_T} P(z_T) \ln P(z_T). \tag{2}$$

Maximising this quantity during training promotes the generation of features that convey the largest amount of shared information between the Target domain samples and the entire set of observed samples from each domain.

2.1.2. Maximum Mean Discrepancy

A brief description of the intended function of the MMD term will be sufficient for understanding its relevance to this work. The key principal that underpins MMD metrics is the idea that if two distributions are equal, then their statistical properties should also be equal. By using MMD, it is possible to perform a hypothesis test upon the functions that transform the input domain distributions into their encoded feature representations. These functions are embedded as a Hilbert space, a convenient mathematical construct which allows linear algebra to be applied to infinite-dimensional vectors.

Formally, the MMD between two distributions A and B on the sets X and Y can be calculated as

$$\begin{aligned}\text{MMD}(A,B) &= ||\mathbb{E}_{X\sim A}[\phi(X)] - \mathbb{E}_{Y\sim B}[\phi(Y)]||_H \\ &= \sup_{f\in H}(\mathbb{E}_{X\sim A}[f(X)] - \mathbb{E}_{Y\sim B}[f(Y)]), \quad (3)\end{aligned}$$

where f is a function in the Hilbert space H and ϕ is the transformation from the input set to the Hilbert space. The supremum means this is equivalent to taking the maximum of the mean difference between the distributions A and B.

In practice, the mean of the feature-space distributions is not known, so the MMD between the two feature-space distributions must be empirically estimated by

$$\begin{aligned}\text{MMD}(Z_S,Z_T) = &\frac{1}{m(m-1)}\sum_{i}^{m}\sum_{j\neq i}^{m}\phi(z_{S_i},z_{S_j}) \\ &- 2\frac{1}{mn}\sum_{i}^{m}\sum_{j}^{n}\phi(z_{S_i},z_{T_j}) \\ &+ \frac{1}{n(n-1)}\sum_{i}^{n}\sum_{j\neq i}^{n}\phi(z_{T_i},z_{T_j}), \quad (4)\end{aligned}$$

where, m and n are the number of samples drawn from Z_S and Z_T, and ϕ is a Gaussian kernel representing the feature mapping transformation. A minimisation of MMD ensures that the distributions Z_S and Z_T are similar across each statistical moment, which aids in making predictions about the unlabelled Target domain.

2.1.3. Domain adaptation-oriented loss function

The Negative Log Likelihood, NLL, cost is used to penalise incorrect classification predictions made by the model and is given by

$$\text{NLL}(\theta) = -\sum_{i=1}^{k}\left(y_i\ln(\hat{y}_{\theta i}) + (1-y_i)\ln(1-\hat{y}_{\theta i})\right), \quad (5)$$

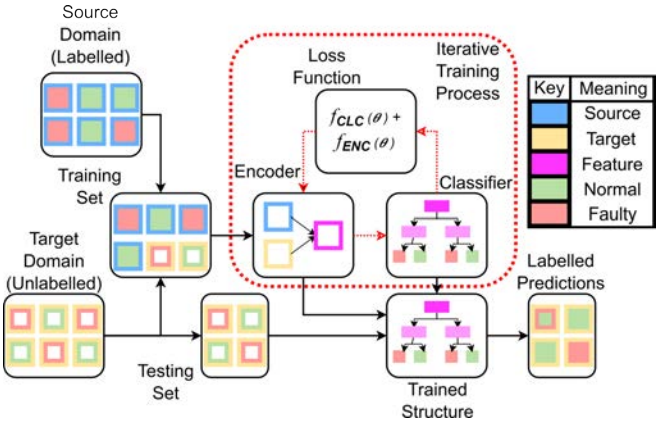

Figure 1. An example of an unsupervised domain adaptation approach. An encoder and classifier are trained simultaneously to generate both a representative feature space and accurate class predictions.

where, θ is a set of probabilities attributed to each class prediction, k is the number of predictions made, y is the true class of each sample and $\hat{y}$ is the predicted class.

To perform domain adaptation the following loss function is used:

$$\mathcal{L}_{DA} = \text{NLL}(\theta) + \text{MMD}(Z_S,Z_T) - \text{MI}(Z_T,Z). \quad (6)$$

This is a common form for a loss function seen in an unsupervised domain adaptation setting, visualised in Figure 1.

For comparison, this work will also use a simplified version of this loss function, $\mathcal{L}_S = \text{NLL}(\theta)$, to represent a loss function used by a conventional supervised learning approach.

3. Methodology

3.1. Data generation

In light of the lack of labelled relevant NPP accident data, RELAP5, a nuclear reactor modelling and simulation tool, was used to generate the data used in this work. Rather than perform domain adaptation between model generated data and real data collected from a plant, a high-fidelity physics models is used under three different configurations that represent data domains with varying levels of divergence between them. The model configurations represent 1) A large four-loop 3600MW civil nuclear plant with nominal historical usage, 2) A similar large plant with a greater historical power usage and 3) A small two-loop 50MW with nominal historical usage.

3.1.1. Model modifications

To replicate the full range of operating conditions of a civil nuclear plant, and for a machine learning framework in this

setting to be trained robustly, data containing examples of dynamic events are provided. These events come not only from the presence of LOCA/faults, but also reflect dynamism in the normal operation of a plant, such as reactivity insertion.

The specification of a general table used to define the core reactivity or power (depending upon the reactor kinetics model used by the script) proved sufficient for providing the kind of input-derived transient events required. Typically, these input demands have magnitude between 1-10% of the input reactivity/steam off-take of that observed at the reactor's steady state rated power output level.

A small degree of Gaussian noise was added to the input reactivity demand profile to simulate process noise. The scale of the input noise was less than 10% of the magnitude of the changes in input demands. Set-points and thresholds that define variable and logical trips for control systems in the model were perturbed to emulate differing operator characteristics on each run.

Each simulation was performed with or without the presence of a LOCA (hence being classed as 'Normal' or 'Faulty').

Breaks were inserted into the primary circuit of the reactor coolant system to simulate a LOCA. Breaks are simulated at the inlet and outlet of the hot and cold legs of the primary circuit, as well as at the outlet of the steam generator in the secondary circuit. All breaks used the counter-current flow model, with standard choking flow. The full abrupt change model was used meaning that all breaks occurred instantaneously, rather than develop throughout the course of one sample of time-series data. The breaks are modelled as a valve with given cross-sectional area. The cross-sectional area of the break-valve is adjusted to define the size of the break relative to the cross-sectional area of the pipe to which the break-valve is located. The break sizes are uniformly sampled in the range $[0.02\%, 0.2\%]$ of the area of the pipe for the 3600MW plant, and the range $[0.1\%, 1\%]$ of the area of the pipe for the small 50MW plant, representing very small breaks. Each simulation is run for 1000 seconds.

A summary of the numerical changes to the high-fidelity physics models is as follows:

- Transient operating power provided by control of reactor rod position or steam off-take at the steam generator. Operating power level varied between +-10% of the rated capacity of each plant.
- Gaussian process noise inserted with transient input signals, scaled to +- 1% of the rated capacity of each plant.
- Control system thresholds shifted by -2%, +2% or unchanged for each simulation.
- Breaks inserted with magnitudes in the range $[0.02\%, 0.2\%]$ and $[0.1\%, 1\%]$ of the cross-sectional area of the pipe in which they are located for the 3600MW and 50MW plant respectively.
- Each simulation is run for 1000 seconds.

3.1.2. Differences between models (domain divergence)

This work focuses on exploring the implication of an increasing divergence between data domains. In this context, this requires multiple high fidelity physics models from which to gather data. The first of the template models used describes a large Four-loop 3600MW PWR with characteristics designed to be a 'fictitious approximation' of values present in a Westinghouse plant.

To provide an example of a relatively small domain divergence, the 3600MW PWR model is used to provide data representative of the same plant at different stages in its operating cycle. To achieve this, different model initialisation applied that define different average operating power output for the first year of operation. An 'Underworked' version of this Four-loop plant was defined to have operated at 2400MW (significantly less than the 3600MW rated capacity) for its first year of operation. This model was used as the 'Source' domain model. A 'Typically worked' version of the same plant is defined to have operated at its rated capacity of 3600MW for the first year of it's operation. Additionally, pump speeds throughout the primary and secondary circuits are increased, allowing for different dynamics to manifest in this version of the plant. The model generated data used for the 'Target 1' domain.

A second, smaller Two-loop 50MW PWR plant was chosen to represent a more drastic domain change. This plant is simulated with the same relative changes in input reactivity and trip set-point attitudes, but possessing disparate dynamics and steady state behaviour owing to the different physical properties of the smaller plant. Data generated from this model is used for the 'Target 2' domain.

A quick understanding of the degrees of divergence between these domains can be gained by observing the first principal component of a principal component analysis performed on each domain, shown in Figure 2. The distribution of the first principal component differs greatly depending upon which domain the data comes from, although the difference between the Source and Target 2 domains is much larger than that between the Source and Target 1 domains. This domain divergence would cause a conventional supervised learning approach to suffer, due to the difficulty in transferring knowledge between disparate domains. Additionally, note the large degree of overlap that exists between 'Normal' and 'Faulty' classes of data in each domain. This implies that, since principal components analysis is a linear technique, a linear classifier would struggle to separate samples of data from different classes.

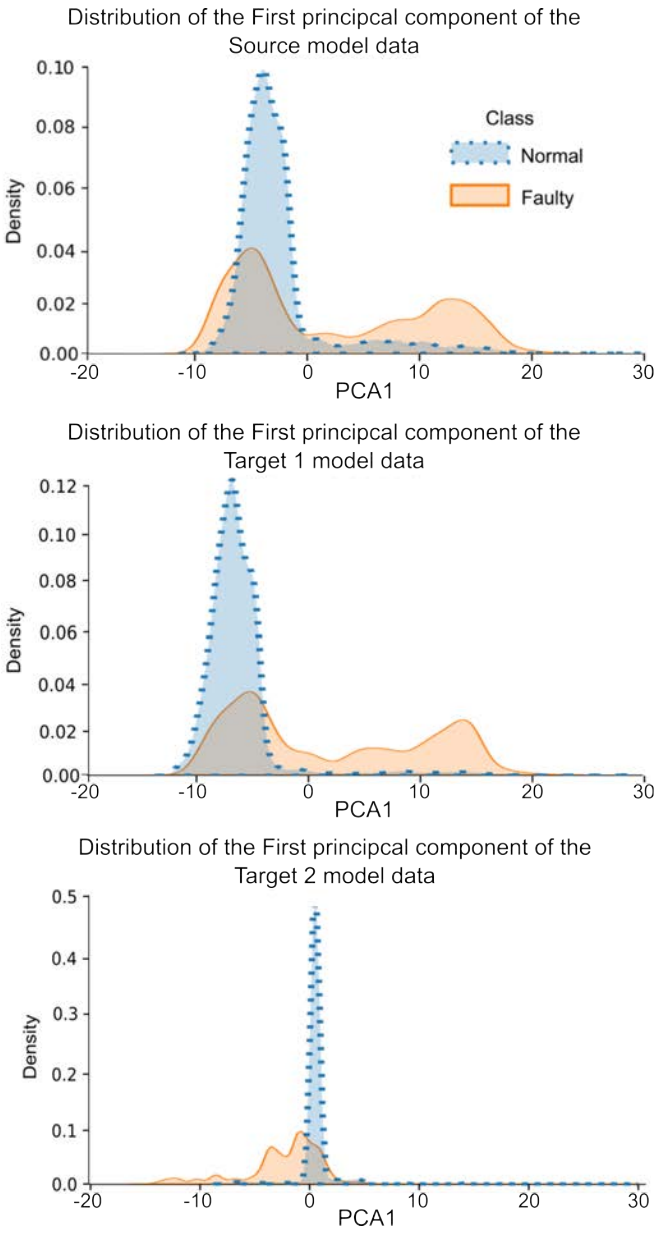

Figure 2. The distributions of the first principal components of the data from each of the three domains. Note the larger difference in distributions between the Source and Target 2 domains.

3.1.3. Processed data structure

Observations of the plants were made by simulating sensors in locations throughout both the primary and secondary circuits, listed in Table 1. In total, 15 data streams were extracted from each simulation, representing pressures, temperatures, mass-flow rates and valve states, with locations shown in Figure 3.

In addition to these measured values, the input reactivity profile (the power demand) and the reactor output power were supplied as part of the data vector provided to the domain adaptation network. Each batch of data the encoder receives is made of samples derived from both the Source and Target domains. At the encoder, these samples are unlabelled. Each sample x is an $N \times T$ vector representing T time-steps of N sensor readings. The input dimension of the encoder is $B \times N \times T$, where B is the number of samples used per batch.

Table 1. A list of the measured values used in this work.

Value specification		
ID	***Description***	***Units***
0	Cold-leg Coolant Pressure	P
1	Cold-leg Inlet Coolant Temperature	°C
2	Cold-leg Outlet Coolant Temperature	°C
3	Hot-leg Coolant Pressure	P
4	Hot-leg Inlet Coolant Temperature	°C
5	Hot-leg Outlet Coolant Temperature	°C
6	Pressuriser Relief Valve State	-
7	Main Steam Isolation Valve State	-
8	SG Feedwater Regulating Valve State	-
9	Cold-leg Coolant Mass Flow-rate	kg/s
10	Hot-leg Coolant Mass Flow-rate	kg/s
11	Reactor Coolant Pump Mass Flow-rate	kg/s
12	SG Feedwater Inlet Mass Flow-rate	kg/s
13	Pressurizer Inlet Mass Flow-rate	kg/s
14	Charging Pump Mass Flow-rate	kg/s

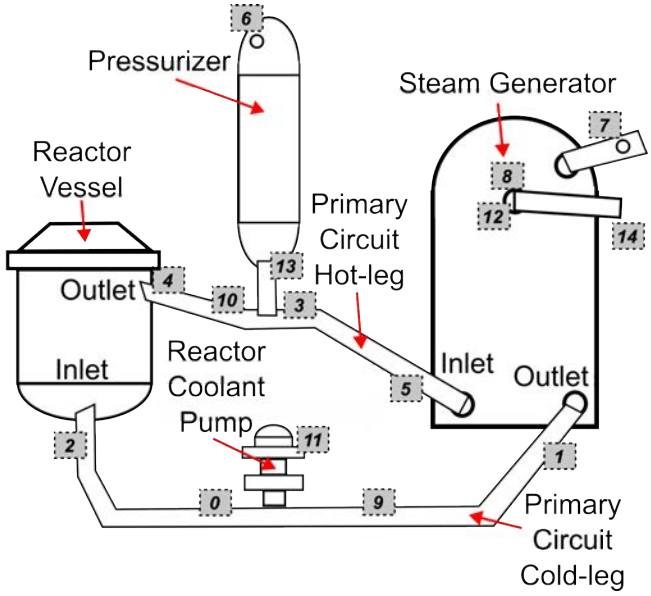

Figure 3. A simplified view of the primary coolant circuit of a PWR. The measured sensor values used in this work have their sensed locations numbered.

3.2. Model architecture

The network described in this work consists of an encoder, tasked with extracting generalised feature maps from the raw input vector data, and a classifier aimed at detecting the presence of 'Faulty' data. Different model architectures were were trialed and they are described in detail below.

3.2.1. Encoder variations

To investigate the impact that the internal structure of the feature-generation stage of the network has in the context of NPP time-series data, several forms of encoder were considered, with increasing degrees of 'connectivity' between different input sensor readings, visualised in Figure 4.

Baseline Encoder: Separate 1D convolutions

Two kernels per input sensor channel, with kernel grouping number set equal to the input dimension at each point in the encoder. This has the effect of training kernels without combining information from multiple sensor channels simultaneously. Kernels act along the time dimension of each sensor reading.

Aggregate Encoder: Summed 1D convolutions

Grouping number for convolutional layers set to 1, meaning kernels are passed along a single time-series sensor reading, before being combined in a weighted sum to generate a convolution which contains information from each sensor measurement simultaneously.

Recurrent, Fully-Connected Encoder: Gated Dense 1D convolutions

The summed 1D convolutions have been performed as above followed by a fully-connected layers Additionally, a gated recurrent unit (GRU) layer is used before the second set of convolutions.

These modifications attempt to allow the encoder to efficiently consider long-term dynamics that may be important to fault detection in this context.

3.2.2. Classifier & loss function

The classifier is shared by each of the different encoder variations described above. The classifier consisted of a series of fully connected layers followed by batch normalisation layers, shown in Figure 5. A dropout layer is included to encourage regularisation and avoid over-fitting.

4. Experimental validation

The loss function used by each model varies depending upon whether domain adaptation is used. When a model is applied without domain adaptation, the loss $\mathcal{L}_S$ is used. The loss $\mathcal{L}_{DA}$ is used when domain adaptation is required. The 'Baseline' model was tested in each data domain twice, once using $\mathcal{L}_S$ and once using $\mathcal{L}_{DA}$. The Aggregate Encoder and Recurrent Fully-Connected Encoder were tested on all data domains using the loss $\mathcal{L}_{DA}$.

4.1. Hyper-parameter tuning result

The model hyper-parameters were tuned heuristically for each model variant. Hyper-parameters were chosen as

Baseline Model:

- Learning rate: $8e-4$

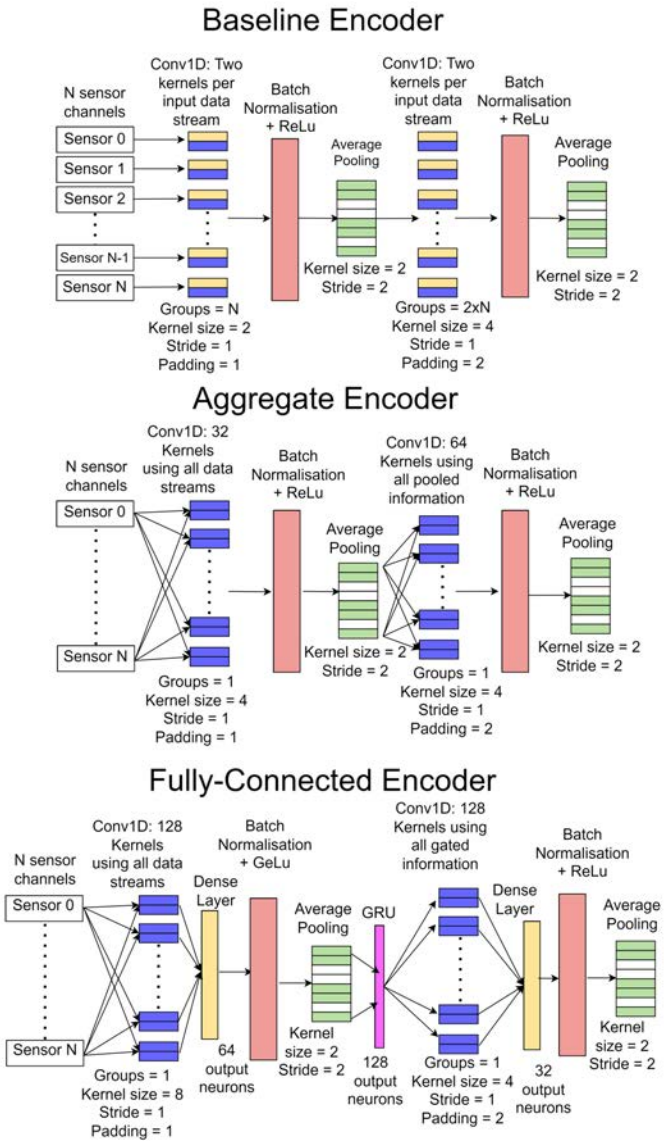

Figure 4. Architectures of three different encoders used in this work, with increasing degrees of connectivity between the input sensor readings.

- Dropout percentage for classifier input: $7.0\ \%$
- Scaling factor for MMD term in loss function: 0.5

Aggregate Encoder Model:

- Learning rate: $9e-4$
- Dropout percentage for classifier input: $4.1\ \%$
- Scaling factor for MMD term in loss function: 0.5

Fully-Connected Encoder Model:

- Learning rate: $6e-4$
- Dropout percentage for classifier input: $5.6\ \%$
- Scaling factor for MMD term in loss function: 0.5

4.2. LOCA detection

This section, detailing the results from this work, is divided into three parts covering, binary LOCA classification performance, detection performance by break size and detection performance by break location.

4.2.1. Binary classification performance

When tested on the the Source domain, each model performed similarly in classification accuracy, with over 93% of the samples observed being correctly classified as either 'Normal' or 'Faulty' for each model variant, as shown in Table 2. Without the necessity for domain adaptation in this case, each model was able to create a robust feature map of the distribution of data observed in the Source domain. The increased complexity of the Aggregate and Fully-Connected Encoders offered little to no benefit in this conventional supervised setting, with the training and testing sets being drawn from the same domain.

Disparities in model performance start to appear when the testing set is drawn from the Target 1 data domain. This testing set represents a slight shift in data distribution from the Source domain training set, which reveals the importance of the inclusion of model architectures specifically designed to aid in domain adaptation. The models utilising the more sophisticated domain adaptation-oriented loss function retain the majority of their classification performance when compared to test results from the Source domain, whilst the Baseline supervised model, using $\mathcal{L}_S$, suffers a sizeable reduction in classification accuracy.

This difference in performance is owed to the fact that the domain adaptation-oriented loss function contains terms that inform the encoder about the statistical properties of the generalised feature space that it is tasked with creating. Consideration of the MI between the entire feature space and the encoded representation of the Target 1 domain data helps to reduce the likelihood of encountering unlabelled Target 1 domain samples during testing that do not possess some information that the model has previously observed during training. Prompting this overlap in shared information increases that chances that the model will hold some 'relevant' feature space representation for these 'unique' unseen phenomena, which is crucial due to the high variability of the generated data. Additionally, minimisation of the MMD at the encoder aids the classifier with inferring class labels belonging to the unlabelled Target 1 domain data. This is explained by the fact that a reduction in MMD between the encoded representations of the Source and Target 1 domains implies that samples belonging to one class (for example, 'Faulty') that exist in one region within the encoded Source domain feature space, should exist in a similar 'relative' location within the encoded Target domain feature space. It is through this knowledge transfer that Source domain information can be leveraged to support Target domain class predictions.

The final domain shift, between training on Source domain model data and testing on the Target 2 domain data represents a more severe divergence between domains. As is evident from the average test accuracies, the conventional supervised model fails to bridge this gap between differing data distributions and records a poor performance of less than 50% classification accuracy. It is at this magnitude of domain divergence that the increased complexity of the Aggregate and Fully-

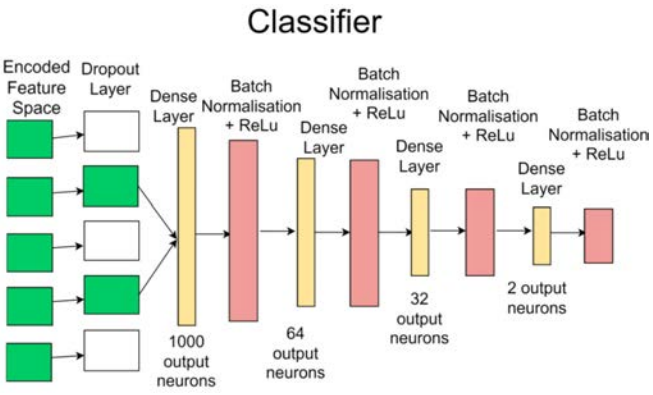

Figure 5. Architecture of the classifier used in this work.

Table 2. Average test accuracies (%) of each model type on each domain set, after being trained on the Source data domain.

Model Type	Source Domain	Target 1 Domain	Target 2 Domain
Baseline Supervised (No DA)	93.41	78.02	45.57
Baseline With DA	-	91.24	81.46
Aggregate Encoder	93.96	91.02	89.85
Fully-Connected Encoder	93.22	91.27	89.57

Connected Encoders demonstrate value. Although the DA-focused loss function is enough to restore the majority of the lost performance for the baseline model, the less-connected Encoder lacks the ability to consider the more disparate dynamics evident in the Target 2 domain.

In the context of this work, allowing the encoder to combine input sensor channels at the first convolutional layer before performing the convolution (such as in the Aggregate and Fully-Connected encoders), may allow the models to exploit class-specific relationships between sensed quantities. For example, in the presence of a LOCA, a brief divergence of primary circuit hot-leg temperature and pressure may occur. If these sensed values were provided to the same convolutional kernel at the input layer of the encoder, then the kernel could utilize this relative disparity to generate a recognisable identifier of a LOCA class sample. This improvement in performance compared to the 'Baseline With DA' model suggests that there is more information available with respect to the problem of LOCA detection if the sensed values are processed relative to each other, rather than processed in parallel.

Although the nature of LOCA simulated in this work vary drastically in magnitude and location within the modelled plants, there exists the possibility for other fault cases to transpire in an NPP. Without explicit knowledge of the existence of these faults (other than LOCA), the accurate classification of these samples as 'Faulty' would depend upon the similarity of these encoded samples to the 'Normal' encoded data. The performance of the models in this work on LOCA-specific fault detection is good, meaning the classifier used can differentiate between 'Normal' data, and all other LOCA data. If another fault case, previously unseen by the models described, manifested in a similar fashion to a LOCA, it is likely it would be identified as 'Faulty'. However, as can be observed in later analysis on model performance by break location, there can be large difference in classification accuracy for a single model across faults from multiple locations, so it would not be reliable to depend upon these methods as part of generic 'anomaly detection' techniques.

An understanding of the impact of the encoder in this work can be understood if the distributions of the encoded data from each domain are observed, shown in Figure 6. The data used in this figure are drawn from the Fully-Connected encoder. Viewing the first principal component of the post-encoder data from each domain reveals that the three domains appear much more similar to each other once expressed in the generalised feature space the encoder provides. As observed previously, the encoded distributions still share a large degree of overlap between 'Normal' and 'Faulty' data. Since principal components analysis is a linear transformation, this suggests that a linear classifier would struggle to reliably predict the class of unlabelled samples, and that the models used in this work which perform well must consider nonlinearities in the data.

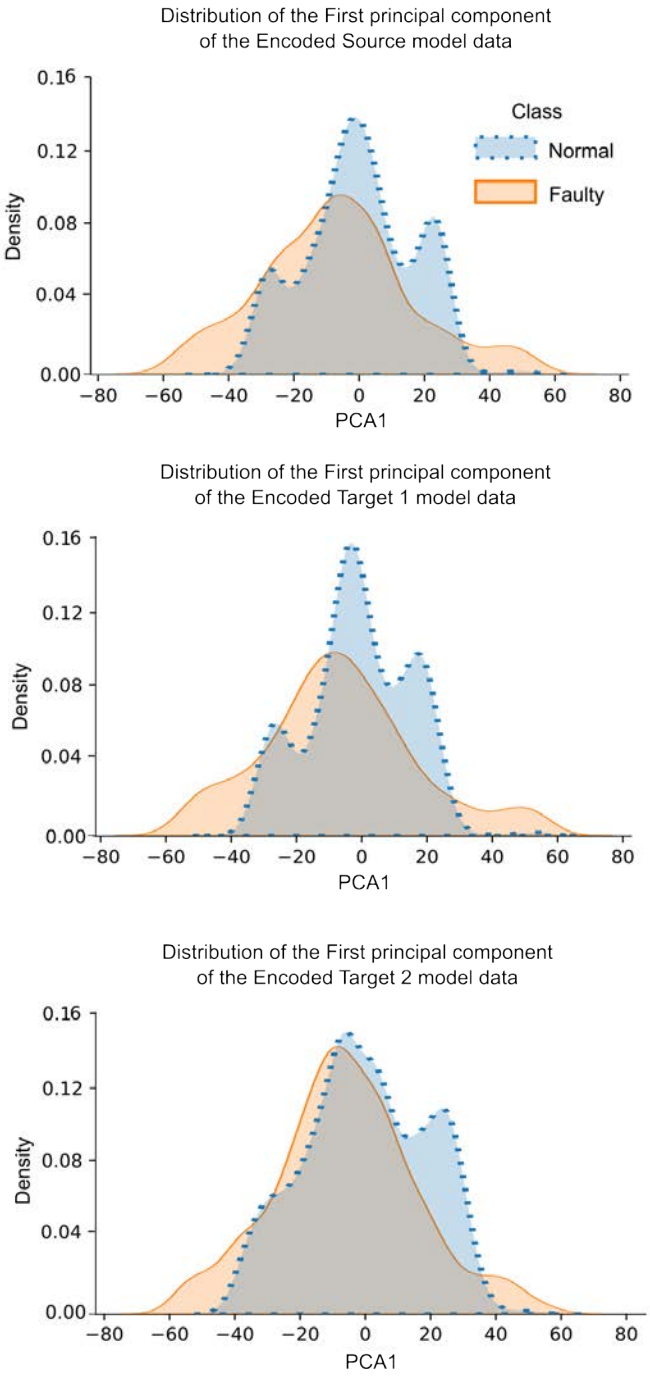

Figure 6. The distributions of the first principal components of the encoded data from each of the three domains. Note the more similar distributions compared to the first principal component of the input space.

4.2.2. LOCA detection by break size

An interesting perspective by which to consider the performance of these models in the context of NPP fault detec-

tion is to observe only the primary circuit breaks and identify the thresholds above which each model can always identify a LOCA. LOCA detection by break size results are shown in Figure 7.

In the Source domain setting, each model could reliably categorise fault data with break size above 0.1% of the pipe cross-sectional area as 'Faulty'.

The performance is retained when the models are tested on the Target 1 domain set, however the rate at which the baseline model without domain adaptation can successfully categorise samples below 0.1% is substantially lower than in the source domain.

The performance loss is exaggerated as the gap between domains increases further still: without considering domain adaptation, there is no size of primary circuit break that the baseline model can always categorize correctly as 'Faulty'. With the only alteration being the inclusion of domain-adaptation focused terms in the loss function, the Baseline model (With DA) can, on average, identify 20% more faults successfully.

The other models retain a substantial proportion of their ability to successfully categorize all break sizes, even in this most extreme domain divergence example.

4.2.3. LOCA detection by break location

The 'Faulty' samples in this work were not only drawn from a range of possible sizes, but also placed at varied locations throughout the primary and secondary circuit of each PWR. Primary circuit breaks occur at either the inlet or outlet of the hot or cold legs. Secondary circuit breaks were inserted at the outlet of the steam generator for the respective loop. LOCA detection by break location results are shown in Figure 8.

When tested in the native Source domain setting, both the Baseline Supervised and Aggregate Encoder models correctly classify all nominal operation data, along with a consistently high successful classification rate of primary circuit breaks as 'Faulty'. The Fully-Connected Encoder sacrifices the successful classification of a small number of 'Normal' samples in order to correctly identify each primary circuit break observed in this testing environment as 'Faulty'.

Classification of breaks located at the steam generation outlet was comparatively poor. This is perhaps due to the lower number of observed examples of secondary circuit breaks during training, or the potential for secondary circuit breaks to be harder to identify under the lower-fidelity of the secondary circuit physical model in comparison to the primary circuit. Only the Fully-Connected Encoder model is able to correctly classify any of these samples as 'Faulty', which suggests that secondary circuit breaks appear more similar to 'Normal' operational data from the perspective of these classifiers.

In the Target 1 domain, representing a slight shift in domain

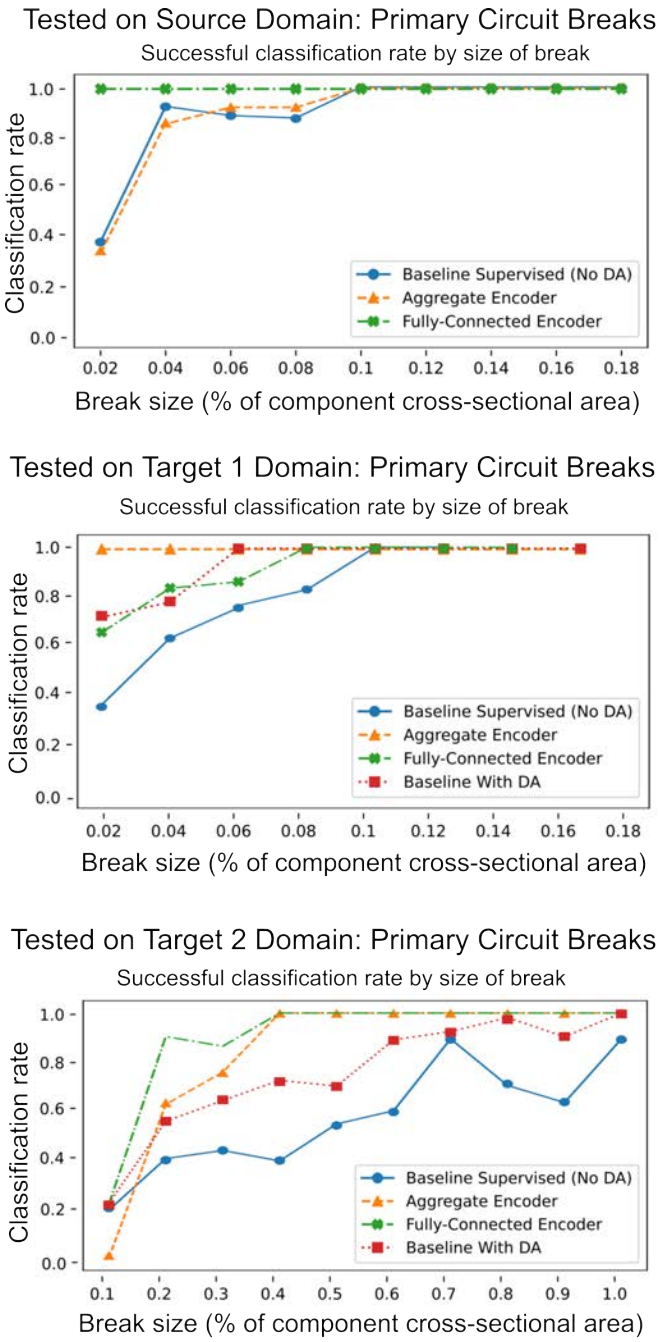

Figure 7. Successful classification rate by fault break size for each model combination, when tested on each domain.

distribution from the source domain, the Baseline Supervised model retained its ability to identify 'Normal' operational data, whilst 'Faulty' sample classification accuracy degraded. As in the Source domain, the Baseline Supervised and Aggregate Encoder models were not able to correctly identify any secondary circuit breaks as 'Faulty'. The Baseline With DA model (using $\mathcal{L}_{DA}$) gives some improvement in primary cir-

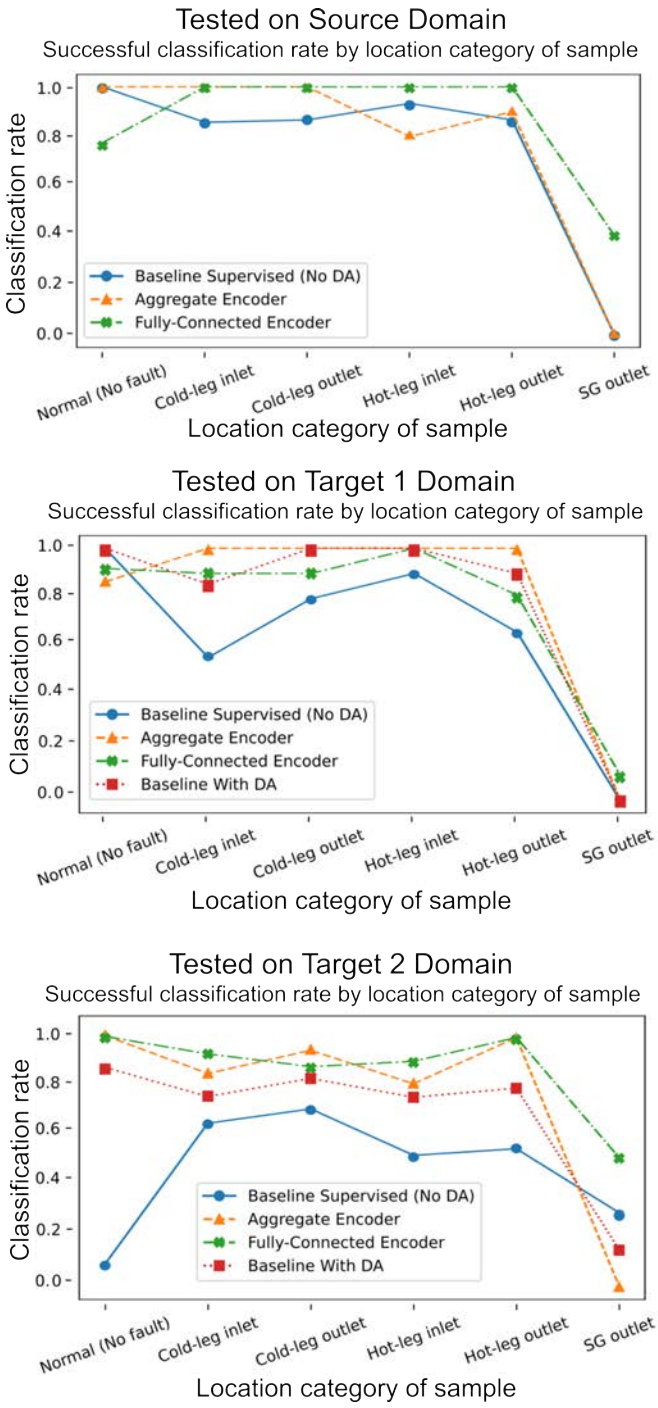

Figure 8. Successful classification rate by fault location for each model combination, when tested on each domain.

cuit break identification, but remains unable to recognise the 'Faulty' class of secondary circuit break samples. As in the previous testing domain, the Fully-Connected Encoder is the only model capable of correctly classifying any steam generator outlet samples, albeit a very small proportion of the samples it observed.

In the most extreme example of domain divergence between the Source domain and the Target 2 domain, the classification ability of the Baseline Supervised model, using $\mathcal{L}_S$, deteriorates. In this unfamiliar domain, the Supervised model is barely able to correctly classify any 'Normal' data. The Baseline model using $\mathcal{L}_{DA}$ restores some classification ability of 'Normal' samples, and improves the detection of 'Faulty' samples in all locations except the secondary circuit. Once again, the Fully-Connected Encoder displays the best detection performance for secondary circuit breaks. This indicates the importance of combining the sensor channels at the Encoder level in order to generate generalised features which can remain relevant between disparate training and testing domains.

5. Conclusion

The results detailed in this work highlight the value in incorporating domain adaptation techniques in scenarios where discrepancies exist between the training and testing data domains. Even when the scale of these discrepancies can become large, fundamental DA concepts provide a significant improvement in performance when compared to a conventional supervised learning approach. Additionally, the results draw attention to the importance of combining input sensor channels in this context. Models which consider information from multiple sensed sources simultaneously during their construction of each encoded feature map retained a much greater proportion of their classification ability seen in the Source domain classificaiton performance.

ABSTRACT

Conventional data-driven predictive maintenance (PdM) solutions learn from samples of run-to-failures (R2F) to estimate the remaining useful life of an asset. In practice, such samples are scarce or completely missing. Simulation models can be oftentimes used to generate R2F samples as a replacement. However, due to the complexity of the assets, creating realistic simulation models is tedious, or even impossible. Thus generated R2F data cannot be used to create reliable PdM models as they are highly sensitive to noises in the sensors or small deviations in system working condition. To address this, we present a new concept of simulation data generation based on supervised domain adaptation for a regression problem where the remaining useful life (RUL) or the health index (HI) of the system is predicted. Apart from input and output domain shift, given the changes in the dominant failing component and its degradation process, the function mapping sensor readings to RUL and/or HI is also prone to changes and thus is a random process itself. Therefore, we aim to generate R2F training data from different working conditions and possible failure types using parameter randomization in the simulation model. By sampling from various configurations within simulation model's parameter space, we ensure that the trained data-driven PdM model's performance is not impacted by the initial conditions and/or the changes in the degradation of the system's condition indicators. Our results indicate that the model is robust to signal reading manipulation and showcases a more spread-out feature importance across a wider range of sensor readings for making predictions. We also demonstrate its applicability on the real-world factory physical system whilst our models were mainly trained using generated data.

1. INTRODUCTION

Accurate prediction of a production asset's health state enables effective implementation of a predictive maintenance (PdM) solution. Such a solution can help reduce both the cost and occurrence of unscheduled maintenance of the targeted production asset (Cui, Du, & Hawkes, 2012; Rahat et al., 2022). With the advancements in sensor technologies, data acquisition and analysis, numerous PdM solutions predict the remaining useful life (RUL) and/or the health index (HI) by either date-driven models, model-based models or hybrid of the two.

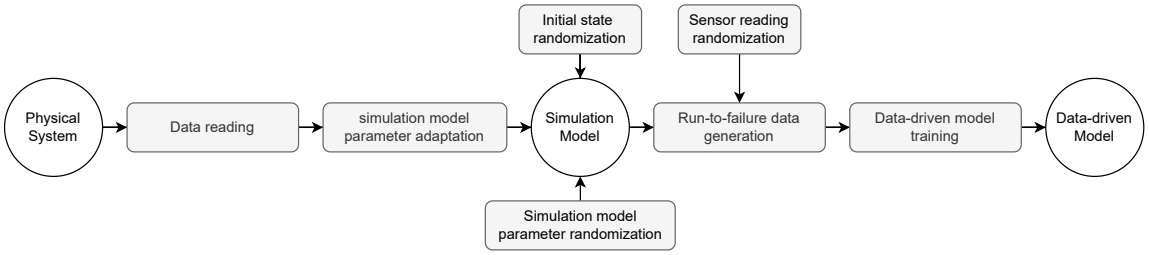

Figure 1. Overview of the proposed method

The *data-driven models* use historical data to train the model of RUL, so their quality depends on the data quality. It is thus of utmost importance that the training data meets the minimum data quality requirements (Liu, Wang, Ma, Yang, & Yang, 2012). However, it is rarely the case that the available data from a production asset not only has enough samples of failure, but also covers all possible failure types of the system (Fathi, van de Venn, & Honegger, 2021).

This in turn raises the need for the data generation via simulation models, which underlines the importance of currently missing related work on simulation-to-real transfer and domain adaptation (DA) techniques for RUL and/or HI estimation in PdM.

The *model-based approaches* leverage mathematical and physical models to estimate the RUL. This usually requires parameter tuning, *e.g.,* using Markov process model or Winner process, for converging to the behavior of the physical system (Hanachi, Liu, Banerjee, Chen, & Koul, 2014; Si, Wang, Hu, Zhou, & Pecht, 2012; Thelen et al., 2022). The parameter tuning is highly sensitive to the parameter initialization, which is normally based on the empirical knowledge from the physical system (Lei et al., 2016). Even when the system parameters are estimated correctly, any changes in the production setting and/or the production asset itself requires a re-calibration.

Both the data-driven and the model-based approaches suffer from inadequacy in practical solutions: the relevant data is either missing, or the models are not robust enough, respectively.

Hybrid PdM models combine the two approaches by learning from both the historical data and the data synthetised from the simulation models. The hybrid models have proven to be effective in terms of reliability and efficiency, and address some of the issues of pure data-driven or model-based solutions, such as reduction in data acquisition time and increased model robustness (Chang, Fang, & Zhang, 2017; D. Chen et al., 2022; Lin, Yu, Wang, Che, & Ni, 2022; Didona & Romano, 2014). In practice, the sampling from simulation models can not come up for the lack of historical data, so the conventional hybrid PdM models are also heavily dependant on annotated data. They are normally applied to systems for which extensive labelled datasets are available, *e.g.,* RUL prediction for lithium-ion batteries and aircraft engine (Fei, 2022; Saxena, 2023). As large datasets are not available for production assets in a manufacturing factory, the conventional hybrid models are inapplicable in the manufacturing setting.

In this paper, we focus on hybrid modelling for this specific scenarios where gathering extensive labelled data from the physical system is non-trivial (or even impossible), and where precise and robust simulation models are unavailable. To compensate for that, we propose to extract as much value as we can from both sources by applying the *domain adaptation* between the simulation and the real-world scenarios (see Fig. 1).

In the same vein, we further improve the robustness by considering the data distribution shifts which are a common consequence of diverse manufacturing requirements in an Industry 4.0 setting due to flexible and adaptable production (Fathi, Sadurski, Kleinert, & van de Venn, 2023). In order to cover as much of the parameter space of the system as possible, we alter accordingly the modelling of the initial condition and the degradation of the system.

The main contribution of this paper is thus four-fold. We:

1. Propose a hybrid PdM solution which relies mainly on the data from a simulation sub-module and few samples from the target domain for training its data-driven sub-module (supervised DA),
2. Propose a new concept of simulation data generation aiming for domain adaptation called Parameter and Data Perturbation (PDP), for covering as much of the parameter and degradation space of the physical system as possible,
3. Inspect the impact of the changes in the generated data from the simulation sub-module and the physical system on the performance of the data-driven sub-module,
4. Demonstrate how the additional simulation data used for model training results in a more spread-out feature importance across a wider range of sensor readings from the system while making predictions.

The rest of the paper is outlined as follows. First, some related work addressing synthetic data generation from simula-

tion models for dealing with scarce labelled data and domain adaptation are presented. Afterwards, the details of the simulation model are provided. Thereafter, the results of model training using the simulation model data with PDP are presented. Lastly, discussion and the future work of this work are presented and some conclusions are drawn.

2. Related Work

2.1. Lack of annotated data from the target system

One method used for reducing the time spent gathering data from the target application using hybrid modelling is *boostrapping* (Didona & Romano, 2014). The main idea of *boostrapping* is to rely on a simulation model of the target use case and to generate initial synthetic training set for the data-driven model training. Thereafter, the data-driven model tries to incorporate knowledge from the target system as soon as a data point is available. In (Didona & Romano, 2014), the authors propose to remove the synthetic data points in the vicinity of samples from the target system to prevent obfuscating information from the real samples. However, for the purpose of RUL prediction in PdM, the annotated samples from the physical system are scarce and costly to gather. Hence, we propose to instead to keep these valuable samples and to combine them with data from different working conditions of the system generated from the simulation model

2.2. Adaptation to different working condition

Another important issue impacting the performance of data-driven PdM models is the varying working condition of the production assets in industry. These constant changes can make models trained with a specific working condition (a.k.a. source distribution) obsolete as changes occur in the system (Ragab, Chen, Wu, Kwoh, & Li, 2020). They cause a data distribution shift between the data employed to train the PdM model and the data acquired during the model's deployment in the production line. This discrepancy between the source and target distribution raises the need for techniques such as domain adaptation. In fact, domain adaptation aims to train a model on multiple source domains which are annotated so that the model can generalized to new and unseen target domains (Farahani, Voghoei, Rasheed, & Arabnia, 2021).

To the best of our knowledge, no other PdM work adopted domain adaptation methods for robust RUL and HI estimation in light of lacking annotated historical data from the physical system using simulation-to-real transfer techniques. Moreover, the current literature (Farahani et al., 2021; Yu, Fu, Ma, Lin, & Li, 2021; Rahat et al., 2022; Yang, Lei, Jia, & Xing, 2019; Gao, Liu, Huang, & Xiang, 2021; Wang, Taal, & Fink, 2021) reduce PdM to be a binary or a multi-class variable. We treat it as estimating the RUL or HI as a continuous value for better adaptability to different scenarios.

In addition, given the degradation process of different critical components of a production asset, the labelling function mapping the input space to the output space, can not only be different in the target domain, but also change in the target domain given the dominant degradation process of any arbitrary critical component (Cortes & Mohri, 2011; Nejjar, Geissmann, Zhao, Taal, & Fink, 2024)

These two, the estimation of RUL and/or HI as a continuous variable under the assumption of scarcity of annotated data from the target domain, and the possibility of data distribution shifts in the target domain are the primary motivation behind the proposed PDP method outlined in this work (Fig. 2).

2.3. Simulation-to-real transfer

Numerous application, especially safety-critical system, suffer from lack of labelled data as gathering such datasets is costly or endangers the human operator (Kaufmann et al., 2020; Tiboni, Arndt, & Kyrki, 2023). Therefore, simulation models are used to recreate different scenarios which are also labelled for model training. Nonetheless, modelling errors and the complexity of physical systems prevent the zero-shot deployment of data-driven models trained with such simulation models. One way for increasing the robustness of the trained models is randomize the dynamic parameters of the system which is a.k.a. *domain randomization* (Peng, Andrychowicz, Zaremba, & Abbeel, 2018). Doing so increases the robustness of the trained model at the the cost of its optimality (Tiboni et al., 2023). In this paper, we use the same method to cover as much as the parameter and degradation dynamics space as possible. Different starting conditions, model parameter and degradation processes are the main sources of domain randomization in this paper (Fig. 2).

3. Simulation model

Data-driven monitoring systems require continuous data collection that must extend over a period of time before they can provide effective results (Bonomi et al., 2021). Such data collections, referred to as run-to-failure (R2F) data, are normally expected to start from a healthy production asset state and end with the asset failing or malfunctioning. In the present scenario, there is the additional consideration that R2F tests are, by their nature, long-lasting while accelerated destructive testing is not always possible. Additionally, these tests are expensive with uncertain success. We propose to use a simulated model of the system to obtain realistic data (Ferrario et al., 2019) on its response to the system's most common types of wear and tear.

The model creation phase is critical because it must satisfy several conflicting requirements:

- The model must be complex enough to represent deteriorating operating conditions realistically.

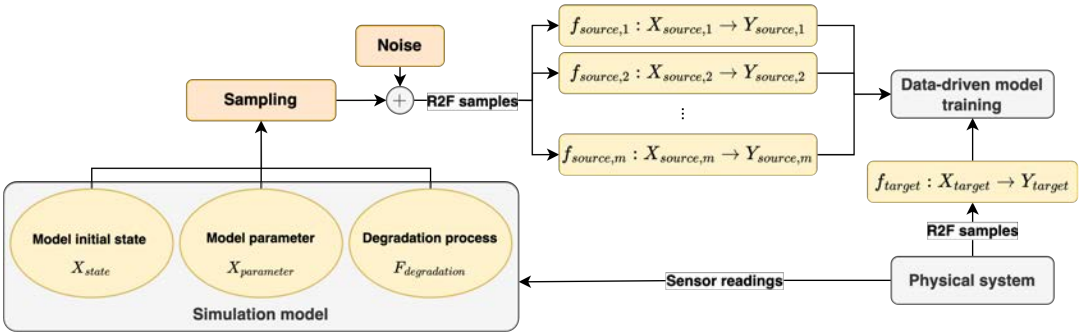

Figure 2. DA via PDP

- The model must be simple enough to be calibrated in a short time and from accessible data.
- The model must take into account the system whose condition is being monitored, the measurement instruments used, and how the data are processed. To some approximation, it must also take into account the context in which the system operates (*e.g.*, the effect of other components).

To meet all these needs, we developed a system with the following characteristics:

- Our models follow the multi-physical system (*Simscape*) as a concentrated variable model. This allows parameters to be easily configured.
- The model is wrapped in a Python script that allows generating the random parameters, handles post-processing, and eventually repeats or recovers the simulation scenarios in case of failure.

3.1. Overview of the simulation model

Our specific use case is the condition and life monitoring of a series of pneumatic cylinders. Based on its characteristics, we separate the model into 5 macro blocks (Fig. 3):

1. **Control system block:** modeled as timed output signals.
2. **Air feeding system and sensor block:** modeled while taking into account the fluid dynamic aspect and the characteristic times of the sensors (*i.e.*, thermometer, pressure switch and flow switch). The generated data are saved as time series on temporary files.
3. **Valve blocks:** modeled as adjustable restrictions controlled with a Boolean signal taking into account the fluid-dynamic aspect and implementation delays (Fig. 5).
4. **Pipe blocks:** modeled from the fluid dynamics and heat transfer point of view.
5. **Cylinder block:** the fluid-dynamic, mechanical, and thermal parts of the cylinders are modeled. The latter takes into account the velocity damping systems included in the final section of the cylinder and the speed controller valves outside the cylinder. This block also contains the modeling of possible failure types: air leakage is modeled as an adjustable restriction between the two chambers or between the chambers and the outside, and the state of the seal as a parameter that changes the friction force of the plunger. These parameters can be set with configurable constants prior to simulation. (Fig. 4).

After simulation, we read the simulated time series and compare them against the readings of the measuring instruments with the goal of obtaining the same results as the real system. During the reading, the acquisition frequency of the real system, the interaction with the cylinder's limit sensors, and any post-processing are taken into account.

In order to optimize the computing load and the amount of data transmitted, we later do not to use the time series directly. Instead, we represent the operation of the system with only a few particular values. For example, for each pneumatic cylinder, the actuation delay, the time of arrival, the airflow at departure, the airflow at arrival, the maximum airflow, the amount of air absorbed during the movement, the average pressure, and the minimum pressure are collected.

After the model is created, a calibration is performed using the available data, and the values obtained are compared with the actual values to check for a match.

To model wear damage, after an analysis of component failure modes (Nakutis & Kaškonas, 2008; Belforte, Raparelli, & Mazza, 1992; J. Chen, Zio, Li, Zeng, & Bu, 2018), effective parameters are identified to represent the state of the system. In the analyzed use case, the possible leakage is characterized as three adjustable local restrictions (between the first chamber and the environment, between the second chamber and the environment, or between the chambers) while the seal state is an adjustable friction coefficient.

Simulations are performed from an ideal operating state corresponding to the HI of 100% (the state of the part at the time of system calibration, assumed to be healthy) to a failure state, corresponding to the HI of 0%. The law by which the condition is calculated depends on the use that is made

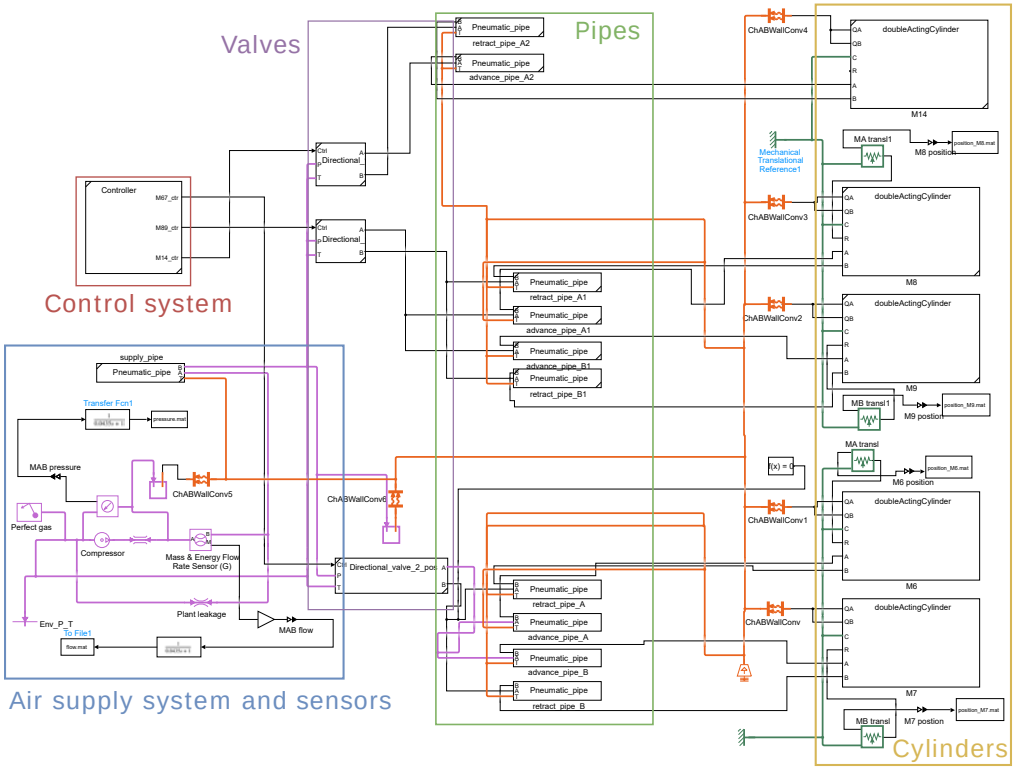

Figure 3. View of the physical model with macro blocks and the structure of major ones highlighted.

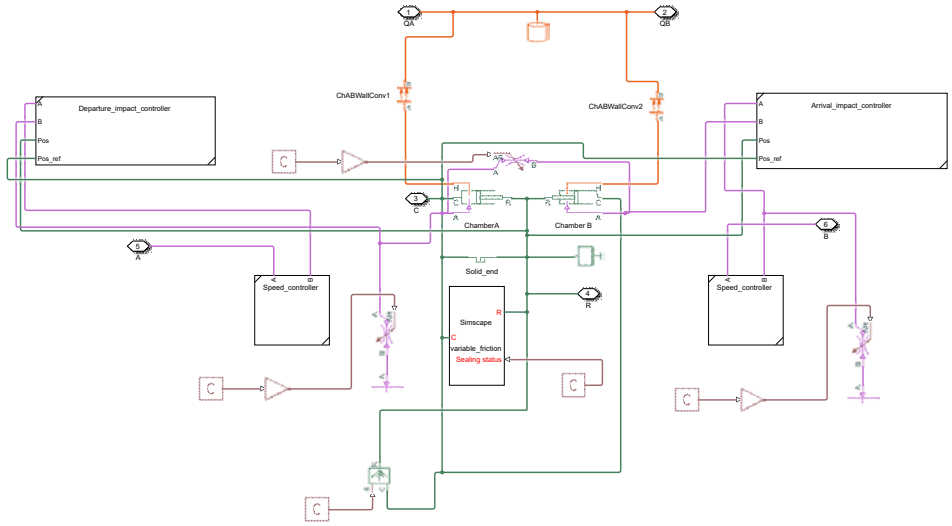

Figure 4. Detail view of one of the blocks modeling the behavior of pneumatic cylinders. It can be seen the variable restrictions that model leakage and the customized block that models seal friction.

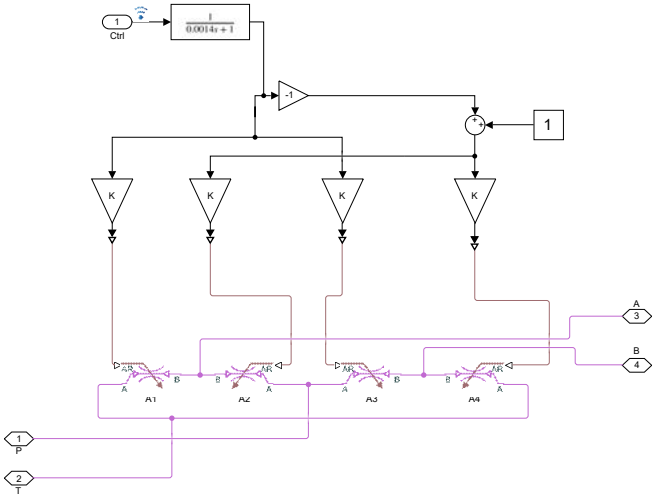

Figure 5. Detail view of one of the blocks modeling the behavior of pneumatic valves.

of the monitored machine and the requirements that it must have. For example, in the case of pneumatic cylinders, it is calculated based on the change in movement time and energy used.

3.2. Parameter perturbation in simulation model

To make the model effective under different operating conditions, we run several simulations by varying the system boundary conditions and the damage progression law. In the logic of keeping the algorithm simple and applicable to different types of models, each failure mode was treated independently (thus each parameter modeling wear progresses at different rates but does not affect others). Of course, the effects that these parameters have on the operation of the simulated device sum up and affect the HI.

This process can be schematized in the following points (see Fig. 6):

1. **Preparation:** The model is calibrated from the conditions measured in the real system. Then it is determined what is the critical value of each of the parameters that represent the damage (the value that alone would bring the part HI to 0) through a series of simulations in which the main operating parameters are varied (see Fig. 7) and from which matrices of critical values are obtained.

2. **Generation of the modeled system:** At this stage, the system's own characteristics, those that are not expected to change over time are determined. These parameters are the damage progression laws for each component and each failure mode, and also additional static parameters such as the position of the control valves. Every damage progression is determined by a quadratic law defined as follows:

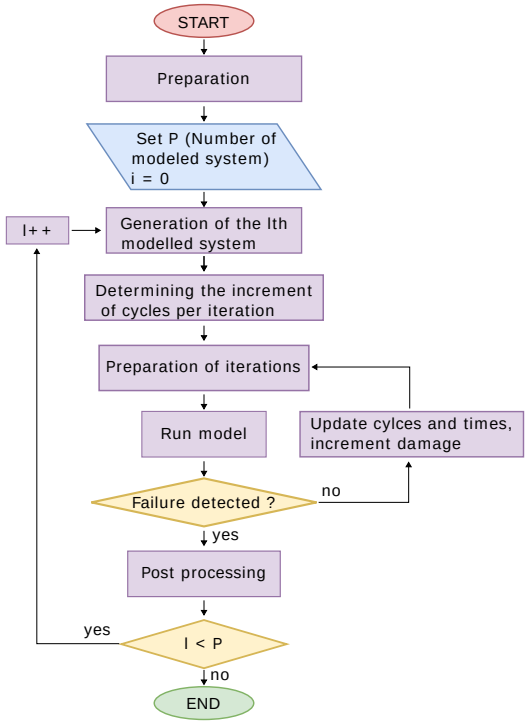

Figure 6. The flowchart of the script running the simulations

$$\begin{cases} (n < n_f): & Kd_{i,j}(n) = n^2 \cdot \frac{(2-4\cdot nli)}{n_f^2} + n \cdot \frac{4\cdot nli-1}{n_f} \\ (n \geq n_f): & Kd_{i,j}(n) = \frac{2n_f(2nli-1)-x(4nli-3)}{n_f} \end{cases} \tag{1}$$

model where $Kd_{i,j}$ is the damage progression coefficient for the failure mode i of the device j, n is the number of cycles made by the device, $nli \in [0.25, 0.7]$ is the *non-linearity index*, n_f is the number of cycle that, would bring the part to failure. The law is formulated to be always increasing while being parabolic up to the n_f value, and then proceeds linearly. The damage progression coefficient multiplied by the critical damage values determines the value of the corresponding failure parameter.

3. **Determining the increment of cycles per iteration:** For each model defined in the previous step, a series of simulations must be run in which the number of cycles performed by the machine increases progressively so as to increase the various damage parameters. The simulations must proceed until the HI of at least one of the parts drops to 0. To keep the computation time acceptable, it was decided that only one cycle is actually modeled in each simulation while the cycle counter and time are recalculated using these formulas:

$$n_k = n_{k-1} + min\left(n_{f,i,j}\right)/N \tag{2}$$

$$t_k = t_{k-1} + min\left(n_{f,i,j}\right) \cdot t_n \tag{3}$$

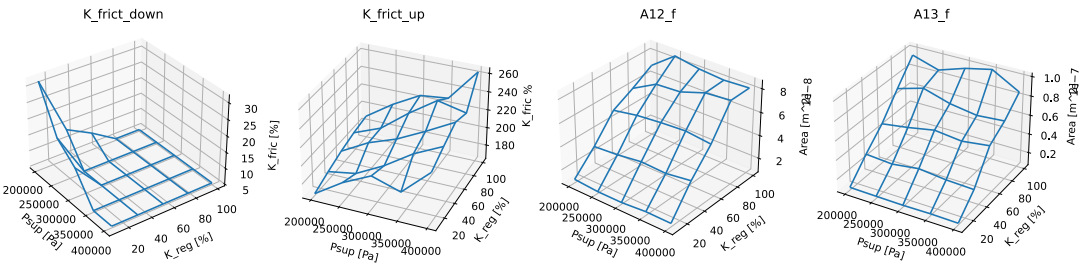

Figure 7. The figure shows the critical matrices for a pneumatic cylinder. The matrices represent the critical value of various damage parameters (friction reduction, friction increase, leakage between chambers, leakage between the second chamber and the environment) as a function of supply pressure and speed control valve adjustment. It can be seen that the critical friction is greatly influenced by pressure while the critical value of leakage is more influenced by valve adjustment.

Where, n_k in the number of cycles made by the device in the iteration k, $n_{f,i,j}$ is the cycles to fail for the failure mode i of the device j, N is the desired number of iterations, t_k is the virtual time in which the simulation k takes place, and t_n is the number of cycles performed in the unit of time.
This reduces the computational time by simulating only a number of cycles equal to about N, which are equally spaced. In practice, the number of simulations may vary in relation to N, as the overlapping effects of increasing different damage parameters may dampen or accentuate their impact on the part condition.

4. **Preparation of iteration:** Before each simulation, some parameters that may vary during the lifetime of the part, such as environmental parameters, are randomly calculated. Specifically, in the presented use case, the pressure of the air supply system, the ambient pressure, the ambient temperature, the sampling start time, the pressure drop of the supply system, and the friction coefficient of the sealing of each cylinder are varied.
5. **Run to failure:** For each iteration first the damage parameters are calculated using the equation:

$$P_{i,j,k} = Kd_{i,j,k}\left(n_k\right) \cdot P_{crit,i,j} \tag{4}$$

where $P_{i,j,k}$ is the damage parameter for the failure mode i of the device j and the iteration k, $Kd_{i,j,k}\left(n_k\right)$ is the damage coefficient for the failure mode i of the device j and the iteration k (see Eq. 1 and 2), $P_{crit,i,j}$ is the critical parameter value for the failure mode i of the device j computed from the critical matrix crested in the preparation phase.
After the computation of the damage parameters, the physical model is run, and finally, the HI of each part is calculated. In case one of the parts has a HI equal to or less than zero the iterative process is terminated otherwise the next one is run.
6. **Post-processing:** At the end of the iterations, the collected data is saved and labeled with the RUL and the HI (depending on the use case) related to the corresponding iteration.

4. Data analysis and prediction model performance

In the conducted studies we assume that labelled data from the target domain (physical system) is available, which categorizes the proposed method as a supervised DA solution (Motiian, Piccirilli, Adjeroh, & Doretto, 2017). In fact, as soon as the generated R2F data from the simulation and the labelled asset sensor readings are available, the acquired data can be used to train a prediction model. In addition, gradient boosted trees (T. Chen & Guestrin, 2016) have been used to estimate the health status of the physical system, defined as HI or RUL, given the sensor readings from it. For evaluating the performance boost from PDP, two separate regression models (XGBR) with the same complexity will be trained using the following datasets:

- Limited annotated data (10% of the available data) from the physical system (the model trained with this dataset is referred to as **XGBR1**)
- Limited annotated data (10% of the available data) from the physical system and the R2F from the simulation model by employing PDP (the model trained with this dataset is referred to as **XGBR2**)

4.1. Use cases and experiments

In this industrial project, two different systems, from SMC Schweiz AG[1] and TCI engineering[2], are tested as use cases to inspect the scalability of the proposed method. The former, is a pneumatic pick and place demonstrator which can be used to mimic different failure types given various working conditions (*e.g.*, by changes in the main pressure of the compressed air). For this use case, the deployed model is used to predict the RUL of the system as degradation in the physical system does not cause any significant financial loss. In fact, this demonstrator is used to create real R2F data for testing the accuracy of the RUL predictions.

The latter; however, is used in a production line owned by

[1]https://www.smc.eu/de-ch
[2]https://www.tci-sa.ch/en/

a third-party company and thus no failures can be artificially built during production. For this use case only the HI of the system is predicted as no failure samples are available from the physical system. As shown later, given the changes in the working conditions, the customer's needs and minor inspections, there are numerous fluctuations in the HI values, resulting them not to be monotonic.

In what follows, the results of model performance comparison for predicting the RUL and HI is provided in detail. However, the similar results of feature importance distribution for RUL and HI predictions, subsection 4.3, and the robustness to the noise, subsection 4.5, are not included in order to conserve space. Nonetheless, this omission does not diminish the completeness of this paper in any manner.

4.2. Model accuracy for predicting the HI

The XGBR1 and XGBR2 prediction models are tested on the data attained from the physical system which were not previously exposed to them during model training. These model have the R^2 scores of 0.676 and 0.853 respectively, which indicates the superiority of the model trained with simulation data. Moreover, for ensuring that sample selection does not impact the accuracy comparison between XGBR1 and XGBR2, these accuracy values are calculate as the mean of accuracy given different seeds for sampling data from the physical system.

In addition, Fig. 8 demonstrates the progression of the HI of the physical system during approximately 3 months. Given the fact that, the data acquisition from the physical system did not start right after a maintenance, there is no reference asset behavior which represent a fully healthy behavior. Therefore, the calculated HI values are equally biased to start from a value which is as close to 1 as possible. In addition, as stated in subsection 4.1, numerous internal and external factors constantly impact the physical system during production, which prevents a monotonic HI sequence.

4.3. Feature importance distribution

The trained XGBRs can provide insight about the importance of different sensor readings from the system. In fact, importance values indicate how influential one feature is in determining the output of the prediction model. Considering that, data reading from industrial assets is not always perfect, it can be expected that there are scenarios where the attained data from an asset contains noise, has missing values or in an extreme case the installed sensor does not provide any data. In such situations, it is vital to determine the role of different sensor readings and also try to train models which use a wider range of sensor readings from the physical system. By doing so, erroneous predictions from the model are prevented, resulting in enhanced model reliability.

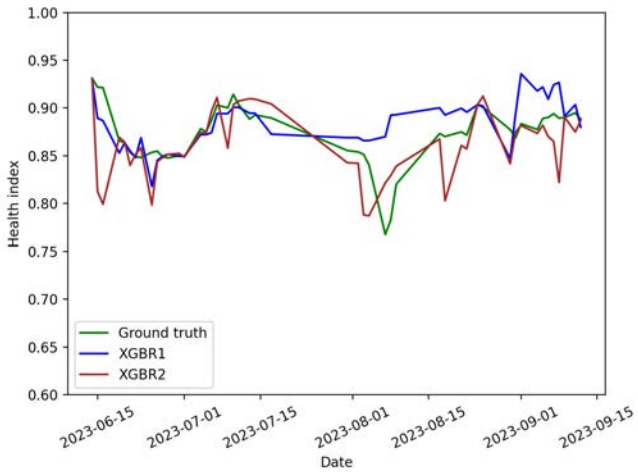

Figure 8. Asset HI along with XGBR1 and XGBR2 predictions

On a separate note, by comparing the significance of different asset readings, it is also possible to verify if the trained prediction model has converged to a PdM solution or is merely a preventive maintenance model relying on the cycle number.

As it can be seen in figures 9 and 10, given the sparsity of data from the physical model, the XGBR trained only using the data from the physical system has a highly unbalanced feature importance across different readings of the studied asset. Therefore, from a model reliability point of view, the simulation model can significantly enhance the performance of the model. Please note that for sake of anonymity and data protection for the involved industrial partner in the conducted studies, hashed sensor reading names are provided in the aforementioned figures.

4.4. Model comparison for predicting the RUL

The XGBR1 and XGBR2 trained for the SMC Schweiz AG demonstrator have fairly similar R^2 scores of 0.980 and 0.917 respectively. The higher accuracy in predicting the RUL is partially attributed to fact that the controlled laboratory setup allows us to control all the boundary conditions. Whereas in the shopfloor, the system is influenced by numerous factors that cannot be controlled or predicted, *e.g.*, a drop in pressure or regulation intervention. Additionally, it is also due to the fact that the induced failure in the system is a result of (semi-)linear opening of the valves in the demonstrator for mimicking leakage in various parts of the system. Nonetheless, as discussed in subsection 4.3, the XGBR1 model puts more emphasis on the information about the cycle count and ignores the information from the rest of the available sensor readings making it a less desirable solution given PdM requirements, especially in case that a faster failure than the ones seen before during model training occurs in the system.

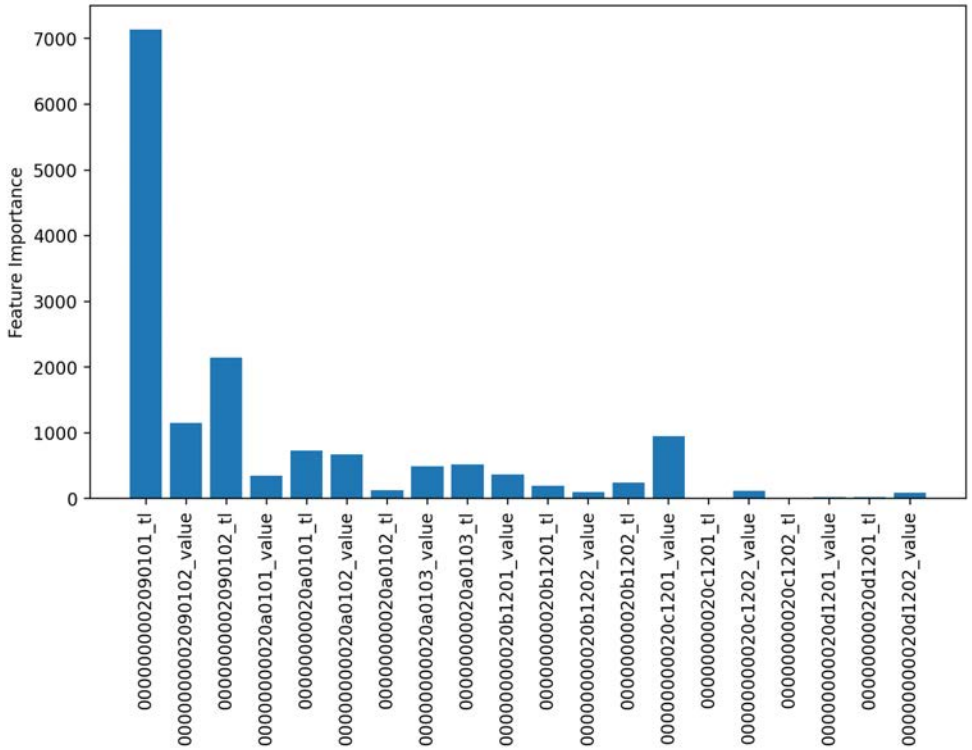

Figure 9. Feature importance among different asset sensor readings for XGBR1 model. This model relies on a limited number of sensor readings from the system

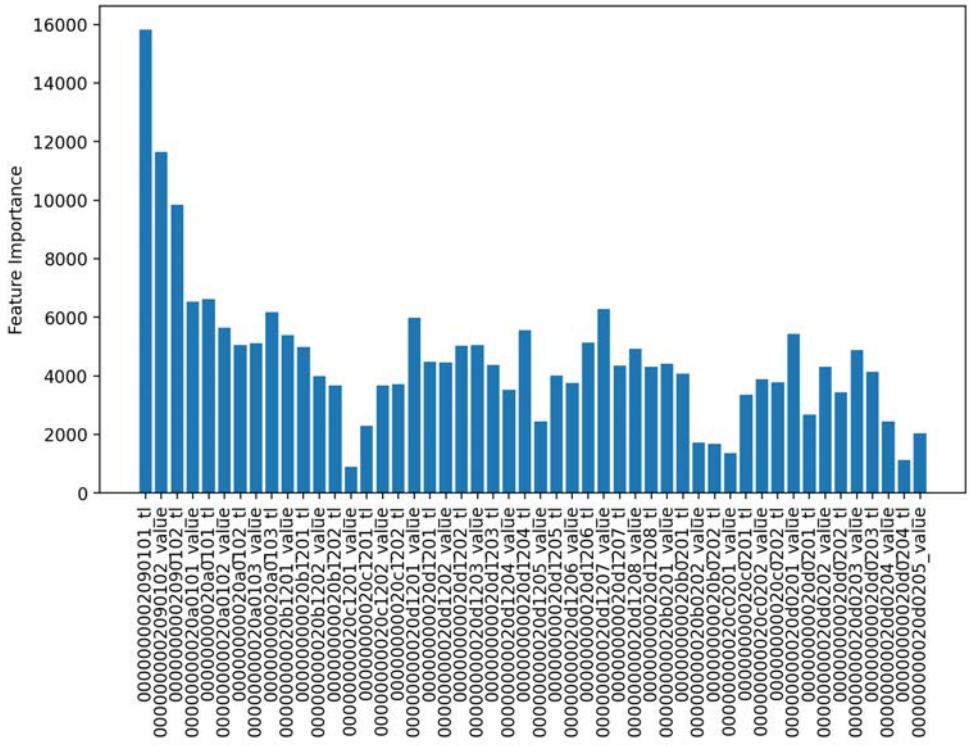

Figure 10. Feature importance among different asset sensor readings for XGBR2 model. This model has a more spread-out feature importance across different sensor readings of the system

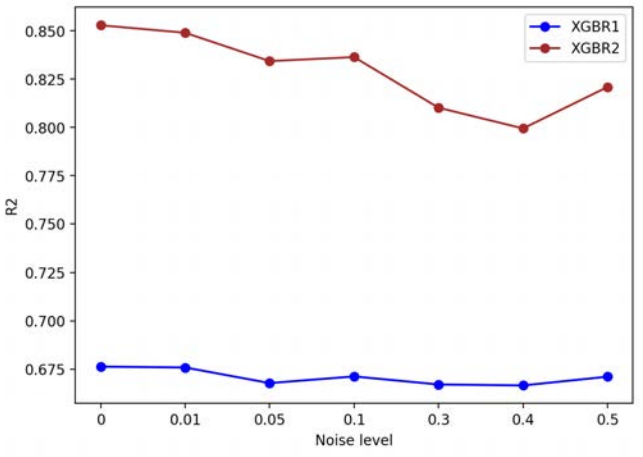

Figure 11. Impact of asset reading noise on the accuracy of the trained prediction models

4.5. Robustness to asset sensor reading noise

In this part of the conducted studies, the impact of noise on the most decisive asset readings on the accuracy of the XGBR1 and XGBR2 for the TCI engineering case are examined. For manipulating the asset sensor readings, 8 of the most influential features given the values in figures 9 and 10 are selected. Thereafter, samples of each of these features ($x^i \in X$) are distorted as follows:

$$x^i_{new} = x^i + Max\{x^j\}_{j=1}^{|X|} \times noise\,level \times d \sim N(0,1) \quad (5)$$

where $|X|$ is the total number of feature readings, $noise\ level$ is scalar value (see Fig 11) and d is a sampled value from $N(0,1)$ which represents normal distribution with mean of 0 and standard deviation of 1. Fig 11 shows the impact of noise on the R^2 score of the predictors. As it can be seen, regardless of the added noise value, the performance of the model trained with the additional simulation data is superior which suggest the robustness of the trained model compared to the prediction model trained only with scarce data from the physical system.

5. Discussion and Conclusion

Gathering annotated data from a physical system for developing PdM solutions is one of the most time-consuming and expensive steps which inhibits many end users in industry for utilizing the full potential of their production assets. In the conducted studies, we aimed to introduce a novel approach for RUL and HI prediction model training which uses data generated from a simulation model and a minimal set of samples from the physical system as apposed to complete R2F datasets from the asset. We aimed to highlight the importance of simulation data generation with PDP for covering as much as of the parameter space of an asset for enhancing the performance of the prediction model despite the scarcity of asset readings. It was shown how the proposed method, in the best case scenario, increases the R^2 score of the trained model by 26% while simultaneously using a wider range of sensor readings from the physical system. Furthermore, the results of model performance deterioration in presence of asset reading noise demonstrated that, regardless of the added noise to the readings, the R^2 score of the model trained with the additional simulation model data is higher. For the future work, we aim to develop classifiers for different working conditions of an asset and then find the corresponding regions of the data generated from the simulation model for a more fine-tuned data generation. In addition, we aim to inspect the performance of the prediction model in different regions of the parameter space and generate data from the simulation model which explicitly can boost the performance of the model in the chosen region of the parameter space.

ABSTRACT

Dynamic models of gears are recognized for offering a promising platform for gaining a profound understanding of the dynamic response, particularly the vibration signature. Wear is considered among the most common and concerning fault mechanisms in gears, yet its recognition and subsequent diagnosis remain challenging. In this study, we introduce an existing dynamic model of spur gear vibrations and extend its validation for distributed wear-like faults. The novelty of this work lies in addressing the complexities associated with modeling distributed faults using simplified yet sophisticated approaches. These involve variance among defected teeth, calculation of time-variant gear mesh stiffness, and consideration of the forces induced by the fault. The model is validated through pioneering controlled experiments, analyzing dozens of degrading distributed wear-like faults. This comparison verifies our capability to generate realistic simulations of vibration signals from worn gears. To bridge the discrepancy between the induced and simulated faults, the model first constructs the healthy profile of the inspected gear, incorporating manufacturing errors and tooth modifications. Subsequently, meticulous photography enables the replication of faults in the model with a high resemblance to the experiment. The results demonstrate a strong correlation between measured and simulated signals, as verified through trend analysis of features extracted from synchronous average signals in both the cycle and order domains. This study lays the groundwork for in-depth investigation into the physics of gear wear, paving the way for potential applications such as fault severity estimation and intelligent fault diagnosis in future studies.

1. INTRODUCTION

Predictive maintenance of gear wear is crucial, considering gears' pivotal role in rotating machinery and their constant susceptibility to failure due to operation in harsh regimes. Gear fault types can be broadly classified into localized faults such as breakage and cracks, and distributed faults such as abrasive wear and fatigue pitting. Abrasive wear, caused by oil contamination and sliding motion, leads to continuous destruction of the tooth surface, posing a viable risk of catastrophic failure due to reduced gear efficiency and high stress concentrations. Nevertheless, Feng, Ji, Ni, and Beer (2023) reviewed the latest developments in gear wear monitoring and demonstrated that diagnosing gear wear through vibration analysis is still challenging due to the intricate patterns manifested in the signature that remain unresolved. Physical models, such as tribological models (Archard, 1953) and dynamic models (Liang, Zuo, and Feng, 2018; Mohammed & Rantatalo, 2020), have been suggested over the years in order to bridge this gap.

Most of the published dynamic models of gear wear typically analyze the effects of wear on the time variant gear mesh stiffness (gms). Liu, Yang, and Zhang (2016) utilize a spur gear model to study the changes in the gms and transmission error due to wear, as well as the wear expression in the vibrations. Brethee, Zhen, Gu, and Ball (2017) introduce a helical gear model, validated through endurance tests, and analyze both the gms and the increase in frictional excitation with wear. Many other studies (Chen, Lei, and Hou, 2021; Cui et al., 2023; Ren & Yuan, 2022; Shen et al., 2020), incorporate Archard's tribological model in the dynamic model to calculate the worn surface, demonstrating the effect of wear on the dynamic characteristics. However, most of these models lack experimental validation, and in general, the coefficients in Archard's equation are largely unknown, making their evaluation in the models nontrivial.

In this work, we introduce a novel approach for modeling distributed wear-like faults in spur gears, validated through

experimentation. By leveraging simplifying assumptions, this modeling approach effectively captures the dynamic response of worn gears, while also facilitating its adaptation by other scholars in their models. In Section 2, we introduce the framework of the existing dynamic model, establishing the groundwork for this study. Section 3 delves into the simplified wear modeling approach, while Section 4 presents the experimental setup. Model validation is detailed in Section 5, accomplished through vibration analysis of the synchronous average signals and their spectrum. Finally, Section 6 concludes this work, providing insights and suggesting potential directions for future research.

2. DYNAMIC MODEL

This study adopts the dynamic model for spur gears proposed by Dadon, Koren, Klein, and Bortman (2018), which has been experimentally validated for healthy gears and various localized faults, serving as the foundation for this study. The simulated system has an open gearbox with torsional shafts connecting the driving pinion to a motor and the driven gear to a brake applying external torque, as illustrated in Figure 1. The vector of generalized coordinates (u) consists of 13 degrees of freedom: six for each wheel, representing linear displacement (x_i,y_i,z_i) and angular position (θ_i,φ_i,ψ_i) in space (where i=p,g), and another for the brake's angle (θ_b). Figure 2 presents a block diagram illustrating the model's stages. The vibration signal is generated by solving the Euler-Lagrange equations of motion, as described in Eq1.

$$M\ddot{u} + C\dot{u} + K(u) \cdot u = F(t, u) \quad (1)$$

Here, M, C, K, and F are the mass, damping, and stiffness matrices, and the excitation force vector, respectively. The non-linearity in $K(u)$ arises from the time-variant gear mesh stiffness (gms), computed using the potential energy method. The model is configured with parameters such as gear module, number of teeth, tooth width, and surface quality, alongside operational conditions like input speed and load. In contrast to many published models, where the gms is the sole non-linear component, this model introduces non-linearity in the excitation force vector. It incorporates deviations from the involute profile, such as surface roughness and faults, as displacement inputs along the Line of Action (LoA), which are subsequently transformed into forces by appropriately multiplying them with the gms. Thus, the excitation force consists of three components overall: the motor torque, the brake torque, and the force induced by displacements along the LoA, as shown in Eq. 2.

$$F = k_{\theta_p}\theta_m \cdot \hat{\theta}_p + T_b \cdot \hat{\theta}_b + gms \cdot \delta \cdot \bar{c} \quad (2)$$

Here, k_{θ_p} is the input shaft torsional stiffness, θ_m is the motor's angle, T_b is the brake's torque, δ is the displacement along the LoA, and $\bar{c}$ is a vector of geometric coefficients projecting this force onto u. $\hat{\theta}_p$ and $\hat{\theta}_b$ are unit vectors pointing to θ_p, θ_b, respectively.

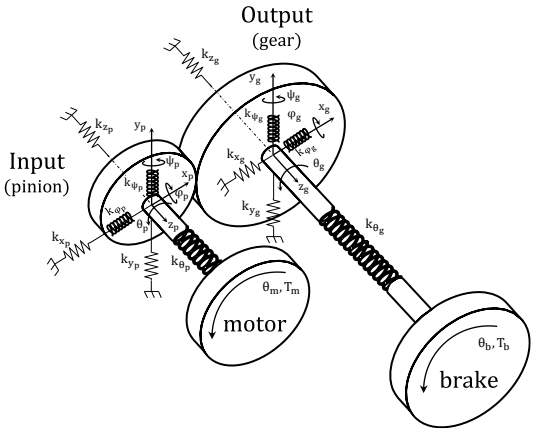

Figure 1. The simulated system (Dadon et al., 2018).

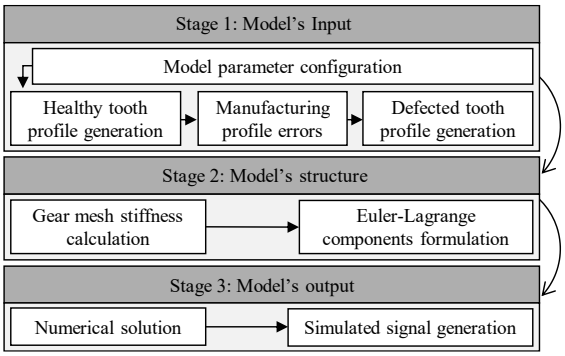

Figure 2. A schematic block diagram of the dynamic model.

3. GEAR WEAR MODELING

Any model development is grounded in premises that aim to balance the tradeoff between simplicity and reality (Mohammed & Rantatalo, 2020). We make the following assumptions that simplify our ability to simulate gear wear:

Assumption I: The worn profile is linear (or piecewise linear) and uniform along the tooth width, as illustrated in Figure 3.

Assumption II: The nominal parameters of the worn profile vary slightly among teeth.

Assumption III: The worn profile influences the cross-section properties of the tooth, thereby impacting the potential strain energy and, consequently, the gms.

Assumption IV: Contact properties such as contact ratio, pressure angle, and initial contact point remain unchanged. However, any deviation from the nominal LoA is treated as a displacement input in the excitation force.

It is crucial to acknowledge the limitations of these assumptions, as the gear wear mechanism is more complex, involving details not covered by these simplifications, such as sliding motion and improper contact. Nonetheless, these simplifications establish a foundation for comprehending the general wear behavior. The following subsections explore the effects of wear on the gms and the excitation force.

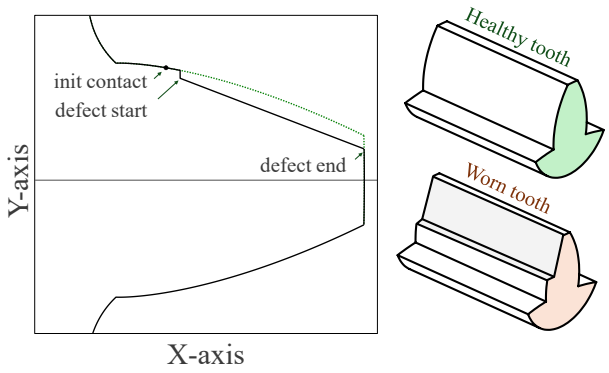

Figure 3. The simulated worn profile.

3.1. Effects of Wear on the Gear Mesh Stiffness

The computation of the gms commonly involves two steps, both are affected by wear. The first step employs the potential strain energy method for calculating the equivalent stiffness of a meshing tooth pair from engagement to separation. In this case, the influence of wear is self-evident, as tooth geometry is changed, and potential strain energy is derived from integration with respect to volume. The second step involves combining the equivalent stiffness of all tooth pairs based on the contact ratio governing the transition from a single pair to a double pair. In a healthy state, the equivalent stiffness can be computed once and then replicated and concatenated to form the cyclic gms. This procedure stays largely similar in case of localized faults, except for swapping the equivalent stiffness of one healthy pair with that of the defected pair. However, with distributed wear faults, where the worn profile varies among teeth, the equivalent stiffness is calculated individually for each tooth pair, and then meticulously combined, as depicted in Figure 4.

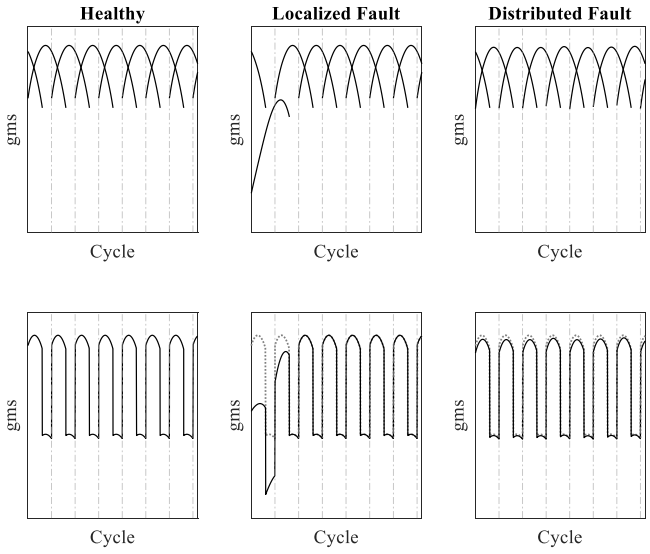

Figure 4. Construction of the gms signal in case of a healthy status, localized fault, and distributed fault.

3.2. Effects of Wear on the Excitation Force

One of the non-trivial assumptions made is that contact properties remain wear-invariant. While this assumption may be controversial, it is not without basis when appropriately compensated. As explained previously, deviations from the LoA are treated as displacement inputs in the excitation forces. The computation of the fault displacement involves straightforward geometric manipulations according to Eq. 3, using parameters depicted in Figure 5. Given that the fault displacement is unique for each tooth, it is multiplied by the equivalent stiffness of its corresponding pair, and the resulting product is then combined using the same procedure as in the gms, as depicted in Figure 6.

$$\delta_{\text{fault}} = (Y_{\text{invlt}} - Y_{\text{def}}) \cdot \frac{\cos(\gamma)}{\cos(\varphi + \gamma)} \tag{3}$$

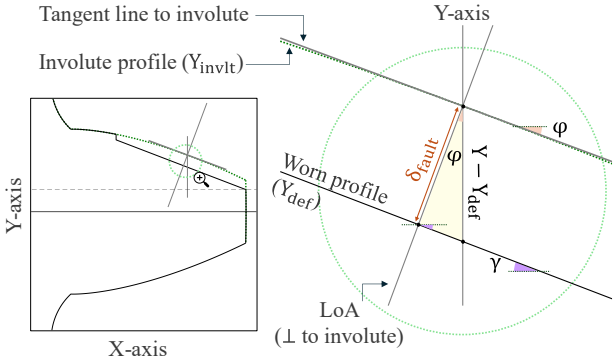

Figure 5. An illustration of the fault displacement calculation and the required parameters.

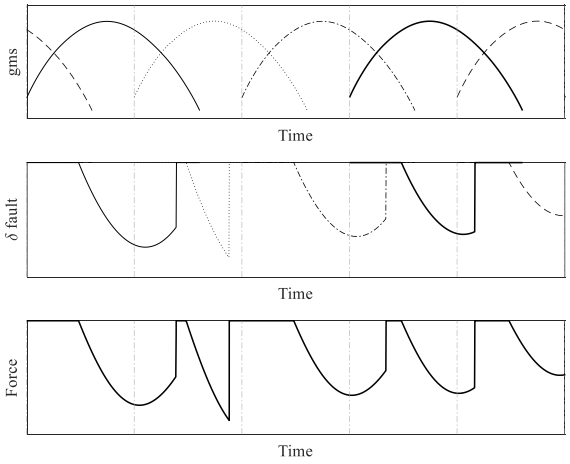

Figure 6. Generation of excitation force through fault displacement along the LoA, multiplied by the gms.

4. Experimental Setup

We conducted an extensive controlled experiment for model validation, employing a dedicated test apparatus for spur gears. Vibration data were collected for both a healthy (H) status and 35 degrading wear cases (W_i), using piezoelectric

accelerometers, alongside rotational speed measured by tachometers, as depicted in Figure 7. Details regarding the experimental program and gearbox parameters can be found in Table 1. The degradation of a reference tooth throughout the experiment is showcased in Figure 8. This figure includes photographs illustrating three cases corresponding to the beginning, middle and the end of the experiment. Additionally, a heatmap depicts the contour of all wear cases, with the color gradient correlating with fault severity.

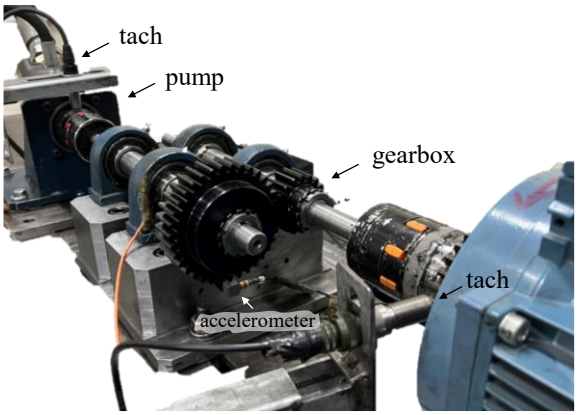

Figure 7. The experimental setup employed for validation.

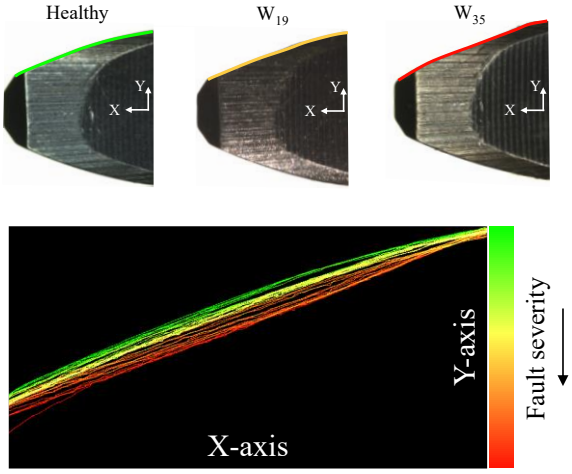

Figure 8. Photographs and heatmap depicting the profile degradation of a reference tooth throughout the experiment.

Table 1. Gearbox parameters and experimental program.

Gearbox parameters	
Module	3mm
Reduction ratio	35:18
Precision grade	DIN8
Experimental program	
Input speed	15rps, 45rps
Output Load	10Nm
Sampling rate	50kS/s
Signal duration	60s
Health status	H, $\{Wi\}_{i=1}^{35}$

5. Model Validation

The validation of the proposed wear modeling approach is empirical, relying on a qualitative comparison between simulation and experiment. This comparison involves analyzing trends in energy-based (such as rms) and shape-based (such as kurtosis) features extracted from the synchronous average (SA) signal and the difference signal in the cycle domain, and the SA spectrum in the order domain (Matania, Bachar, Bechhoefer, and Bortman, 2024). For both simulated and measured data, the SA is computed after the raw vibration signal undergoes angular resampling based on the output shaft's speed. It is essential to note that while the simulated signal is directly calculated at the wheels' center, the measured signal is significantly influenced by the transmission path between the gearbox and the sensor. This influence results in expected differences in spectral behavior, such as attenuations and resonances (Bachar et al., 2021, 2023). Consequently, experimental and simulated results are presented with left and right y-axes, with energy-based features normalized by the healthy (H) status according to Eq. 4, ensuring comparability of general trends.

$$F_{norm} = \frac{|F - F_H|}{F_H} \tag{4}$$

5.1. SA Analysis in the Cycle Domain

Figure 9 compares SA signals at 45rps in healthy status and for severe wear. Expected impulses appear in all the SAs. Both experiment and simulation show an amplified signal without sharp and rare impulsive responses due to wear, as expected. This observation highlights challenges in wear monitoring, as faulty signals may not emphasize the fault, creating a false impression of a healthy transmission.

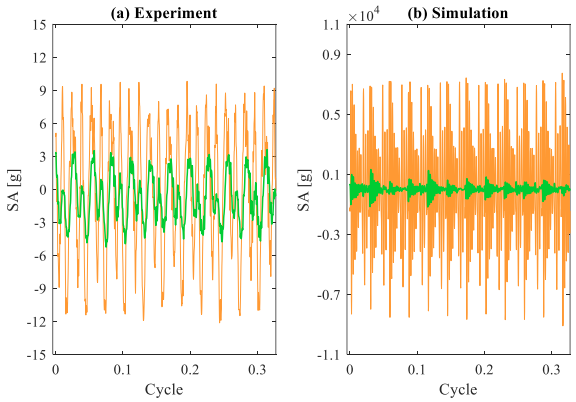

Figure 9. Comparison of SA signals between simulation (right) and experiment (left) at 45rps, in healthy (green) and severe wear (orange) statuses.

Figure 10 analyzes trends in SA rms, difference rms, and difference kurtosis across fault severity. Experimental results are depicted with error bars representing the scattering in the feature values. The following insights can be derived from these results:

- There is a strong correlation between simulation and experiment in rms trends, particularly evident in difference rms, where rms increases monotonously with wear degradation. Moreover, the "wavy" trend is observable in both simulation and experiment, suggesting that this behavior may have a physical basis.
- The higher speed (45rps) exhibits superior correlation between simulation and experiment. The purportedly weaker correlation at 15rps may be attributed more to the effects of speed and transmission path on the vibration signature (Bachar et al., 2021) rather than discrepancies.
- Kurtosis values are generally low and remain relatively stable. Given that kurtosis emphasizes sharp, rare impulses, which distributed wear faults are not expected to, it might not be suitable for gear wear monitoring. This insight is evident both in simulation and experiment.
- In most cases, discrepancies between simulation and experiment are more evident in more severe faults.

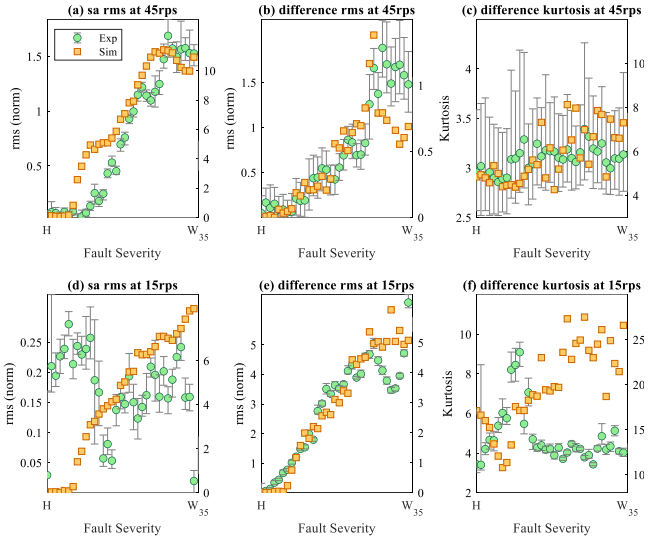

Figure 10. Trend analysis of features extracted from the SA and difference signals across fault severity at 45rps (top row) and 15rps (bottom row).

5.2. SA Analysis in the Order Domain

A comparison of the SA spectra across fault severity is presented in the spectrograms in Figure 11. For clarity, the top row in each spectrogram, corresponding to the healthy status (H), is thicker and separated from the degrading wear cases by a line. High amplitudes at the gearmesh harmonics are observed in all spectra, as expected. Furthermore, across both speeds and for both simulation and experiment, the general behavior with respect to fault severity is similar; that is, the spectral energy mostly varies monotonously with health degradation. However, the optimal wear manifestation for fault detection and degradation monitoring varies across different frequency bands for each combination of data source and rotational speed, as expected. The differences in spectrum background are expected to lead to such discrepancies, but as long as they are acknowledged, focus can be placed on the similarities obtained between experiment and simulation.

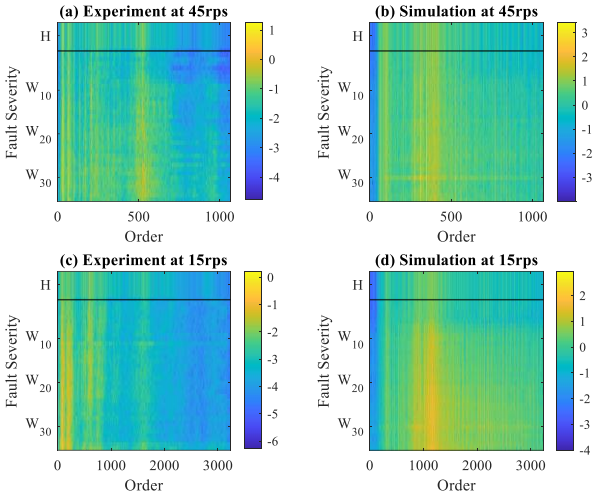

Figure 11. SA spectra across fault severity between experiment (left) and simulation (right) at 45rps (top) and 15rps (bottom).

Early research on gear monitoring (Randall, 1982) demonstrates the impact of distributed wear faults on gear mesh harmonics and modulation sidebands in the spectrum. To capture similar behaviors between simulation and experiment, we compute the gear mesh energy (gme) and modulation sideband energy (sbe) in the spectrum (X) according to Eq. 5-6 and compare their trends across fault severity, as depicted in Figure 12.

$$\text{gme} = \sum_{n=1}^{gm_{max}} |X(gm \times n)| \tag{5}$$

$$\text{sbe} = \sum_{n=1}^{gm_{max}} \sum_{m=1}^{gm/2} |X(gm \times n \pm m)| \tag{6}$$

Here, gm_{max} is the maximum number of gearmesh harmonics available within bandwidth. The following insights can be derived from the spectral analysis results:

- There is a strong correlation between simulation and experiment in both gme and sbe trends, closely mirroring the energy-based feature analysis in the cycle domain in Figure 10.
- Both spectral energies exhibit a monotonic variation with wear degradation, displaying the same "wavy" trend as discussed in the cycle domain analysis.

The spectral analysis aligns with the feature analysis in the cycle domain, confirming the similarity between simulated

and measured signals. Despite relying on a set of non-trivial assumptions, the proposed simplified modeling approach successfully captures the general wear patterns in the simulated signal. Moreover, while features for monitoring localized faults focus mainly on signal shape and modulation sidebands, gear mesh energy is also crucial for diagnosing wear faults. This holds true in both simulation and experiment across different speeds. Discrepancies between simulation and experiment, stemming from the assumptions made, are more pronounced in severe wear faults, as expected due to the challenging assumption of invariant contact properties with wear. Nevertheless, the strong similarities between simulation and experiment validate the model's ability to generate a simulated vibration signal reflecting the fundamental characteristics of gear wear.

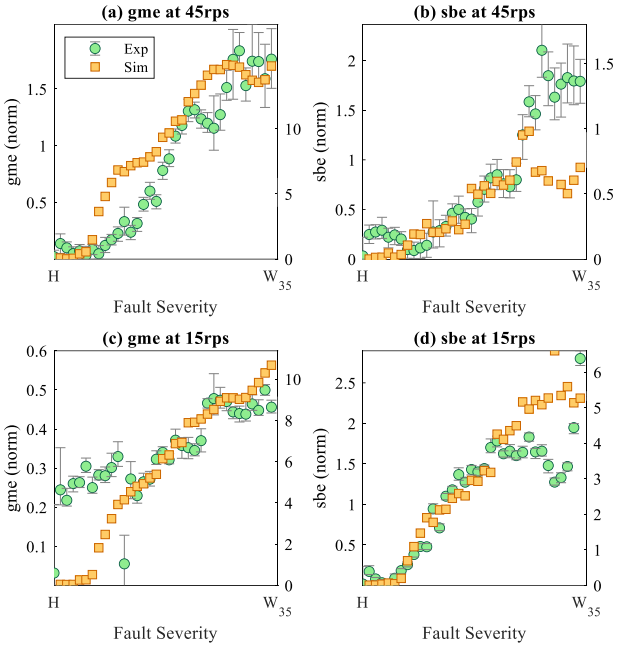

Figure 12. Comparison of spectral analysis of the gme (left) and sbe (right) between simulation and experiment at 45rps (top row) and 15rps (bottom row).

6. Conclusion

Gear wear monitoring is crucial for predictive maintenance, yet identifying patterns in the vibration signature associated with wear remains challenging. This study aims to bridge this gap by introducing a novel, simplified approach for simulating distributed wear-like faults. We make a set of assumptions to investigate wear characteristics essential for health monitoring, incorporating wear faults into an existing framework of dynamic model for gear vibrations. We demonstrated the impact of wear on the non-linear gear mesh stiffness and the excitation force according to the proposed modeling. Extensive controlled experiments validate our approach, comparing experimental and simulated results across different speeds and fault severities. A visual examination of the synchronous average signal and its spectrum across fault severity confirms that the proposed wear modeling closely resembles the experimental results, yielding similar insights. In-depth trend analyses of features in both cycle and order domains reveal crucial insights into the intricacies of wear monitoring, capturing "wavy" trends as the fault deteriorates. This underscores the importance of analyzing energy-based features, such as gear mesh energy and sideband energy, rather than shape-based features, for monitoring distributed wear faults. The strong correlation between experimental and simulated results confirms the feasibility of our approach, suggesting it as a simple yet effective enhancement for simulating wear faults in any standard dynamic gear model. Our study opens avenues for practical applications, including refining the simplified model for real-system applications and developing novel methods for wear prediction in future work.

ABSTRACT

When analyzing vibration and sound signals from rotating machinery, accurately tracking individual orders is crucial for diagnostic and prognostic objectives. These orders correspond to sinusoidal components, also known as deterministic signals, whose amplitude and phase are modulated in response to the angular speed of the machine. The extraction of these components leads to a more comprehensive approach to differential diagnostics. When the machine operates under varying conditions, consistently tracking the orders becomes challenging, particularly in nonstationary regimes with very fast variations. Typically, this issue is addressed using common techniques such as Vold-Kalman filter (VKF), where the bandwidth of the selective filter is adjusted to handle the speed variations. However, in the presence of high-speed fluctuations, manual adjustment of these weights becomes difficult to balance the compromise between achieving accurate tracking by effectively filtering around the speed variations, and maintaining a low estimation bias by reducing noisy errors. To overcome this constraint, the proposed methodology is driven by the need to integrate speed fluctuations into an optimal solution using VKF. This adaptation involves the consideration of angular acceleration profiles within the innovation process. In this context, the bandwidths are automatically adjusted to their optimal values according to the machine's regime. Optimality is achieved by crafting a model dependent on the order signal-to-noise ratio (SNR) and the auto-regression coefficient. This optimization allows for a practical adjustment tailored to the distinctive characteristics of each order. A comprehensive analysis of the resulting model transfer function reveals crucial insights into the impact of the given order SNR and the speed fluctuations. Subsequently, the methodology undergoes performance assessment through simulations and synthetic cases, showcasing its viability and effectiveness across various regimes. Notably, its practical application is highlighted in envelope-based bearing diagnosis, during operations characterized by variable-speed conditions, thus underlining its promise in real-world applications.

1. INTRODUCTION

In mechanical systems, gears and rolling-element bearings play vital roles in power transmission, necessitating reliable operation (Randall & Antoni, 2011). Vibration and acoustic signals emitted by these mechanical pieces (Braun, 1986) exhibit distinct cyclostationary (CS) behavior (Antoni, 2009). Gears generate first-order cyclostationary (CS1) components with a periodic mean, forming a harmonic spectrum corre-

sponding to their fundamental period. Rolling-element bearings, on the other hand, exhibit second-order cyclostationary (CS2) components marked by periodic autocovariance and an instantaneous envelope. These distinctions are crucial for differential diagnosis (Antoni & Randall, 2002), providing insights into overall system health. In stationary conditions, Fourier analysis simplifies the identification of CS1 components, which are characterized by their corresponding amplitude and phase. This facilitated the rise of order tracking, enabling the extraction of these characteristic components. These orders correspond to sinusoidal signals, also termed deterministic components, wherein its amplitude and phase modulations are influenced by the machine angular speed with respect to a reference angle. Subtracting the tracked ones reveals residual random aspects, including the CS2 environment, offering a comprehensive diagnostic perspective.

However, as mechanical systems venture into varying nonstationary regimes, the complexity deepens. These distortions are mainly introduced by the change of the machine power intake and the effect of transmission from the excitation source to the sensor. Even with the application of angular resampling to address frequency modulations stemming from nonstationarity (McFadden, 1989; Bonnardot et al., 2005; Borghesani et al., 2012), the Fourier coefficients representing an order in the spectrum lose their pristine sparsity. This degradation arises from the dynamic evolution of the envelope and is highly emphasized in the presence of high speed fluctuations.

An essential technique in navigating this complexity is the Vold-Kalman filter (VKF) (Vold et al., 1997). Proposed by Vold and Leuridan, VKF has been a cornerstone in the estimation of individual order components instantaneous amplitude and phase. This selective filtering is adapted by adjusting its bandwidth correspondingly to handle nonstationary conditions for each order (M.-C. Pan & Wu, 2007b). Further advancements have led to schemes that simultaneously estimate multiple orders, such as the angular-displacement (AD) (M.-C. Pan & Wu, 2007a) and angular-velocity (AV) (M. Pan et al., 2016) VKF. Considering other notable methods, the Sliding Window Tracking (SWT) (Pai & Palazotto, 2009) technique was introduced to track the varying instantaneous amplitude of a noise-contaminated signal with a moving average. It employs a constant and a pair of windowed regular harmonics to fit the data, providing implicit noise filtering capabilities. Recently, the so-called local synchronous fitting (LSF) has been proposed (Abboud et al., 2022). It was introduced as an enhancement to the global one (GSF) (Daher et al., 2010) in the sense that it estimates a cyclic-nonstationary (CNS) mean, but through a local polynomial fit, using the well-known Savitsky-Golay filter (Savitzky & Golay, 1964). The properties of the filter was also discussed in (Abboud et al., 2019). Interested readers can refer to (Randall et al., 2011) for a comparison among more relevant separation techniques.

While SWT, LSF and VKF are highly accurate in terms of envelope estimation, their limitations become pronounced when mechanical systems transition into fast nonstationary variations. On the one hand, even though SWT attempts to address nonstationary behavior, it assumes a fixed sliding window length, which is not optimal for handling high speed fluctuations. On the other hand, LSF suffers from the estimation of the Fourier coefficient from the centered signal by applying a linear angle-invariant convolution. In fact, from a signal point of view, this operation aims at estimating the mean (trend) of a non-stationary time series. While the classical low-pass filtering is efficient when the noise is (angle-stationary), it can be highly compromised in the case of non-stationary noise, in particular when the noise is impulsive. Finally, while the VKF's bandwidth can be customized to handle nonstationary speed variations, the compromise between accurate tracking and maintaining low estimation bias is emphasized. In addition, within high speed variations, manually adapting the filter nonstationary parameters may pose challenges in achieving optimized solutions leading to unbalance this compromise. Other variants and extended versions of the filter considered tracking the components of interest by maximizing the kurtosis (Dion et al., 2013) and tuning the bandwidth accordingly (Feng et al., 2022) to take into account the high amplitude fluctuation. The high-speed environment necessitates a methodology that explicitly incorporates speed fluctuations into its definition. Consequently, rather than adjusting the filter bandwidth parameters to meet predefined objectives, an optimal approach involves integrating speed fluctuations directly into the model.

Therefore, the paper aims to present a novel VKF optimized solution where the innovation process is directly affected by the speed fluctuations, thus the bandwidth is automatically adapted, yielding stationary hyper-parameters to be tuned: the order signal-to-noise ratio (SNR) and the auto-regression coefficient. Section 2 states the problem with a particular attention to formulating the transmission path effect from a CNS view, followed by a detailed exposition of the methodology in Section 3. Sections 4 and 5 validate the effectiveness of the proposed solution on numerical and experimental signals. In light of the obtained results, the paper is sealed with a general conclusion in Section 6.

2. Problem Statement

This section introduces the basic model that will serve to define the solution, which consists of Fourier series whose complex exponentials are function of the variable angle, θ, being a reference angle in the machine, and the coefficients are only dependent on the speed $\omega = \frac{d\theta}{dt}$, with the load effect omitted. Practically, when vibration and acoustic responses are measured from rotating and reciprocating machinery, the effects of flow noise, turbulence, and transient events are captured, in addition to the sum of rotational dynamics $x(t)$, such that

the total measured signal $y(t)$ is:

$$y(t) = x(t) + \nu(t), \tag{1}$$

where $\nu(t)$ is causal and uncorrelated with $x(t)$ such that it doesn't affect its generation or behavior. A temporal representation of a rotating machine's excitation is defined as

$$x(t) = \sum_k a_k(t) e^{j2\pi\alpha_k\theta(t)+\Phi_k}, \tag{2}$$

where the harmonic cyclic order $\alpha_k = \frac{k}{\Theta}$ such that Θ stands for the angular period of the rotating component of reference, $\theta(t)$ is the angular position of the reference expressed in [rad] and a_k and Φ_k are respectively the slowly varying complex envelopes and phases. In the particular case of constant operating speed (i.e. $\theta(t) = \omega_0 t$), $a_k(t)$ become essentially constant over time, representing the Fourier coefficients in the harmonic series. In such scenario, the synchronous average (SA) is one of the most used tools to extract such components (Braun, 1975; McFadden, 1987), with minimum disruption in the residual signal (Randall et al., 2011). The SA simply consists in slicing the signal (often after an angular resampling step) into cycles equal to the rotation period of the mechanical piece of interest and performing an empirical average to reject (or reduce) non-synchronous components including noise and interfering components. However, in the case of speed varying excitation, the complex envelopes $a_k(t)$ become slowly varying and principally dependent on the operating speed and its fluctuations (Abboud et al., 2016). Despite mild conditions under which higher derivative orders can be neglected, high-speed fluctuations still induce non-stationary behavior in the envelope, potentially leading to inaccurate estimations for each given order. Therefore, the study focuses on the first derivative order to showcase the impact of speed fluctuations on the deterministic component evolution, given by:

$$x(t) = \sum_k a_k(\omega(t)) e^{j2\pi\alpha_k\theta(t)+\Phi_k}. \tag{3}$$

3. Proposed Methodology

The mechanical vibration nature specifies that the envelope functions should be smooth and slowly varying over time. One way of specifying this, is to demand that a repeated difference should be small, which satisfies the following VKF equation in stationary mode,

$$\frac{\partial^q a_k(t)}{\partial t^q} = \varepsilon_k(t), \tag{4}$$

where q is the derivative order and ε_k is a process of uncertainties that degrades the envelope. During this study and for simplicity, an order $q = 1$ will be elaborated. This leads to the fact that, in stationary regime, the envelope will tend to be constant with stationary uncertainties. However, this model turns out to be more sophisticated in the case where $\omega(t)$ is varying with respect to time because the uncertainties also become nonstationary. This can be formulated as follows:

$$\frac{\partial a_k(\omega)}{\partial \omega} = \varepsilon_k(\omega). \tag{5}$$

With the angular velocity varying over time, the application of the chain rule leads to the formulation:

$$\frac{\partial a_k(\omega(t))}{\partial t} = \dot{\omega}(t)\varepsilon_k(\omega(t)). \tag{6}$$

Given the existence of multiple regime scenarios, it is essential to consider both stationary and nonstationary modes, allowing for a generalized modeling approach. This results in envelope uncertainties attributed to

$$\frac{\partial a_k(\omega(t))}{\partial t} = (1 + \lambda\dot{\omega}(t))\varepsilon_k(\omega(t)), \tag{7}$$

where λ serves as a weighting coefficient. To optimize the model based on diverse domain processes derived from (1) and (7), a discrete-time realization is established. The main processes are expressed as follows:

$$\begin{cases} y_k[n] = a_k[n]e^{j\alpha_k\theta[n]} + \nu[n] \\ a_k[n] - \beta_k a_k[n-1] = (1 + \lambda\dot{\omega}[n])\varepsilon_k[n] \end{cases} \tag{8}$$

where $y_k[n]$ represents the raw noisy component corresponding to the k^{th} harmonic and β_k is the auto-regression coefficient whose value is close to 1. In the following, both $\nu[n]$ and $\varepsilon_k[n]$ are supposed to follow complex Gaussian normal distributions with respective variance σ_ν^2 and $\sigma_{\varepsilon_k}^2$: $\nu[n]$ ~ $CN(0, \sigma_\nu^2)$ and $\varepsilon_k[n]$ ~ $CN(0, \sigma_{\varepsilon_k}^2)$. Since $\dot{\omega}[n]$ and $\varepsilon_k[n]$ are independent, one can deduce that their product variance is equal to $(1+\lambda\dot{\omega}[n])^2 \times \sigma_{\varepsilon_k}^2$. Thus, the definition of the two processes:

$$P_1 : \mathbf{Y}_k - \mathbf{A}_k\mathbf{E}_k = \mathbf{V}, \tag{9}$$

where $\mathbf{Y}_k$, $\mathbf{E}_k$ and $\mathbf{V}$ are expressed as follows:

$$\mathbf{Y}_k = \begin{bmatrix} \vdots \\ y_k[n] \\ \vdots \end{bmatrix}, \mathbf{E}_k = \begin{bmatrix} \ddots & & \\ & e^{j\alpha_k\theta[n]} & \\ & & \ddots \end{bmatrix}, \mathbf{V} = \begin{bmatrix} \vdots \\ \nu[n] \\ \vdots \end{bmatrix}.$$

$$P_2 : \mathbf{D}_k\mathbf{A}_k = \mathbf{\Psi}\xi_k, \tag{10}$$

such that $\mathbf{A}_k$ and the sparse matrix $\mathbf{D}_k$ are expressed as

$$\mathbf{A}_k = \begin{bmatrix} \vdots \\ a_k[n] \\ \vdots \end{bmatrix}, \mathbf{D}_k = \begin{bmatrix} 1 & 0 & 0 & \dots & 0 \\ -\beta_k & 1 & 0 & 0 & 0 \\ 0 & -\beta_k & 1 & 0 & 0 \\ \vdots & 0 & \ddots & \ddots & 0 \\ 0 & 0 & 0 & -\beta_k & 1 \end{bmatrix},$$

along with $\mathbf{\Psi}$ and $\boldsymbol{\xi}_k$ expressed as:

$$\mathbf{\Psi} = \begin{bmatrix} \vdots \\ 1 + \lambda\dot{\omega}[n] \\ \vdots \end{bmatrix}, \boldsymbol{\xi}_k = \begin{bmatrix} \vdots \\ \varepsilon_k[n] \\ \vdots \end{bmatrix}.$$

3.1. A Posterior Estimate of the Envelope

With regards to the envelope's dependencies, one can explicitly describe its likelihood and prior distribution. As a result, the a posterior estimation of A_k can be defined by the Maximum a posteriori estimate (MAP):

$$\begin{aligned} \hat{\mathbf{A}}_k &= \text{Argmax}(P(\mathbf{A}_k|\mathbf{Y}_k)) \\ &\propto \text{Argmax}(P(\mathbf{Y}_k|\mathbf{A}_k)P(\mathbf{A}_k)). \end{aligned} \tag{11}$$

After setting $\mathbf{\Gamma}_k = \mathbf{D}_k\mathbf{A}_k$ to simplify the process formulation, the Bayes Theorem can be applied to P_2 in order to compute $P(\mathbf{A}_k)$ as follows:

$$P(\mathbf{A}_k) = \int P(\mathbf{A}_k, \mathbf{\Gamma}_k) d\mathbf{\Gamma}_k. \tag{12}$$

One can deduce from Eqs (10) and (12) that

$$P(\mathbf{A}_k) = P(\mathbf{\Gamma}_k)|\mathbf{D}_k|, \tag{13}$$

To initiate the MAP estimate, the likelihood conditional probability $P(\mathbf{Y}_k|\mathbf{A}_k)$ and the prior one $P(\mathbf{A}_k)$ can be expressed accordingly:

$$P(\mathbf{Y}_k|\mathbf{A}_k) = \frac{1}{\pi\sigma_\nu^{2N}} e^{-\frac{\|\mathbf{Y}_k - \mathbf{E}_k\mathbf{A}_k\|^2}{\sigma_\nu^2}}, \tag{14}$$

$$P(\mathbf{A}_k) = \frac{1}{\pi\sigma_{\varepsilon_k}^{2N}\mathbf{\Omega}} e^{-\frac{\|\mathbf{A}_k^T\mathbf{D}_k^T\mathbf{\Omega}^{-1}\mathbf{A}_k\mathbf{D}_k\|}{\sigma_{\varepsilon_k}^2}} |\mathbf{D}_k|, \tag{15}$$

where $[\mathbf{\Omega}]_{ij} = \delta_{ij}\mathbf{\Psi}[i]^2$ and δ_{ij} is the Kronecker delta. Plugging Eqs (14) and (15) into Eq (11) result minimizing an objective function $J(\mathbf{A}_k)$ represented by:

$$J(\mathbf{A}_k) \approx \frac{\|\mathbf{Y}_k - \mathbf{E}_k\mathbf{A}_k\|^2}{\sigma_\nu^2} + \mathbf{A}_k^T\mathbf{D}_k^T\frac{\mathbf{\Omega}^{-1}}{\sigma_{\varepsilon_k}^2}\mathbf{D}_k\mathbf{A}_k \tag{16}$$

such that $\mathbf{M}^T$ represents the transpose of $\mathbf{M}$. In order to find the minimum, the derivative of $J(\mathbf{A}_k)$ with respect to the variable of interest $\mathbf{A}_k$ is set to 0: $\frac{\partial J(\mathbf{A}_k)}{\partial \mathbf{A}_k} = 0$. As a result, the estimated $\hat{\mathbf{A}}_k$ can be computed as

$$\hat{\mathbf{A}}_k = \left(\mathbb{I} + \frac{\sigma_\nu^2}{\sigma_{\varepsilon_k}^2}\mathbf{D}_k^T\mathbf{\Omega}^{-1}\mathbf{D}_k\right)^{-1}\mathbf{E}_\mathbf{k}^\mathbf{H}\mathbf{Y}_k \tag{17}$$

such that $\mathbf{E}_k^H$ is the conjugate of $\mathbf{E}_k$ and $\mathbb{I}$ is the identity matrix. It can be identified from the resulted model that, $\hat{\mathbf{A}}_k$ depends on the constant ratio $\rho_k = \frac{\sigma_\nu^2}{\sigma_{\varepsilon_k}^2}$ which is none other than the inverse SNR of the k^{th} harmonic.

3.2. Filter Frequency Response Function

In order to interpret the model frequency response function (FRF), a simple scheme is considered in Fig. 1 such that the objective is to find $|H_k(f)|^2$ that would result in $A_k(f)$ from $Y_k(f)$. In order to define $|H_k(f)|^2$, the speed $\omega(t)$ is assumed

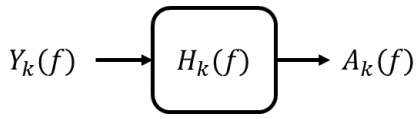

Figure 1. Scheme illustrating the transfer function $H_k(f)$ processing input $Y_k(f)$ to produce output $A_k(f)$.

to be constant or slowly varying, ensuring fixed frequency and allowing the FRF to make sense for each frequency, which results in $\dot{\omega}[n] \approx 0$. In addition, it is noteworthy that, as the filter automatically adapts to speed fluctuations, its stationary parameters remain valid regardless of the operating regime. Consequently, the FRF will be analyzed primarily under stationary conditions, ensuring correct parameters estimation. Recalling the processes described in Eq. (8), its respective power spectral densities would take the following form:

$$S_{Y_k}(f) = E|Y_k(f)|^2 = E|A_k(f)|^2 + E|V(f)|^2, \tag{18}$$

$$S_{A_k}(f) = E|A_k(f)|^2 = \frac{E|\xi_k(f)|^2}{|1 - \beta_k e^{-j2\pi f}|^2}. \tag{19}$$

Knowing that $E|V(f)|^2 = \sigma_\nu^2$ and $E|\xi(f)|^2 = \sigma_\varepsilon^2$, S_{H_k} can be computed as follows:

$$S_{H_k}(f) = \frac{S_{A_k}(f)}{S_{Y_k}(f)} = \frac{1}{1 + \rho_k|1 - \beta_k e^{-j2\pi f}|^2}. \tag{20}$$

Based on Eq. (20), it seems to behave like a low pass filter. For a comprehensive understanding, it is crucial to investigate the parameters of the FRF and the frequencies associated with typical filters. In this analysis, the following parameters are defined in the logarithmic:

$$\begin{cases} \ln(|H(0)|^2) = -\mu_0 \\ \ln(|H(f_p)|^2) = -\mu_p \\ \ln(|H(f_s)|^2) = -\mu_s \end{cases} \tag{21}$$

such that

1. f_p: The passband frequency.
2. f_s: The stopband frequency.
3. $-\mu_0$: Log of the FRF at $f = 0$.
4. $-\mu_p$: Log of the FRF at the passband frequency f_p.
5. $-\mu_s$: Log of the FRF at the stopband frequency f_s.

To illustrate these parameters, consider Figure 2 that depicts an example of lowpass filter with the passband frequency f_p, stopband frequency f_s and other associated parameters.

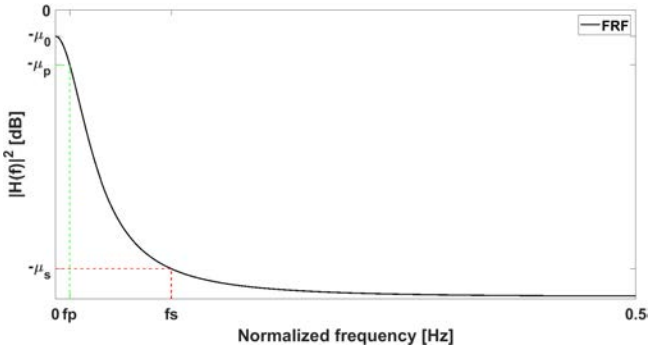

Figure 2. Illustration of a theoretical first-order lowpass filter with the corresponding characteristics.

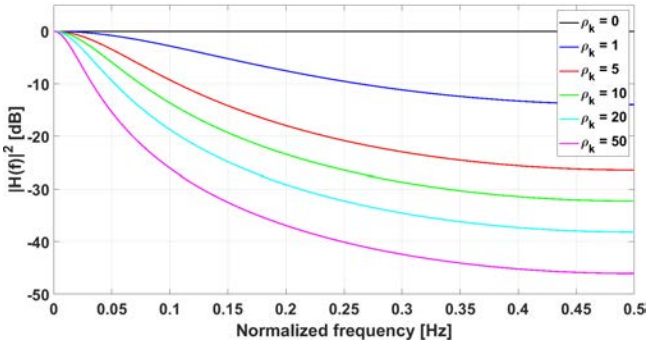
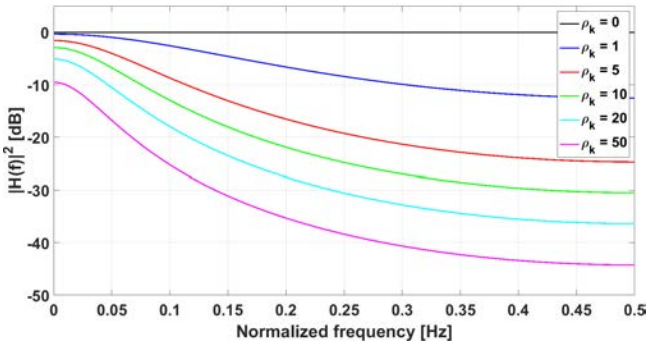
In Figures 3a and 3b, the FRF for the proposed filter is illustrated under various conditions. Each figure depicts the FRF for different values of ρ_k, showcasing the impact of this parameter on the filter's behavior.



(a)



(b)

Figure 3. Plots of the frequency response function using various ρ_k values with respect to (a) $\beta_k = 1$ and (b) $\beta_k = 0.8$.

Furthermore, the illustrations explore the influence of β_k, presenting results with $\beta_k = 1$ & $\beta_k = 0.8$ respectively. The distinctive curves in each plot reveal the sensitivity of the filter to the model parameters ρ_k and β_k, providing valuable insights into its performance characteristics.

4. Numerical Experiment

Deterministic components encountered in rotating machine signals operating under nonstationary regimes are generally sinusoidal components whose amplitudes and phases are modulated through smooth functions. These amplitude modulations typically arise from resonance encounters or shifts in internal forces. Phase alterations may stem from variations in time delays resulting from mechanical system transfer functions interacting with excitation frequencies, or from torsional oscillations in shafts. To capture these dynamics, the following sinusoidal model is adopted:

$$y[n] = \sum_{k=1}^{3} a_k[n] sin\left(2\pi k \sum_{m=0}^{n} \omega[m] + \Phi_k[n]\right) + \nu[n] \tag{22}$$

where

1. $y[n]$ is the generated signal sampled at 10kHz over a 10 second acquisition window (i.e. resulting in 100 ksamples)
2. $\omega[n]$ stands for the instantaneous frequency of the reference rotating shaft (i.e. the fundamental frequency of the process associated with the order 1) simulated using a first order autoregressive process (see top Figure 4),
3. $a_k[n]$ and $\Phi_k[n]$ are respectively the amplitude and the phase modulations associated with the k^{th} harmonic (see middle and bottom Figure 4), made of linear combination of the square of $\omega[n]$, $\nu[n]$ is a stationary gaussian noise.

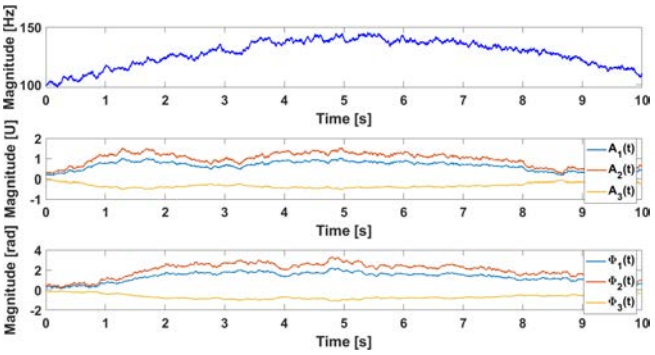


Figure 4. Plots of: (top) the speed constructed using a first order auto-regressive process, (middle) the 3 amplitudes $a_k[n]$ and (bottom) the 3 phase modulations $\Phi_k[n]$ associated with the sinusoids of the synthetic signal.

The signal-to-noise (power) ratio equals -10dB. The proposed methodology is implemented on the signal, alongside three other methods for comparative analysis: SWT, LSF, and VKF with stationary bandwidth in order to assess the efficacy of the speed adaptation proposed in this study. For SWT, the window length was optimized to achieve the best performance,

resulting in a length of 125 samples per sliding window. LSF is applied to the signal after resampling in the angular domain, employing a polynomial order of 5 and a window length of 75 samples. The conventional and proposed VKF parameters, namely β_k and ρ_k, are fine-tuned to achieve the values presented in Table 1. These parameters are crucial as they directly impact the filtering process and subsequent signal analysis. The actual (noise-free) signal, the estimated signals and corresponding errors are displayed in Figure 5 for each method. It is clear from the figure that the proposed estimation is more accurate than the other used techniques: Table 2 shows that the proposed error signal has a significantly lower relative mean error compared to SWT, LSF and VKF.

Table 1. Filter tuned parameters for the simulation case.

Parameters	Value
β_k	$\{0.988, 0.991, 0.957\}$
ρ_k	$\{45, 35, 75\}$
λ	1

Table 2. Relative mean errors of each used method.

Used method	Relative mean error %
SWT	4.18
LSF	8.44
VKF	6.60
Proposed method	**1.84**

For further interpretation of the proposed methodology, the envelope estimation is visualized in Figure 6 to assess the evaluation with respect to the reference one (actual envelope). It is essential to see how the model kept track of the envelope related to each of the 3 cyclic orders. In addition, the FRF along with the extracted component of the first cyclic order are displayed in Figures 7 and 8 to have a better comprehensive understanding of the model with respect to the chosen

parameters β_k and ρ_1. It can be seen in the resiudal within the Figure 8 that the first tracked order was completely extracted after using the FRF displayed in 7. After iterating

over the 3 orders, the spectrograms of the raw, extracted and residual signals are displayed in Figure 9. Since the signal is generated in a nonstationary regime, time-frequency representation (TFR) is a popular tool to present those time-variant components before resampling into the angular domain. This

is done to show that the proposed methodology filters well the 3 harmonics of interest from the raw signal.

5. Application

This section presents the evaluation of the methodology using real experimental data acquired from the KU Leuven Diagnostic test rig (Yazdanianasr et al., 2024), as depicted in Figure 10. The test rig comprised an electric drive motor, a first housing containing a healthy bearing, and a second housing with two cases: one featuring large damage to the inner race of the test bearing and another case involving small damage to the outer race. The bearings used are SKF 2206 ETN9 bearings. The experimental setup also included the mounting of two ICP accelerometers (PCB-model number 352A10) on the housing of the bearings. Additionally, two B&k type 4188 microphones were installed as seen in the figure of the test rig. Furthermore, a smartphone, capturing through its microphone (considered as the low quality microphone in this acquisition), was placed behind the second microphone. Finally, an encoder was installed on the end of the electric motor to keep track of the angular position, providing a reliable estimate of the angular speed. Notably, the sampling frequency for all sensors, excluding the smartphone, was about 102.4 kHz. Given the smartphone's sampling frequency of 44.1 kHz, resampling was necessary to synchronize its data with that of the other sensors. The experiment aims to discern

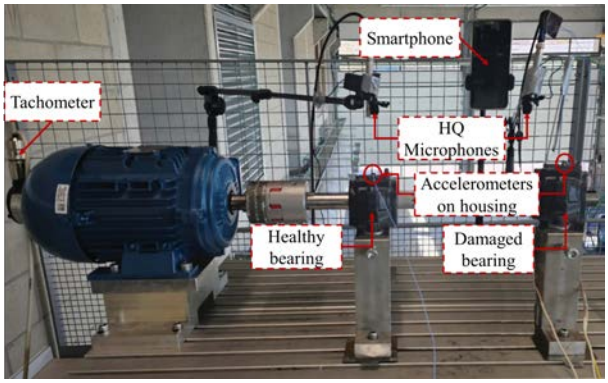

Figure 10. KU Leuven Diagnostic test rig.

both types of faults mentioned before, captured under a non-stationary regime. Naturally, signals from the accelerometer positioned on the upper part of the damaged bearing housing provide insights into significant damage to the inner race fault case. However, the experiment goes a step further by utilizing signals from the smartphone, which captures data from a distance near the upper part of the housing, revealing small damage for the outer race case. This small fault presents a significant challenge, as its detection amidst the presence of CS1 components can be particularly difficult to achieve, polluted by additional noise from the outside environment. Therefore, the experiment will be divided into two cases: the Large Inner Race Fault Case and the Small Outer Race Fault Case.

5.1. Large Inner Race Fault

In this initial experiment, the speed profile employed, as depicted in Figure 11, primarily exhibited random behavior to provide a highly nonstationary condition. The corresponding raw accelerometer signal is also displayed in Figure 12. In

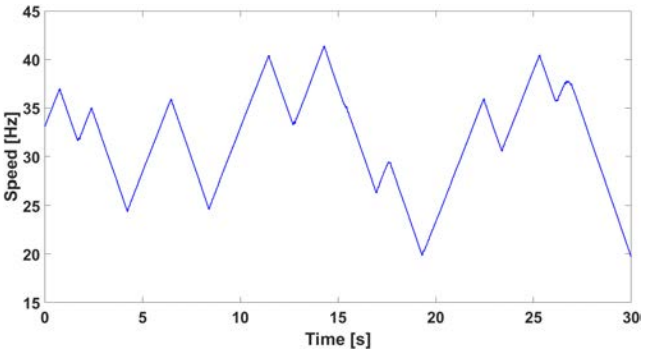

Figure 11. First experiment random walk-like speed profile

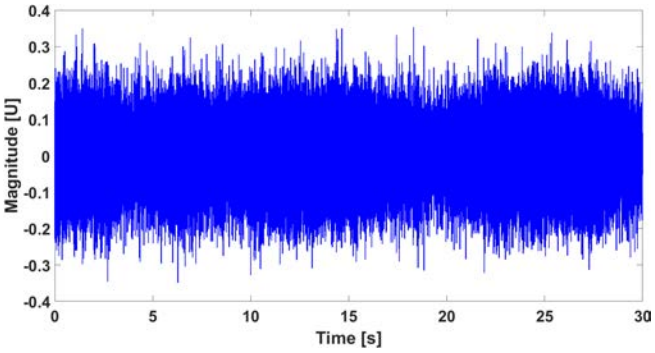

Figure 12. First experiment raw accelerometer signal depicting the varying signal envelope.

the initial phase, pinpointing the bandwidth containing critical CS2 information is essential. Utilizing the well known kurtogram (Antoni & Randall, 2007) can facilitate the detection of pertinent details. In this instance, the bandwidth yielding the highest kurtosis fell within the range of [815, 865] shaft order. Consequently, the CS1 orders to be tracked align with the speed components that reside within the frequency

band of [16300, 17300] Hz. After identifying 6 speed dependent orders, their deterministic components were extracted using the proposed technique. Upon fine-tuning the parameters of the methodology, the values shown in Table 3 were attained. The speed fluctuation weight λ was set the same for all harmonics to control the stationary-nonstationary adjustment. To evaluate the impact of the model with the specified parameters, close-up spectrograms of the raw signal, the extracted CS1 components, and the residual are presented in Figure 13. This enables observation of the significant attenuation of the speed components, tracked with the defined orders. Additionally, the speed profiles corresponding to the tracked orders are displayed with red dashed lines. The described processing steps are applied both to the raw signal and the residual one to compare the attenuation of speed dependent deterministic components. Initially, angular resampling is performed to mitigate frequency modulations. Subsequently, both angular signals undergo filtering within the specified bandwidth to isolate bearing signature information. A Hilbert transform is then employed to extract the envelope of the resulting complex signal. Finally, the squared envelope spectrum (SES) of the angular filtered signals is computed for evaluation. Figure 14 compares both SES, emphasizing the bearing fault contribution after the elimination of the extracted components. The analysis reveals that while extracting deterministic components, it also impacted the BPFI modulations. These modulations, typically associated with CS2 components, showed attenuation due to interactions with deterministic speed components. This suggests that the BPFI signature, not being entirely random, led to the attenuation of its deterministic part.

Table 3. Filter tuned parameters for the first experiment.

Parameters	Value
β_k	$\{0.995, 0.987, 0.999, 0.979, 0.988, 0.954\}$
ρ_k	$\{4320, 7664, 4211, 8853, 5333, 9912\}$
λ	0.01

Squared envelope spectrum of: (top) raw signal and (bottom) residual signal highlighting the BPFI multiples (red dashed lines), the speed harmonics (blue dashed lines) and the modulations of the first BFPI (purple markers), showing the attenuation of the speed components in the residual one.

5.2. Small Outer Race Fault

In the second experiment, the utilized speed profile, illustrated in Figure 15, primarily demonstrated a steady-hop behavior. The corresponding raw smartphone microphone signal is also displayed in Figure 16 to demonstrate the variation of its envelope in tandem with the changes in speed. Similar to the initial steps taken in the first experiment, efforts were made to identify the bandwidth containing crucial CS2

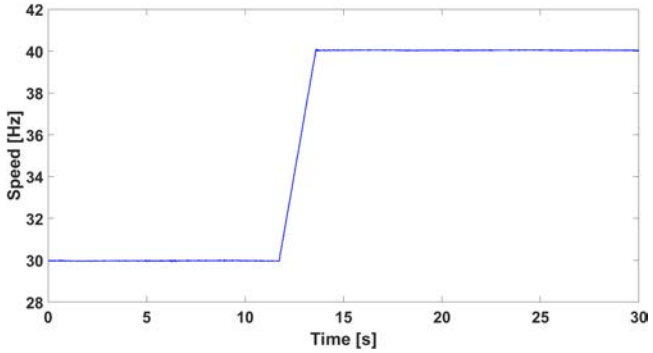

Figure 15. Second experiment steady-hop speed profile

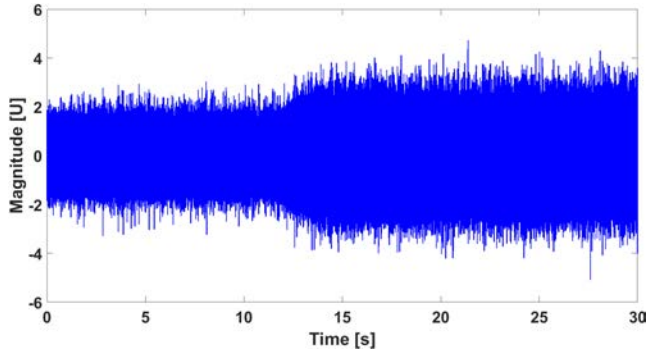

Figure 16. Second experiment raw smartphone microphone signal depicting the variation of the signal envelope mirroring the changes in the speed profile.

information. However, in this instance, the analysis was performed using data acquired from the smartphone instead of the accelerometer. The analysis revealed that the bandwidth with the highest kurtosis, as determined by the kurtogram, fell within the range of [333, 353] shaft order. For the second experiment, a similar process was followed to identify 8 speed dependent orders and extract their deterministic components using the proposed technique. The parameters of the methodology were fine-tuned to achieve the values described in Table 4. To assess the impact of the model with these specified parameters, close-up spectrograms of the raw signal, the extracted CS1 components, and the residual are provided in Figure 17 which facilitates observation of the significant attenuation of the speed components tracked with the defined orders.

Table 4. Filter tuned parameters for the second experiment.

Parameters	Value
β_k	$\{0.947, 0.955, 0.994, 0.936, 0.961, 0.887, 0.947, 0.984\}$
ρ_k	$\{12206, 11791, 8645, 13662 \; 9197, 21111, 12206, 10167\}$
λ	0.01

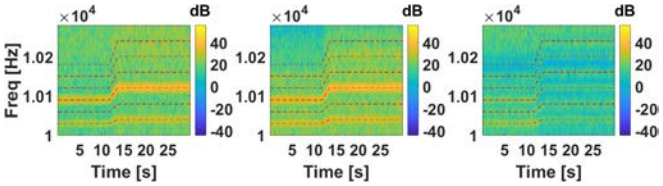

Figure 17. Second experiment close-up spectrograms of the vibration signals. (Left) Raw signal, (Middle) extracted components, and (Right) residual signal with tracked speed profiles (red dashed lines).

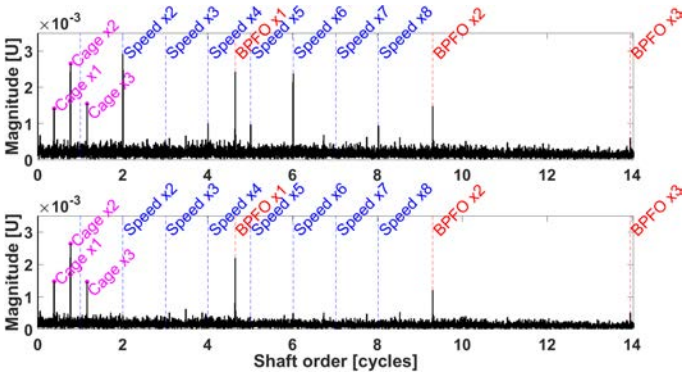

Figure 18. Squared envelope spectrum of: (top) raw signal and (bottom) residual signal highlighting the BPFO multiples (red dashed lines), the speed harmonics (blue dashed lines) and the cage frequencies (purple markers), showing the attenuation of the speed components in the residual one.

Similarly, for the second experiment, the processing until the computation of the SES was carried out on the raw signal and its residual to identify the Ball Pass Frequency Outer Race (BPFO). A comparison of both raw and residual SES are illustrated in Figure 18.

6. Conclusion

The paper introduced an extension of the Vold-Kalman Filter for better tracking of large nonstationary operating regimes. This extension is achieved by dynamically adapting the filter's bandwidth to accommodate fluctuations in speed. In the preliminary analysis, the frequency response function is also examined to provide insights into the filter's behavior. Numerical simulations are conducted to evaluate and compare the performance of conventional techniques against the proposed methodology. Additionally, the dependency on speed fluctuations is tested in a real-world application, specifically for enhanced bearing diagnostics. The adaptability to speed fluctuations ensures consistent and accurate performance across varying operational conditions, enhancing the effectiveness of machinery health monitoring. Looking ahead, future research could explore extending the proposed methodology to a higher filter order and automating the hyperparameter selection.

ABSTRACT

This paper introduces a novel approach to machinery fault diagnosis, addressing the challenge of domain generalization in diverse industrial environments. Traditional methods often struggle with domain shift and the scarcity of balanced, labeled datasets, limiting their effectiveness across varied operational conditions. The proposed method leverages the abundance of healthy machinery signals as a reference for extracting domain-specific information. By doing so, it removes the domain-related variances from the observation signals, focusing on the intrinsic characteristics of faults. The methodology is validated with a case study, demonstrating enhanced diagnosis accuracy and generalization capabilities in unseen domains. This research contributes to the field of vibration-based intelligent fault diagnosis by providing a robust solution to a long-standing problem in machine condition monitoring.

1. INTRODUCTION

In the domain of industrial maintenance, ensuring the reliability and efficiency of rotating machinery is a central challenge. Among the various strategies employed, vibration-based fault diagnosis stands out as a proven technique for preemptive detection and mitigation of potential failures (Randall, 2010).

The advent of the Industrial Internet of Things (IIoT) and the proliferation of sensor technologies have led to an unprecedented availability of machinery data. This, in turn, has facilitated the application of intelligent diagnosis methods (Liu, Yang, Zio, & Chen, 2018) which showed impressive performance. Despite this, the use of these methods in real industrial scenarios has been proven difficult, mainly because it relies on a central assumption which is often hard to meet. Indeed, most Machine Learning (ML), including Deep Learning (DL) diagnosis techniques learn a representation of the training data in order to generalize to unseen examples. The unseen examples, also referred to as test data, must then follow the same distribution as the training data to ensure effective generalization by the model. The unpredictability of industrial environments and the varying working conditions of rotating machines significantly challenge this assumption. This results in overfitting on the working conditions the model has been trained on, and leads to a dramatic decrease in performance when conditions change.

Transfer learning has emerged as a popular strategy to address this challenge, aiming to leverage knowledge from one domain to improve performance in another. Specifically, methods employing distance metrics to bridge the gap between source and target domains have shown promise. However, these approaches typically assume availability of the target domain data during training, a scenario often impractical in the field. (Azari, Flammini, Santini, & Caporuscio, 2023). Indeed, despite the wide availability of surveillance data provided by IIoT sensors, the vast majority of available data predominantly reflects healthy working conditions, as faults are infrequent.

Domain generalization is then a more fitting problem formulation for situations where the target domain remains unknown during the model training phase. Unlike domain

adaptation, domain generalization aims to produce models which generalize well to domains unseen during training. For instance, in (Zhao & Shen, 2023) the authors proposed a mutual-assistance network for semi-supervised domain generalization, while in (Shi et al., 2023) a dynamic weighting strategy and a batch spectral penalization regularization term was employed to tackle the domain generalization problem. In (Jia, Li, Wang, Sun, & Deng, 2023) a deep causal factorization network is used, taking advantage of the causal properties in bearing signal models. The authors of (Zheng et al., 2021) combined apriori expert knowledge on vibration analysis and a deep neural network to generalize to unseen operating conditions. In (Wang et al., 2023) the authors used domain-specific discriminators to explicitly remove domain-specific information from the signals, creating domain-invariant representation, yielding to better generalization to unseen working conditions. However, the current landscape of domain generalization solutions is primarily characterized by complex deep learning architectures. Although effective, these architectures tend to obscure the interpretative transparency of these models, thus contributing to the 'black box' phenomenon often cited as a major pitfall of state-of-the-art models. Consequently, recent works such as (Kim et al., 2024) proposed an explainable diagnosis technique for single-domain generalization tasks using a priori knowledge to produce domain-invariant representations, showing increased performance on unseen target domains.

By tackling the domain shift challenge, our research introduces a novel preprocessing technique tailored to address the domain shift problem and the challenges induced by non-stationary vibration signals. This technique leverages the abundance of healthy signal data as a reference for identifying domain-specific information. We operate under the assumption that healthy signals contain such domain-specific information, which can impede the generalization capabilities of the models.

This approach aims to systematically eliminate domain-specific characteristics from the diagnosis data using advanced signal processing techniques, thereby isolating the intrinsic characteristics of faults. By focusing on the features that are truly indicative of machinery health, irrespective of operational conditions, our method proposes a step towards achieving domain-agnostic fault diagnosis. This approach allows us to benefit from the excellent performance state-of-the art intelligent models without increasing their complexity to achieve cross-domain fault diagnosis tasks.

The contributions of this paper are as follows:

1. A sparse representation-based signal processing technique is proposed to decompose the non-stationary noisy signals into their relevant components
2. Decomposed reference healthy signals are used to remove domain-specific information from the observation signals
3. The domain-invariant signals from a source domain are used train a simple classification model. Preprocessed signals from target domains are used to validate the generalization improvements on domains unseen during training.

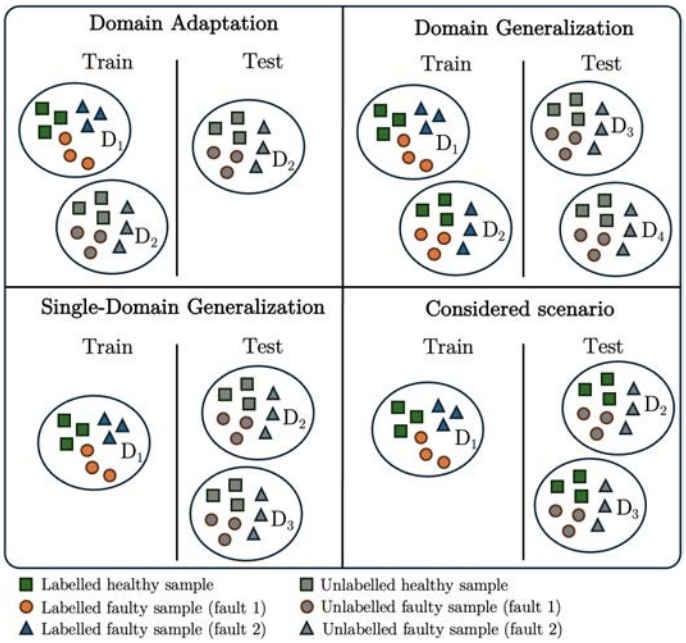

Figure 1. Generalization paradigms

The rest of this paper is organized as follows: in section 2 the method for domain-specific information removal is exposed, in section 3 an experimental setup and protocol is proposed to validate said method, and in section 4 the results are presented.

2. BACKGROUND

2.1. Domain generalization

Let us consider a rotating machine having N different working conditions, which translate into N different domains noted as $D^i = \{(x_j^i, y_j^i)\}_{j=1}^{n_i}$, where (x_i, y_i) is the data-label pair for the jth sample in the ith domain. Let us also consider the situation where the label space is shared across domains, but only one domain is fully labelled and accessible during training, while in all others only healthy samples are known as such and are unseen until testing. This constitutes a realistic data availability scenario, where healthy data is abundant but fault data is scarce and usually represent a small subset of possible working conditions. The differences between domain adaptation, domain generalization, single-domain generalization and the Considered scenario are illustrated in Figure 1.

In this single-domain generalization scenario, the goal is to train a classifier considering the limited data availability and then demonstrate the generalization capability on unseen domains.

2.2. Vibration signals under time-varying working conditions

Rotating machines operating under varying working conditions not only cause the domain shift problem. Their vibration signals also contain specific challenges which makes them hard to process.

Vibration signals generated by rotating machines operating under constant or almost-constant working conditions can be described using Eq. 1.

$$x(t) = d(t) + r(t) + n(t), \tag{1}$$

where $d(t)$, $r(t)$ and $n(t)$ refer to deterministic, random and background noise contributions respectively. Under constant operating conditions, we can formulate several assumptions on the nature of these contributions. Deterministic contributions are almost-periodic as they are phase-locked to the shaft angle, and the random part is often described as cyclostationary (Antoni, Bonnardot, Raad, & El Badaoui, 2004), while background noise is often assumed to be Gaussian white noise coming from sensor and environmental noise.

Under varying operating conditions however, significant changes occur in the vibration signals of rotating machines which significantly challenge the assumptions previously made. For instance, when the rotating speed of the machine varies in time, the deterministic contributions are no longer periodic, while cyclostationary contributions become cyclo-non-stationary (Abboud et al., 2016). This emphasizes the enhancements outlined in this study, which will be discussed in the following section.

3. Proposed method

A preprocessing technique aiming to reduce the effects of domain shift induced by varying working conditions is proposed. The preprocessing technique is composed of two main tasks: the vibration signals must first be decomposed into their relevant parts, then the decompositions from reference signals are used to identify and remove domain-specific information from the signals in each domain. An overview schema of the method is illustrated in Figure 2.

3.1. Decomposition of vibration signals based on Sparse Representation

Many signal processing techniques have been proposed over the years to accurately handle vibration signals produced by rotating machines operating under time-varying working conditions. Considering the shortcomings of classical frequency-domain techniques, methods such as time-frequency analysis are often a suitable tool to handle these signals (Zhang & Feng, 2022). However each time-frequency has its own drawbacks, and choosing the right technique is often difficult. In this study, the Sparse Representation (SR) (Feng, Zhou, Zuo, Chu, & Chen, 2017) framework is adopted to decompose the vibration signals using a redundant basis.

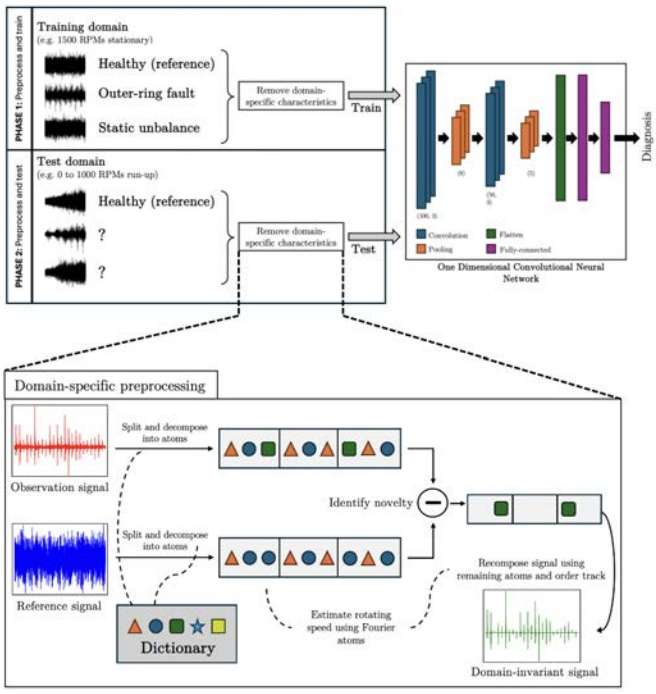

Figure 2. The proposed method to produce domain-irrelevant signals

Considering the morphological specificities of the different contributions present in vibration signals, SR allows not to be limited by the choice of a single basis, which might not be able to accurately represent all types of contributions. Instead a union of basis can be used, with the assumption that a more efficient and sparse representation can be achieved.

This union of basis is referred to as a dictionary, and each element of the dictionary is an atom. Several dictionaries have been proposed over the years, for instance the author of (Qin, 2018) used an impulse wavelet along with Fourier atoms to denoise bearing fault signals, while in (Cai, Selesnick, Wang, Dai, & Zhu, 2018) the authors used a union of a Discrete Cosine and a Short-time Fourier basis to diagnose faults in a gearbox.

These analytic dictionaries are very useful to identify components whose morphological characteristics, such as the natural frequency of the system, are known a priori. However in most cases there's a very limited amount of prior information

available on industrial machines. Therefore, this study adopts a minimalistic dictionary approach, accommodating both deterministic and stochastic elements in vibration signals. This is achieved through integrating Fourier and Unit bases, representing these contributions respectively.

SR can be achieved through either greedy methods like Matching Pursuit (MP) (Mallat & Zhang, 1993), or optimization-based techniques such as basis pursuit (BP) (Chen, Donoho, & Saunders, 1998). In the latter, the optimization objective is to minimize the reconstruction error, regularized by the norm of the sparse vector, expressed in Eq. 2.

$$\min_x \left\{ F(x) = \frac{1}{2}\|y - Ax\|_2^2 + \lambda\psi(x) \right\}, \qquad (2)$$

where $y \in R^{N\times 1}$ is the input signal of size N, $A \in R^{N\times K}$ is the dictionary where $K > N$, x is the sparse vector, λ is the regularization parameter and ψ is a sparsity-inducing penalty.

In this study, the Generalized Minimax Concave (GMC) penalty is used due to its ability to overcome the amplitude underestimation issue associated with the l_1 penalty, while still preserving the convexity of the overall optimization objective, as highlighted by (Selesnick, 2017). The GMC penalty, defined in Eq. 3, serves as a key component in our approach.

$$\psi_{\text{GMC}}(x) = \|x\|_1 - \min_v \left\{ \|v\|_1 + \frac{\gamma}{2\lambda}\|A(x-v)\|_2^2 \right\}, \quad (3)$$

where $\gamma > 0$ controls the convexity of the GMC penalty, which is set at $\gamma = 0.8$ as advised in (Selesnick, 2017). The λ term is the regularization parameter. In this study, we set empirically $\lambda = 1.4$.

There are many algorithms designed to find the minimizer to this convex optimization problem. In this work we use the forward-backward splitting algorithm.

An example of decomposition using the proposed method is illustrated in Figure 3 where a signal containing a rolling element bearing fault is decomposed using Eq. 2. The different contributions from the Fourier and Unit basis are represented in blue and red respectively.

3.2. Removal of domain-specific components from the observation signals

After windowing and decomposing the signal using the proposed SR method, decompositions of healthy signals from each available domain are utilized as reference. It is assumed that these signals contain domain-specific characteristics that do not carry relevant diagnosis information and may contribute to the domain-shift issue. In every domain, atoms which are used to represent the reference signals are systematically removed from observation signals in order to produce domain-invariant signals, as illustrated in Figure 2.

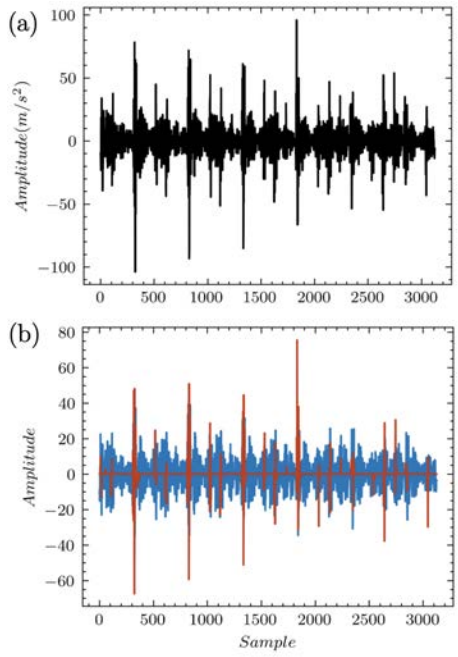

Figure 3. Decomposition of a signal containing an Inner Ring fault (a), into its deterministic contribution (blue in (b)) and random contributions (red in (b).

Additionally, the effects of varying speeds must be considered. Order Tracking is often used to resample the signal from the time domain to the order domain. However it requires information on the instantaneous rotating speed of the machine, which is often not available in industrial scenarios.

Consequently, we use the Fourier atoms from the sparse decompositions in order to estimate the instantaneous rotating speed without the need for additional hardware using the ridge tracking technique proposed in (Iatsenko, McClintock, & Stefanovska, 2016). The signal is then resampled from the time domain to the order domain, so that all domains share the same rotating speed reference.

4. Experimental verification

In this study, the Machinery Fault Simulator from SpectraQuest was used as test rig (pictured in Figure 3). It consists of an 3-phase 1HP motor, a main shaft with two Rexnord ER12K bearings and a gearbox linked to the main shaft by a double groove rubber belt. Three different couplings between the motor and the shaft are available (rigid, jaw, beam). A magnetic brake on the gearbox can be used to manually vary the load applied on the gearbox. The motor's speed can vary from 0 to 6000 RPMs.

Figure 4. The SpectraQuest test bench

Table 1. Considered faults

Defect	Type	Severity
Bearing	Inner ring	High
	Outer ring	High
Rotor	Static unbalance	Low
	Static unbalance	High

The vibration signals are acquired using three IFM VSA005 accelerometers sampling at 25.6 kHz, placed on the rightmost bearing housing. A high sampling rate is indispensable as some faults occur at high frequencies. Several artificial defects representative of most naturally occurring faults are introduced as summarized by Table 1.

In the present investigation, the test bench was employed to generate datasets across five distinct domains. Each domain is characterized by a specific speed curve that exemplifies an acceleration and deceleration cycle—commonly referred to as coast-up and coast-down phases. Such cycles are emblematic of the fluctuating operational conditions frequently encountered within industrial environments.

The domain shift problem is illustrated in Figure 5. A lightweight one-dimensional Convolutional Neural Network (1D-CNN) was used, based on the architecture described in Table 4, was trained on a single domain. The 1D-CNN is recognized as the state-of-the-art architecture (Borghesani, Herwig, Antoni, & Wang, 2023) for intelligent vibration-based fault diagnosis. Despite the impressive performance for working regimes of 1500 RPMs, the model accuracy drops significantly when the rotating speed varies.

Subsequently, five transfer tasks were defined, each depicted in Table III. The construction of these tasks allows defining actual transfer scenarios in the presence of varying working conditions.

The subsequent discussion will illustrate how the suggested pre-processing technique enhances the generalization capabilities of the CNN model, without requiring the adoption of

5. Results and Discussion

The model was trained in each task with 120 samples per source domain, with a sample being a 3125-long vibration signal in 10 different runs. The lambda parameter was set empirically to 1.2, the learning rate to 0.001, the number of epoch to 200. The early stopping strategy was employed to obtain a satisfying trained model. Note that the model itself is not the focus of the present study, it is merely used to demonstrate the generalization capabilities increase enabled by the proposed method.

The accuracies on unseen test domains with and without the preprocessing employed are then compared. It is important to note that whether with or without the preprocessing runs, the target domains were never included in the training data, meaning that the inference is performed on never-seen-before domain distributions.

The diagnosis results on each of the cross-domain diagnosis tasks are shown in Figure 4. Where it can be seen that the proposed pre-processing method increases the cross-domain accuracy of the model. The task 4 yields a diminished increase because the rotating speed of the target domain is identical to the source domain, showing that the proposed method does not decrease the adequate performance of in-distribution classification performance of modern models.

It must also be noted however that the first and sixth task's accuracy are not improved by the proposed method as very low decreasing speed carry very little energy and thus very little information, making it difficult to apply the proposed preprocessing scheme.

This study addressed the common issue of 'domain shift' caused by changes in a machine's operational environment that often lead to errors in machine fault detection by sophisticated computer models. The proposed approach sought to simplify the diagnosis process by filtering out the environmental noise from the signals machines give off, focusing in on the genuine indicators of malfunctions.

To validate the proposed technique, a test bench that simulates a variety of operational conditions and failures machines might encounter in real-world scenarios was utilized. Across

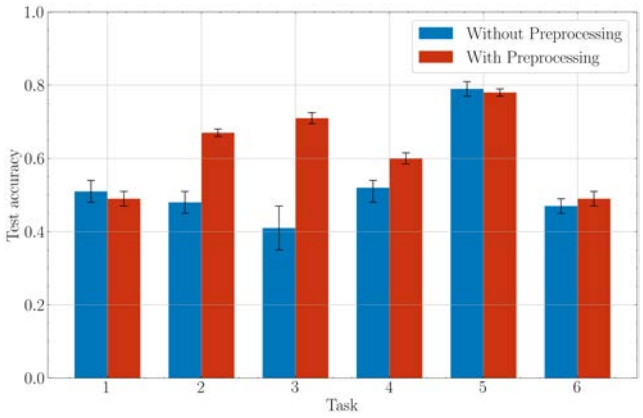

Figure 6. The effects of the proposed preprocessing method on the test accuracy of the model

five different domains, representing a range of typical industrial settings, our results indicate that our method, which employs a simple decision model with few parameters, was capable of identifying machine faults with an efficacy comparable to the more complex, state-of-the-art models currently in use.

6. Conclusion

In conclusion, this paper has presented a preprocessing technique that utilizes sparse representation to extract the domain-agnostic diagnosis information of machinery health signals, thereby significantly reducing the interference of domain-specific noise. The proposed method has been validated through a series of transfer tasks across different domains, revealing a significant improvement in model generalization without the necessity of resorting to complex neural network architectures.

On top of the generalization improvements, the proposed scheme use physically interpretable features which makes it easier to understand the output of the simple lightweight model employed here.

The study's limitations also open up new avenues for research, particularly in the domain of signal acquisition under extremely low-energy conditions. Addressing the shortfall in task 1 and 5 performance, where low decreasing speed results in signals with minimal information content, remains a challenge for future investigation.

ABSTRACT

Efficient gear and bearing diagnosis has become a critical requirement across diverse industrial applications precisely due to their complex design and exposure to difficult operating conditions, which predispose them to frequent failure. Early fault identification remains problematic, as defects are commonly obscured by extensive background noise. Moreover, the exponential increases in gearbox data further complicate the defect classification process, confusing even the most sophisticated algorithms and significantly making the procedure time consuming. Singular Value Decomposition (SVD) has proved to be highly efficient in signal denoising, stability preservation, and feature extraction reliably under varying conditions, filtering out non-linear signals to reconstruct relevant features only. However, its considerable computation time necessitates exploring alternatives like Randomized SVD (RSVD) to mitigate processing time while maintaining classification accuracy. In this work, an intelligent algorithm for gear and bearing fault diagnosis is developed, incorporating Maximal Overlap Discrete Wavelet Packet Transform (MODWPT) and Time-Domain Features for feature extraction. RSVD is employed for signal denoising and feature reconstruction, while K-Nearest Neighbor (KNN) for feature classification. The combined techniques ensure enhanced diagnostic accuracy, addressing critical challenges in industrial maintenance and performance optimization.

Keywords: Fault diagnosis, Gearbox, Feature extraction, Rotating machines.

1. INTRODUCTION

In rotating machines, particularly gearboxes, gears and bearings are susceptible to vulnerabilities due to their complex design and severe operating conditions which often compromise system reliability, leading to frequent failures requiring unscheduled maintenance and, ultimately, machine breakdowns. Notably in wind turbines, over 50% of gearbox faults come from bearings (de Azevedo et al., 2016), while approximately 80% of transmission machine problems are due to faulty gears (Soualhi et al., 2019). Consequently, the urgent need for machine fault diagnosis arises to ensure the safety and reliability of mechanical transmission systems. Moreover, today's competitive, dynamic and technology-driven industrial environment requires industry to adapt to new technologies, and to continually reduce costs (Benaggoune et al., 2020).

Intelligent fault diagnosis techniques primarily rely on machine monitoring parameters, with vibration analysis being a prevalent method for detecting early defects by identifying any deviations in these parameters. Vibration signals are especially favored due to their non-intrusive nature in machinery operation, making them a widely adopted tool for fault detection and analysis (Afia, Gougam, Rahmoune, et al., 2023). This approach enables continuous monitoring of machine health, allowing for timely interventions to prevent potential failures and to optimize maintenance schedules. Extracting fault-related characteristics from vibration signals poses a significant challenge, particularly in the initial fault development stages (Afia, Gougam, Rahmoune, et

al., 2023). Moreover, gears and bearings can incorporate a variety of defects, compounding the fault detection classification complexity. Recognizing these defects requires highlighting relevant information gleaned from measured vibration signals in a mathematically meaningful manner. Features serve as crucial signal characteristics aimed at encapsulating the overall data within a reduced dimensionality, facilitating their utilization in the classification process. Despite the complexities involved, effective feature extraction remains integral to accurately diagnosing faults and ensuring machinery reliability. Many decomposition methods have been developed for feature extraction. For instance, Gilles has proposed the empirical wavelet transform (EWT) (Afia, Gougam, Rahmoune, et al., 2023), in which input data is decomposed into multiple modes using a set of adaptive wavelet filters. The resulting EWT modes are narrow-band functions with fewer mixed modes, beneficial for many applications (Gilles, 2013). Nevertheless, EWT is highly dependent on the mode number selection, with improper selection potentially causing undesirable decomposition results (Adel et al., 2022). Furthermore, the wavelet filtering bandwidth adaptability in EWT is inherently limited, following a linear proportional bandwidth pattern (Adel et al., 2022). Discrete wavelet transform (DWT) is an alternative technique extensively used in fault diagnosis and condition monitoring (Syed & Muralidharan, 2022). DWT decomposes signal data through band pass filters in the time and frequency domains, producing a set of signals with specific frequency bands (Syed & Muralidharan, 2022). Yet, the dyadic step in the subsampling process represents a significant limitation in DWT efficiency (Adel et al., 2022). The Maximal overlap discrete wavelet transform (MODWT) has been developed as an optimized version of DWT to address the issue (Adel et al., 2022). Like DWT, MODWT invariably presents problems associated with poor frequency resolution [6]. As a solution, maximal overlap discrete wavelet packet transform (MODWPT) has appeared as a more suitable choice. MODWPT decomposes complex signals into individual components while maintaining circular shift equivariance, which is crucially important for gear and bearing condition monitoring (Adel et al., 2022). Moreover, MODWPT provides numerous improvements compared to MODWT, including uniform frequency bandwidths, the ability to overcome time-varying transformations, and to reconstruct the original signal without any information loss (Adel et al., 2022). MODWPT can extract relevant features from vibration data without compromising accuracy, thereby enhancing fault diagnosis processes.

Time-energy indicators such as kurtosis, entropy, root-mean square (RMS), etc., represent useful indicators in advanced signal processing algorithms for classifying different fault types (Soualhi et al., 2019; Gougam, Afia, Aitchikh, et al., 2024; Soualhi et al., 2020; Tahi et al., 2020). However, detecting bearing and gear signatures in early stages is extremely difficult as defects features are inherently weak. In such case, acquired vibration signals are often overwhelmed by a substantial amount of low-frequency noise, which makes significant impact on the analysis results' accuracy. For instance, in the event of local failure within the bearing, vibration signals exhibit a distinctly non-stationary behaviour, complicating the diagnostic process even more (Afia, Gougam, Touzout, et al., 2023). Consequently, achieving efficient fault identification continues to be an important issue in rotating equipment fault diagnosis. Addressing this issue is critical for enhancing the efficiency and accuracy of fault classification algorithms, necessitating strategies for noise reduction and optimization in feature selection processes. Singular value decomposition (SVD) is among the most commonly used methods, as highlighted in (Gougam et al., 2018; Touzout et al., 2020) due to its remarkable signal noise reduction and feature extraction capabilities, particularly in complex noise conditions. SVD is able to effectively reflect the matrix features since the singular values represent the intrinsic matrix features (Gougam et al., 2018; Touzout et al., 2020). Furthermore, SVD can maintain stability and improve the robustness of feature extraction under varying conditions. Since it is invariant, stable, and efficient for denoising, SVD has been used in practical applications, such as gear and bearing fault identification, to filter the nonlinear signal and ensure that only useful features are reconstructed. Despite its numerous advantages, the primary limitation of SVD lies in its high computational complexity. Addressing this challenge, Halko et al. proposed randomized SVD (RSVD) as an enhanced version of SVD (Halko et al., 2011). RSVD operates by generating an approximate basis for a range of input matrices through a process of "random sampling," wherein samples of the input matrix are multiplied by a random matrix (Song et al., 2017). This approach effectively captures the fundamental characteristics of the input matrix, including its singular values and most relevant vectors, reminiscent of data compression techniques. By enabling standard factorizations such as QR decomposition and SVD to be computed on a substantially smaller matrix than the original, RSVD significantly diminishes the computational cost (Song et al., 2017).

After feature extraction and noise reduction, K-Nearest Neighbor (KNN) has been widely adopted for gear and bearing fault detection and classification (Afia et al., 2024). The primary objective of this research is to investigate the effectiveness of a machine learning classifier in accurately classifying features extracted from vibration signals using MODWPT alongside temporal statistical indicators and RSVD. This paper presents a gear and bearing fault diagnosis method using vibration analysis, aiming to discern and categorize five distinct gear and bearing conditions. During the feature extraction phase, experimental vibration signals are decomposed by MODWPT, yielding several wavelet coefficients (WCs). Subsequently, 38 statistical features are applied to

each decomposed mode to construct a feature matrix corresponding to each gear and bearing condition. RSVD is then employed to reduce noise and to reconstruct feature matrix, ensuring the retention of pertinent features. Finally, KNN is utilized for feature classification, enabling the detection, classification, and identification of the five gear and bearing health states with precision and accuracy. This methodology represents a comprehensive approach towards enhancing gear and bearing fault diagnosis through advanced signal processing techniques and machine learning algorithm.

2. PROPOSED METHODOLOGY

In this section, the different steps of the proposed methodology are discussed. First, a total of 16 raw experimental vibration signals representing either a gear or a bearing state are decomposed using maximal overlap discrete wavelet packet transform (MODWPT) by 6 levels into 26 wavelet coefficients (WC) with different frequency levels. For one state, 16 matrices of (64×1048560) are produced, wherein 1048560 is the signal points number. Then, 38 combined time features are applied to each WC to construct the feature matrix corresponding to each condition. For one condition and one time feature, each matrix of (64×1048560) would be converted to a vector of 64 rows. Therefore, for one condition (16 measurements), a feature matrix (16×64) is provided to represent each gear or bearing condition. Combining 38 time features gives a feature matrix (608×64). After that, RSVD is used to reduce noise by calculating the right eigenvector, the singular value, and the left eigenvector in which Each feature matrix is reconstructed retaining the useful information only. The reconstructed feature matrices are used as inputs for KNN to detect, identify and classify the different states. To avoid over-fitting during the training and testing phases, 10-fold cross-validation is used, in which the dataset is randomly divided into 10 complementary subsets. Each subset is retained in turn, and the training model is trained on the remaining nine-tenths. Figure 1 provides an overview of the proposed technique.

3. MAXIMAL OVERLAP DISCRET WAVELET PACKET TRANSFORM

MODWPT uses raw data $X = [X_0, X_1, ..., X_{N-1}]^T$ as input for filtering and data decomposition. As with Mallat's algorithm (Gougam, Afia, Soualhi, et al., 2024; Too, Abdullah, Mohd Saad, & Tee, 2019), MODWPT is based on quadrature mirror filters. $\widetilde{g}_l$ and $\widetilde{h}_l q$ respectively represent a low-pass and a high-pass filters, each of length L (assumed to be even).Thus, the developed filters are given in Equation 1.

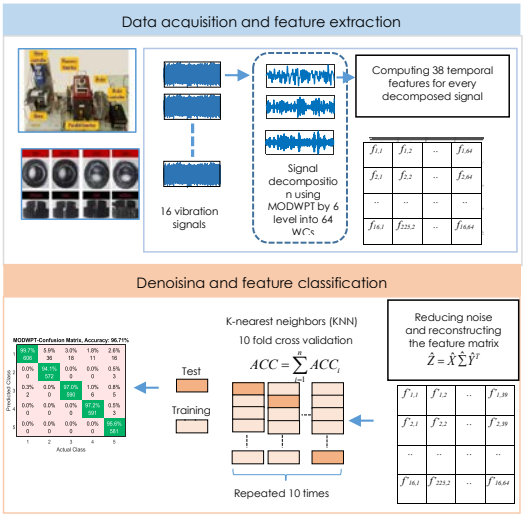

Figure 1. Diagram of the proposed method.

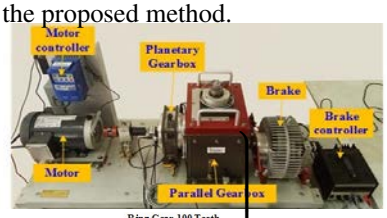
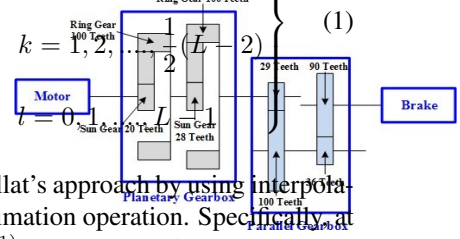
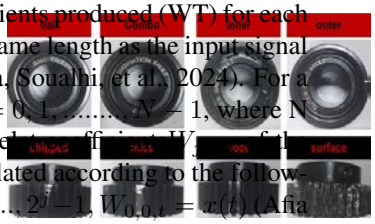
$$\begin{cases} \sum_{l=0}^{L-1} \tilde{h}_l^2 = \frac{1}{2} \\ \sum_{l=0}^{L-1-2k} \tilde{h}_l \tilde{h}_{l+2k} = 0, \quad k = 1, 2, \ldots, \frac{1}{2}(L-2) \\ \tilde{g}_l = (-1)^{l+1} \tilde{h}_{L-l-1}, \quad l = 0, 1, \ldots, L-1 \end{cases} \quad (1)$$





MODWPT differs from Mallat's approach by using interpolation instead of a 2-base decimation operation. Specifically, at each MODWPT level, $2^{(j-1)} - 1$ zeros are inserted between two consecutive adjacent coefficients of $\widetilde{g}_l$ *and* $\widetilde{h}_l$. Thereby ensuring that the wavelet coefficients produced (WT) for each wavelet sub-band maintain the same length as the input signal (Afia et al., 2024; Gougam, Afia, Soualhi, et al., 2024). For a discrete-time sequence $x(t), t = 0, 1, \ldots\ldots, N-1$, where N is the sequence length, the wavelet coefficient $W_{j,n}$ of the nth sub-band at level j are calculated according to the following equations in which $n = 0, 1..., 2^j - 1$, $W_{0,0,t} = x(t)$ (Afia et al., 2024; Gougam, Afia, Soualhi, et al., 2024):



$$\tilde{f}_{n,l} = \begin{cases} \tilde{g}_l, & \text{if } n \bmod 4 = 0 \text{ or } 3 \\ \tilde{h}_l, & \text{if } n \bmod 4 = 1 \text{ or } 2 \end{cases} \quad (2)$$

4. TEMPORAL FEATURES

The aim of this step of the methodology is to detect pattern changes in a given signal, in which statistical parameters are useful for extracting features related to the different machine states, since a failure will produce a change in the overall signal energy. For this purpose, 38 temporal features are used for feature extraction. The used time features are discussed in (Too, Abdullah, Mohd Saad, & Tee, 2019; Too, Abdullah,

& Saad, 2019).

5. RANDOMIZED SINGULAR VALUE DECOMPOSITION

Standard approaches use the extracted features from the previous step and directly train machine learning models for classification. However, achieving efficient fault classification accuracy seems to be a major issue in rotating equipment fault diagnosis, requiring noise reduction and optimization feature selection algorithms. In this situation, RSVD is used to reflect matrix features since singular values represent intrinsic matrix features, thus maintaining stability and improving the feature extraction reliability under varying conditions in practical applications, such as gear and bearing fault identification, by filtering the nonlinear signal and ensuring that only useful features are reconstructed with low computational complexity. For a matrix with m×n as dimension and k as rank, SVD gives this formula of$Z = XSY^*$, in which X is an orthonormal matrix $(m \times k)$, Y is an orthonormal matrix $(n \times k)$, while S is a non-negative diagonal matrix $(k \times k)$ which is defined in (Chakraborty et al., 2017):

$$W_{j,n,t} = \sum_{l=0}^{L-1} \tilde{f}_{n,l} \; W_{j-1,[n/2](t-2^{j-1}l) \bmod N} \tag{3}$$

$$S = \begin{bmatrix} \sigma_1 \\ \sigma_2 \\ \vdots \\ \sigma_k \end{bmatrix} \tag{4}$$

σ_j is the non-negative diagonal matrix S are the singular values of Z arranged as follows: $\sigma_1 \geq \sigma_2 \geq \sigma_3 \geq \sigma_4 \geq \sigma_k \geq 0$. The$XandY$ columns are the left and right singular vectors, respectively, while the singular values are related to the matrix approximation. At each level j, the number$\sigma_j + 1$ is equal to the spectral norm deviation between Z and an optimal rank-j approximation, in which (Too, Abdullah, & Saad, 2019):

$$\sigma_j + 1 = \min\{kZ - Bk \,:\, B\, has\, rank\, j\} \tag{5}$$

And the SVD of a matrix $Z \in R^{m \times n}$ is described as below (Chakraborty et al., 2017):

$$Z = X \sum Y^T \tag{6}$$

With X and Y being orthonormal, while $\sum$ is a rectangular diagonal matrix with diagonal entries being the singular values signified by σ_i. The column vectors of $XandY$representing the left and right singular vectors respectively, are indicated by$x_i and y_i$. In terms of $x_i and y_i$, the truncated SVD (TSVD) approximation of Z as a matrix Z_k is defined by (Chakraborty et al., 2017):

$$Z_k = \sum_{i=1}^{k} \sigma_i x_i {y_i}^T \tag{7}$$

And the randomized SVD (RSVD) is given as follow [23]:

$$\hat{Z} = \hat{X} \hat{\sum} \hat{Y}^T \tag{8}$$

In which and are each orthonormal while is diagonal that has as diagonal entries. The column vectors of and are referred as , and correspondingly. Elucidate the residual matrix of a TSVD approximation and the residual matrix of RSVD approximation are given below (Chakraborty et al., 2017):

$$R_k = Z - Z_k,\, and\, \hat{R}_k = Z - \hat{Z}_k \tag{9}$$

While the random projection of a matrix is elucidated as in (Too, Abdullah, Mohd Saad, & Tee, 2019):

$$Y = \Omega^T Z \;\; or \;\; Y = Z\Omega \tag{10}$$

In which Ω is a random matrix with independent and identically distributed entries. RSVD is an algorithm that examines approximate matrix factorization by employing random projections to divide the entire process into two steps. First, a random sampling is performed to obtain a reduced matrix with a range close to $Z's$ range. Thereafter, the reduced matrix is factorized using the first step on the matrix Z to find the orthonormal column matrix Q for $\xi > 0$ as defined in (Chakraborty et al., 2017):

$$\left\| Z - QQ^T Z \right\|_F^2 \leq \xi \tag{11}$$

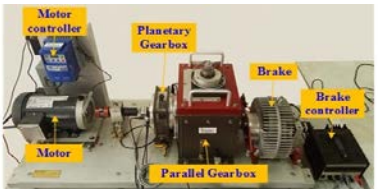
In the second step, the SVD of the reduced matrix $Q^T Z \in \mathbb{R}^{l \times m}$ is calculated, where $l \ll n$. Based on $\hat{X}\hat{\Sigma}\hat{Y}^T$ to denote the SVD of $Q^T Z$, Z is given in the following expression (Chakraborty et al., 2017):

$$Z \approx (Q\tilde{X}) \hat{\sum} \hat{Y}^T = \hat{X} \hat{\sum} \hat{Y}^T \tag{12}$$

Where $\hat{X} = Q\tilde{X}$ and $\hat{Y}$ are orthogonal matrices.

6. K-NEAREST NEIGHBORS

The reconstructed feature matrices are used as inputs for KNN to detect, identify and classify the different states. KNN is a simple and effective supervised classification approach, particularly in the field of pattern recognition, since it operates without the need for specific learning steps (Too, Abdullah, & Saad, 2019). When classifying a new input sample, KNN identifies the nearest neighbors of the training dataset and assigns the most common class to the new sam-



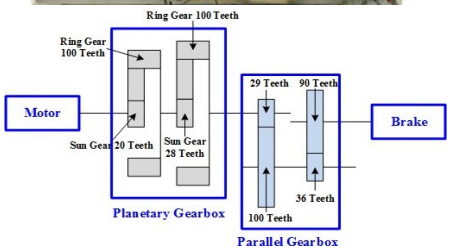


Figure 2. Gearbox setup schematic.

ple on the basis of a similarity measure. This process is conducted via unsupervised algorithmic methods, in which results are ranked on the basis of the majority of KNN categories (Anggoro & Kurnia, 2020). The algorithm works as follows:

1. **D**etermining the parameter k, representing the number of nearest neighbors.
2. **C**alculating the distance between the evaluated and the training data.
3. **S**orting the distances from high to low values.
4. **S**electing the nearest distances up to the order of k.
5. **A**ssigning the appropriate class based on the majority vote among the nearest neighbors.

7. Application and Results

The described methodology is applied to experimental data, which includes various fault states as well as a healthy state. The experimental setup is designed for multi- faults classification. With the proposed methodology, our objective is to evaluate the effectiveness of the extracted features in separating the different health states .

7.1. Case Study

components: motor, brake, planetary gearbox and parallel gearbox (see Figure 2) (Afia, Gougam, Rahmoune, et al., 2023). Defects (Table 1) were investigated in two distinct operating modes, with rotational speeds and loads ($20Hz - 0V$ and $30Hz - 2V$).

Eight 608A11 vibration sensors were placed on the test bench surface, with a 0.5 Hz-10 kHz frequency range, a $\pm 50g$ measurement range and 100 mV/g accuracy. Vibrations in the planetary gearbox directions were measured using three sensors, another three sensors to measure vibrations in the three

Figure 3. Gear and bearing defects.

Table 1. Types of bearing and gear components

Component	Types	Description
Gear	Chipped	Crack in the feet
	Miss	Missing
	Surface	Wear
	Root	Crack
Bearing	Ball	Crack
	Comb	Crack in inner and outer ring
	Inner	Crack
	Outer	Crack

directions of the parallel gearbox, and the remaining sensors monitored the drive motor. Load measurement was provided by an FT293 torque transducer with a measuring range of $\pm 5V$ and an accuracy of 4 Nm/V, placed between the motor and the planetary gearbox. Signal acquisition was achieved using a Spectra PAD compact data acquisition instrument able to process up to 20 channels, with a 1024 Hz sampling rate and a 512 second sampling window (Afia, Gougam, Rahmoune, et al., 2023).

7.2. Result and discussion

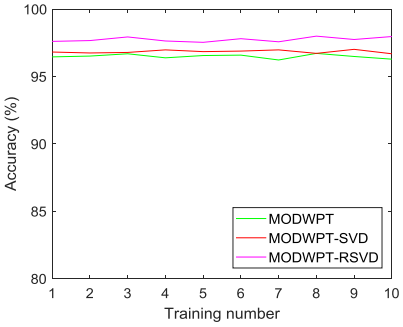
Raw vibration signals measured by the eight accelerometers corresponding to all five bearing and gear states for two operating modes (see TABLE I) are decomposed into 64 WCs using MODWPT. 38 time-based features are applied to each WC to create the feature matrices describing each gear or bearing's health state. Afterwards, RSVD computes right eigenvector, singular value and left eigenvector, and then each gear or bearing's feature matrix is reconstructed. The reconstructed matrices are taken as KNN inputs.

Model stability is an extremely important factor in determining potential model reliability in terms of overfitting, data variability or model sensitivity. By considering accuracy over repeated training iterations, a more complete model reliability assessment is provided. To evaluate the machine learning model's accuracy, TABLE II provides overall accuracy over ten training iterations using the proposed approach with and without RSVD. Figure 4 compares the model accuracy over ten training iterations, while Figs.5 and 6 provide a better illustration of the classifier's overall performance in terms of confusion matrices.

Compared with MODWPT and MODWPT-SVD, MODWPT-

Table 2. Classification accuracy of fa

Method	***Classification accuracy (%)***						
	Gear						
MODWPT	*96.45*	96.51	96.68	96.38	96.55	96.5	6.28
MODWPT-SVD	96.81	96.74	96.78	96.97	96.84	96.8	6.68
MODWPT-RSVD	97.60	97.66	97.93	97.63	97.53	97.8	7.96
	Bearing						
MODWPT	95.23	95.46	95.26	95.53	95.43	94.9	4.77
MODWPT-SVD	95.89	**96.12**	95.72	95.49	95.76	95.4	5.30
MODWPT-SVD	**97.27**	97.01	96.97	96.74	97.20	96.7	7.07



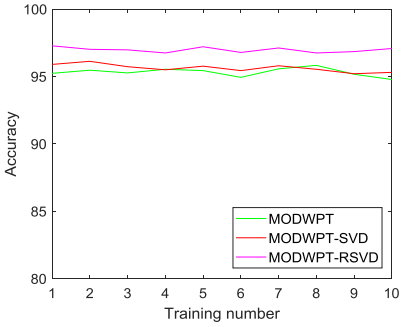


Figure 4. Model accuracy gear (a) bearing (b).

RSVD has achieved the best accuracy rates, mainly 97.99% for gears and 97.27% for bearings. This highlights our proposed method as a superior feature extraction technique, making it the optimal choice among the evaluated methods. Figure 4further confirms the proposed model's stability, providing highly satisfactory results in terms of fault classification. Thus, for accurate early defect detection and classification, MODWPT, with RSVD, provides the optimal approach.

8. Conclusion

The paper presents an enhanced fault diagnosis technique for gearboxes. Feature extraction, classification and experimental processes have been described in detail. The proposed algorithm, applied to real-tune gearbox vibration signals in different health states, successfully identified all gear and bear-

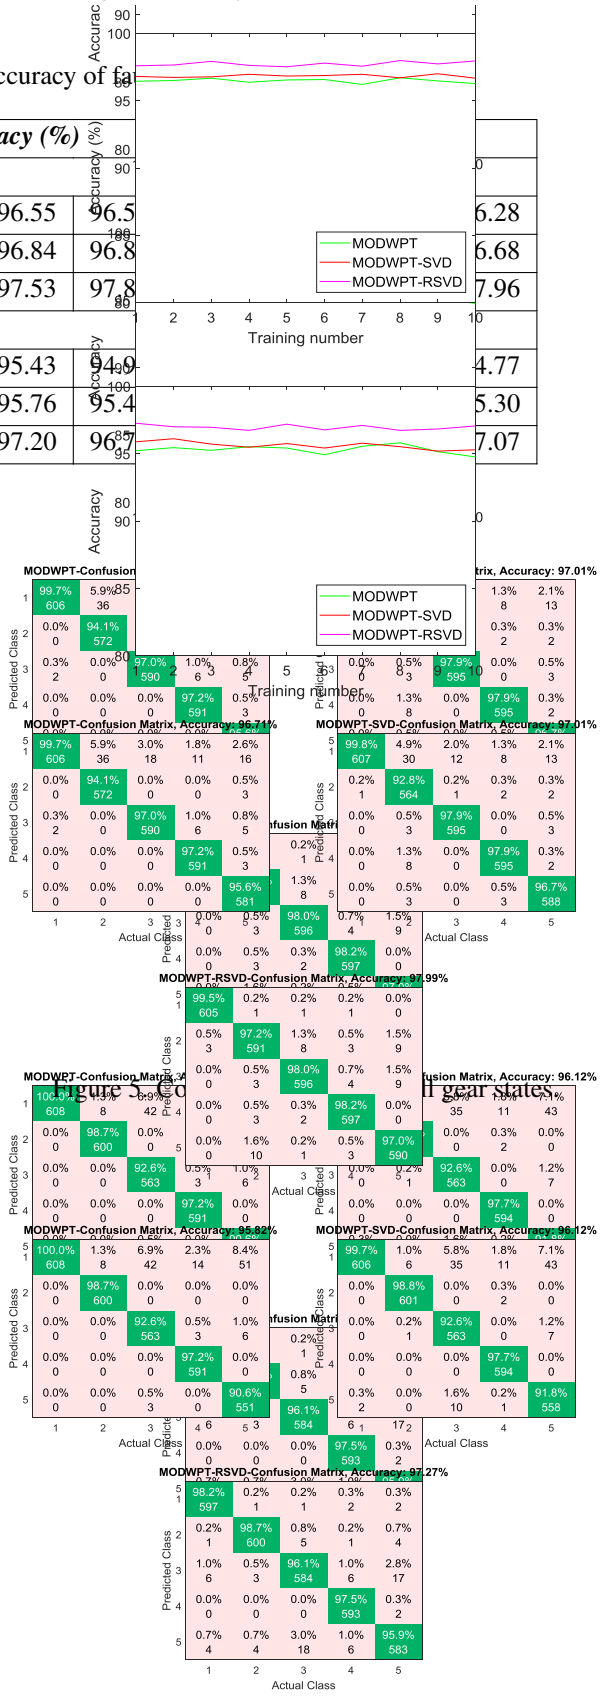

Figure 6. Confusion matrices for all bearing states.

ing states accurately and efficiently.

ABSTRACT

As the main cause of thermal runaway, the prompt identification of Internal Short Circuit (ISC) occurrences in lithium-ion batteries (LIBs) has emerged as a critical priority for ensuring battery safety. To address this critical need, for a comprehensive understanding of ISC behaviors, an electrochemical-thermal-ISC coupled model has been developed in this work to simulate battery performance across various ISC levels. This model is also utilized to validate the efficacy and robustness of the advanced detection approach proposed. By integrating both thermal and electrical aspects using the Pseudo Two-Dimensional (P2D) and Energy Balance Equation (EBE), our model serves as an efficient surrogate for ISC experiments. Key ISC indicators have been analyzed and integrated into the proposed ISC detection algorithm to enhance its effectiveness. The algorithm utilizes an Equivalent Circuit Model (ECM)-based approach for estimating ISC resistance. This research not only advances our understanding of ISC dynamics but also establishes a robust framework for the timely and reliable detection of ISCs. These advancements significantly enhance the overall safety and reliability of LIBs in electric vehicles (EVs).

1. INTRODUCTION

With the increasing growth and application of LIBs, particularly in EVs, concerns over battery safety have escalated due to a significant number of car fire accidents Chen et al. (2021). Among the recognized types of battery failure modes, ISC is considered the most significant safety concern for LIBs B. Liu et al. (2018).

While many studies have used mechanical abuse to induce ISC modes and quantify their effects on temperature, State of Charge (SoC), and other measurements, the precise mechanism of spontaneous ISC during the daily use of EVs remains unclear Huang et al. (2021). Therefore, early detection and accurate identification of ISC before it leads to thermal runaway (TR) have become key research areas.

According to Feng et al., generating failure data is a primary objective in developing a comprehensive online ISC detection approach Feng, Weng, Ouyang, and Sun (2016). Various methods have been employed in previous literature to induce ISC experimentally, including mechanical deformation like the nail penetration test Abaza et al. (2018) and crush tests Zhu, Zhang, Sahraei, and Wierzbicki (2016), as well as heating triggers such as inserting ISC devices within cells Orendorff, Roth, and Nagasubramanian (2011) and overheating Spinner et al. (2015). Additionally, dendrite growth and external short circuit (ESC) substitute tests have been used by L. Liu et al. (2020); Feng, He, Lu, and Ouyang (2018). Due to the challenges associated with reproducibility and safety in ISC experiments, researchers also opt to develop battery ISC models to capture ISC effects on main signals Kim, Smith, Ireland, and Pesaran (2012); Feng et al. (2016).

In this study, we generated ISC data by modeling a high-fidelity ISC model. Given that temperature growth and voltage drop are key ISC indicators Lai et al. (2021); Wu et al. (2023), we coupled a thermal and electrochemical model to simulate these responses for ISC detection algorithm development.

Another primary objective is the formulation of the detection algorithm. Achieving online and onboard diagnosis in EVs relies on signals measured by Battery Management Systems (BMS), necessitating a computationally efficient algorithm. Over recent years, several approaches leveraging voltage signals for ISC detection have been proposed, including observ-

ing abnormal voltage changes Keates, Otani, Nguyen, Matsumura, and Li (2010); Sazhin, Dufek, and Gering (2016); Seo, Goh, Park, Koo, and Kim (2017), capturing differences between predicted and actual values Yokotani (2014), and applying algorithms utilizing voltage signals Seo, Park, Song, and Kim (2020); Hu, Wei, and He (2020). Regarding another key ISC signal, temperature response, only limited works have utilized it through model-based approaches Feng, Ouyang, et al. (2018); Jia, Brancato, Giglio, and Cadini (2024).

In this study, we implemented the Extended Kalman Filter (EKF) algorithm based on a simplified lumped electrical-thermal model, as proposed in our previous work. Model parameters were estimated from a dataset generated by the high-fidelity plant model. Utilizing both the voltage and temperature signals, the direct indicator, R_{ISC}, was set as the state in the algorithm to be estimated to identify ISC levels.

The remainder of this paper elaborates on the detection approach in Section 2, provides a detailed description of the built ISC plant model in Section 3, presents the detection results and validation of the proposed approach in Section 4, and concludes in Section 5 by summarizing the findings and their implications.

2. An Overview of ISC Detection Approach

Figure 1 presents the comprehensive framework of the ISC detection approach proposed in this study.

As shown in the upper part of the figure, a coupled electrochemical thermal model (plant model) is developed to generate a dataset representing the operational behavior of a healthy battery, as detailed in subsequent sections. The Recursive Least Squares (RLS) parameter estimation tool is then employed to derive lumped model parameters, facilitating an accurate representation of battery electrical signals with computational efficiency for online detection algorithms.

The Equivalent Circuit Model (ECM) is chosen as the lumped electrical model due to its simplicity and widespread use in battery State of Charge (SOC) estimation in Battery Management Systems (BMS). The temperature lumped model, represented by Equation 1, incorporates heat generation from internal resistance and ISC resistance, as well as heat dissipation through natural air convection between the battery surface and the environment. To parameterize the ECM, the Hybrid Pulse Power Characterization (HPPC) working profile is applied to the plant model. The HPPC current and voltage simulated from the plant model are utilized for parameter estimation. Details of the estimated parameters applied for the detection algorithm are provided in Table 1.

$$mC_m \frac{dT}{dt} = \frac{V^2}{R_{ISC}} + R_0 I^2 - hA(T - T_a) \qquad (1)$$

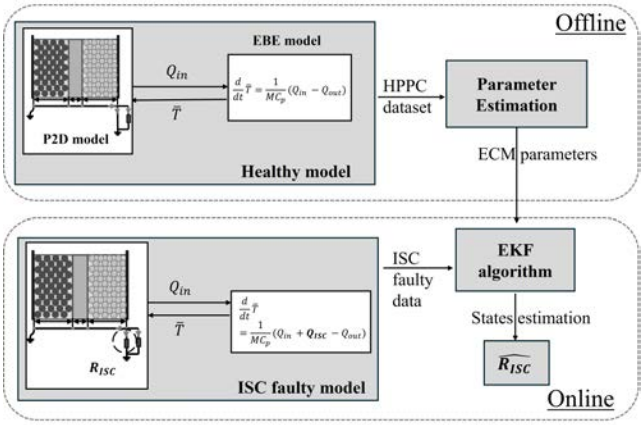

Figure 1. The overall ISC detection approach

Table 1. Battery parameters in lumped model

Symbol	Value	Unit
Q	2.3	Ah
R_0	0.0249	Ω
R_1	0.0072	**m**Ω
R_2	0.3641	**m**Ω
$\dot{\tau_1}$	13.18	s
$\dot{\tau_2}$	9.66	s

Figure 1 shows that, in the lower part (online detection phase), simulated ISC signals are obtained by introducing a parallel resistance as the ISC input for both the electrochemical and thermal models. The ECM-thermal-ISC model integrates parameters generated offline, including an additional item for ISC resistance, as a state to be estimated, into the model-based EKF algorithm for implementation and evaluation.

As highlighted by Hu et al. (2020), the state estimation process in the EKF consists of two primary stages: prediction and update. During the prediction stage, estimated state values are computed using model equations within the algorithm, incorporating the error covariance from the previous estimation step. This stage forecasts the next state based on the current state estimate and system dynamics. In the subsequent update stage, predicted states are refined by integrating measurements from sensors, which in this case are simulated values from the high-fidelity model.

The key aspect of the algorithm employed here involves incorporating the ISC resistance as one of the estimated states by integrating it into the ECM within the framework of the EKF algorithm. The state vector can be expressed as:

$$\mathbf{x} = [z,\ i_{R1},\ i_{R2},\ 1/R_{ISC}]^T, \qquad (2)$$

while the input and output vectors are:

$$\mathbf{u} = [i_t,\ v_t]^T, \qquad (3)$$

$$\mathbf{y} = [v_t,\ T]^T, \tag{4}$$

For further details regarding the functions and implementation of the algorithm, as well as other parameters applied, please refer to our previous work Jia et al. (2024).

3. Model Implementation

In this section, the detail of the electrochemical-thermal-ISC model developed to simulate the battery ISC is further described. The cell we simulated in this research is the A123 LiFePO4 26650.

3.1. Coupled Electrochemical-thermal Model

The electrochemical model employed is P2D model, which is based on a set of Partial Differential Equations (PDEs) describing the dynamics of physical processes within the battery electrodes and electrolyte Jokar, Rajabloo, Désilets, and Lacroix (2016). The main equations of the model are shown as below: Mass conservation of Li+ in the spherical active material:

$$\frac{\partial c_s}{\partial t} - \frac{1}{r^2}\frac{\partial}{\partial r}\left(r^2 D_s \frac{\partial c_s}{\partial r}\right) = 0 \tag{5}$$

where c_s represents the concentration of Li+ in solid phase , r is the particle radius of the electrodes, D_s is the intercalation diffusivity.

Charge conservation in the electrodes:

$$\sigma_{\text{eff}} \frac{\partial^2 \phi_s}{\partial x^2} = j_f \tag{6}$$

where σ_{eff} is the effective elective electrical conductivity, ϕ_s is the electrical potential in solid phase, j_f is the electrode current density (I/A_s) and A_s is the specific interfacial area.

Mass conservation in the electrolyte phased:

$$\frac{\partial(\varepsilon_e c_e)}{\partial t} = \frac{\partial}{\partial x}\left(D_e^{\text{eff}} \frac{\partial c_e}{\partial x}\right) + \frac{1 - t_+^0}{F} j_f \tag{7}$$

where ε_e is the volume fraction of phase in electrolyte phased, c_e is the concentration of Li+ in electrolyte, D_e^{eff} is the elective electrolyte diffusivity, F is the Faraday's constant, t_+^0 is the transference number.

Charge conservation in electrolyte:

$$\frac{\partial}{\partial x}\left(\kappa^{\text{eff}} \frac{\partial \phi_e}{\partial x}\right) + \frac{\partial}{\partial x}\left(\kappa_{\text{D}}^{\text{eff}} \frac{\partial \ln c_e}{\partial x}\right) + j^{\text{Li}} = 0 \tag{8}$$

where κ^{eff} is the effective electrolyte conductivity, ϕ_e is the potential of the eletrolyte phase, j^{Li} is the reaction flux.

Over-potential and cell voltage:

$$\eta = \phi_s - \phi_e - U = \phi_s - \phi_e - (U_{\text{ref}} - (T - T_{\text{ref}})\frac{dU}{dT}) \tag{9}$$

where the T is the temperature of the battery cell.

The detail equations and the specific parameters used in this P2D model are sourced from the research by Prada et al. (2012). The temperature of this model is obtained from the output of the thermal model.

The thermal model is built based on the energy balance theory proposed by Bernardi et alBernardi, Pawlikowski, and Newman (1985). The temperature change with time can be described as Eq. 10

$$mC_m \frac{dT}{dt} = I(U - V - T\frac{dU}{dT}) - hA(T - T_{\text{a}}) \tag{10}$$

In this equation, the first part of the right side is the heat generation while it can be outputted from the electrochemical model, while I is the overall current, U is the open circuit voltage (OCV), V is the terminal voltage and $-T\frac{dU}{dT}$ is the reversible entropy change. The second part of the right is the heat dissipation while h, 10 $W/m^2/K$ is the heat transfer coefficient, A, 0.00634 m^2 is the inner surface area of the battery cell and T_{a}, 298 K is the environmental temperature. In the left side, m, 0.07 Kg is the mass of the battery cell and C_m, 1100 $J/kg/K$ is the heat capacity. These data are extracted from the battery data-sheet and other literature A123 Systems (2012); Song, Hu, Choe, and Garrick (2020); Bernardi et al. (1985).

The P2D electrochemical model and the thermal model can be coupled as shown in the figure 1, similar with Feng et al. (2016). As demonstrated in Eq.9 and Eq.10, the coupling achieved by considering the temperature dependent OCV. To be specific, the average temperature generated from the thermal model based on the heat generation and dissipation is timely converted to the electrochemical model by effecting the OCV.

3.2. ISC Model

As we illustrate in the figure 1, by paralleled the extra ISC resistance to the P2D, the ISC can be simulated. Therefore, the total current will be described as bellow:

$$I = I_{\text{t}} + I_{\text{ISC}} = I_{\text{t}} + \frac{V}{R_{\text{ISC}}} \tag{11}$$

At the same time, the heat generated from ISC counted from the Eq 12. should be added into the overall thermal equation.

$$Q_{\text{ISC}} = I^2 R_{\text{ISC}} \tag{12}$$

3.3. Simulation Result

By setting different values of the R_{ISC} value, various levels of ISC can be simulated based on the P2D-thermal-ISC model implemented here. Lower the R_{ISC} correspond to more se-

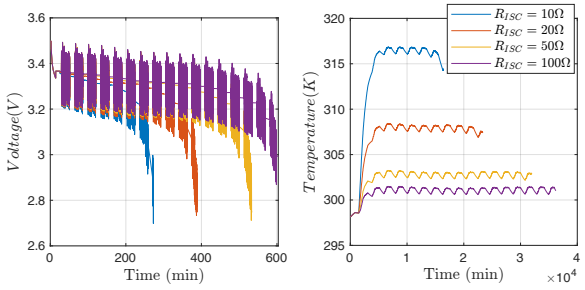

Figure 2. ISC simulation results

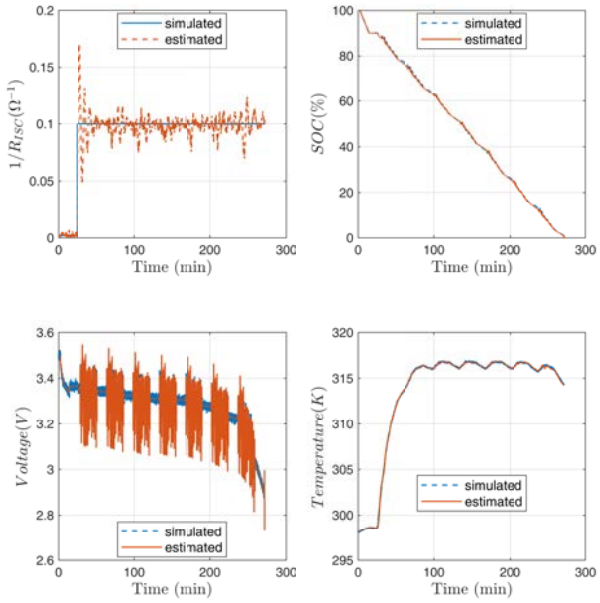

Figure 3. ISC detection results for $R_{ISC} = 10\Omega$

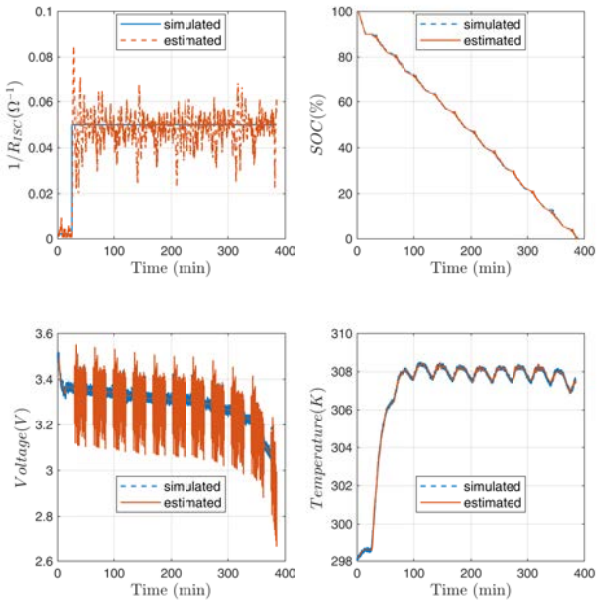

Figure 4. ISC detection results for $R_{ISC} = 20\Omega$

vere ISC conditions. The corresponding measurements simulated from the model are shown in figure 2 . Consistent with the findings in Feng, Ouyang, et al. (2018), the continual loss of SOC and the increase in heat generation are two main indicators of ISC occurrences. This is demonstrated by the quicker voltage drop and higher temperature rise observed with more severe ISC levels.

4. ISC Detection Results

To validate the proposed approach, measurements including voltage and temperature were generated from the built model using the Urban Dynamometer Driving Schedule (UDDS) profile. These signals were utilized by the algorithm to estimate the R_{ISC} online, with ISC simulated by specifying the R_{ISC} profile. The covariance of the measurement noises was set to be 0.1 mV and 2.5 mK, respectively.

For evaluating the performance of the early detection approach, we set R_{ISC} to a moderate level by dropping its value from a relatively high value (representing no ISC) to 10 Ω and 20 Ω, which are considered moderate ISC levels in other research studies (Feng, He, et al., 2018; Hu et al., 2020; Seo et al., 2020). The comparison between the algorithm's estimated states and simulated states from the built model is depicted in the top two sub-figures of Figure 3 and 4. Despite some fluctuations observed in the estimated R_{ISC}, these are attributed to measurement noise and the simplified model used within the EKF algorithm. Nonetheless, the estimated R_{ISC} closely and promptly tracks the simulated ISC value after its occurrence, demonstrating rapid and accurate detection of early ISC.

Specifically, from the results, it can be observed that after ISC is triggered, the estimated value converges to the true value within two minutes, while the temperature rises to 299 K for both cases. This implies that the approach can provide an alarm for severe ISC levels based on the estimated value of R_{ISC} before the temperature reaches a critical threshold, thereby preventing further thermal runaway or loss of battery capacity. Moreover, the SOC estimation displays good consistency with the real value. Furthermore, the voltage drop and temperature rise observed in the simulated results after ISC occurrence, as depicted in the figure, illustrate the primary ISC responses. These indicators demonstrate good consistency between the simulated data and the calculated data generated from the built-in model in the algorithm and the estimated states.

5. Conclusion

In this research, an electrochemical-thermal-ISC model was constructed in COMSOL to simulate ISC events and validate the proposed model-based ISC detection algorithm. This model combines the P2D model for electrical signals with the EBE for the thermal model, coupling them through temperature changes and the relationship between OCV and temperature.

The ECM-based algorithm demonstrated promising performance in early ISC detection. The ECM parameters utilized in the algorithm were derived through parameter estimation using a dataset generated from the high fidelity model under healthy battery conditions. .

In conclusion, the proposed method holds potential for application in BMS for early ISC detection, owing to its simplicity and efficiency. However, future research will focus on developing a more comprehensive battery model that considers the temperature response of physical electrochemical parameters to better capture dynamic responses and temperature distribution within the battery cell. Furthermore, enhancements to the algorithm will aim to incorporate temperature response and achieve precise localization of ISCs.

BIOGRAPHIES

Yiqi. JIA was born in China on January 28, 1996. She holds a Bachelor's degree in Automotive Engineering from Wuhan University of Technology, Wuhan, China (2017), and a Master's degree in Automotive Engineering from the University of Bath, Bath, UK (2018). After working as a vehicle engineer for nearly 3 years at Ford Motor Company, she started her Ph.D. journey in Mechanical Engineering at Politecnico di Milano in November 2021. Her research primarily focuses on the diagnosis and prognosis of Lithium-ion batteries, structural batteries, and more broadly, on mechanical/structural-related behaviors. This includes battery modeling, simulation, and data-based estimation methods for optimal battery management.

Lorenzo. BRANCATO was born in Italy on December 12, 1998. He earned his Bachelor's degree in Mechanical Engineering from Politecnico di Milano in 2020. Subsequently, he pursued a Master's degree in Mechatronic Engineering at Politecnico di Milano, completing his studies in 2022. He has started his Ph.D in Mechanical Engineering at Politecnico di Milano in 2023. His current research focus on the development of advanced diagnostic and prognostic approaches for dynamic, complex systems subject to degradation. This involves high-fidelity multi-physics modeling, simulation and advanced model-based filtering methods.

Marco. GIGLIO is Full Professor at the Department of Mechanical Engineering, Politecnico di Milano. His main research fields are: (i) Structural integrity evaluation of complex platforms through Structural Health Monitoring methodologies; (ii) Vulnerability assessment of ballistic impact damage on components and structures, in mechanical and aeronautical fields; (iii) Calibration of constitutive laws for metallic materials; (iv) Expected fatigue life and crack propagation behavior on aircraft structures and components; (v) Fatigue design with defects. He has been the coordinator of several European projects: HECTOR, Helicopter Fuselage Crack Monitoring and prognosis through on-board sensor, 2009-2011, ASTYANAX (Aircraft fuselage crack Monitoring System and Prognosis through eXpert on-board sensor networks), 2012-2015, and SAMAS (SHM application to Remotely Piloted Aircraft Systems), 2018-2020. He has been the project leader of the Italian Ministry of Defence project in the National Plan of Military Research, SUMO (Development of a predictive model for the ballistic impact), 2011-2012 and, SUMO 2 (Development of an analytical, numerical and experimental methodology for design of ballistic multilayer protections), 2017-2019. He has published more than 210 papers, h-index 27 (source Scopus) in referred international journals and congresses.

Francesco. CADINI (MSc in Nuclear Engineering, Politecnico di Milano, 2000; MSc in Aerospace Engineering, UCLA, 2003; PhD in Nuclear Engineering, Politecnico di Milano, 2006) is Associate Professor at the Department of Mechanical Engineering, Politecnico di Milano. He has more than 20 years of experience in the assess-

ment of the safety and integrity of complex engineering systems, entailing (i) artificial intelligence (machine learning)-based approaches for classification and regression, (ii) development and application of advanced Monte Carlo algorithms for reliability analysis (failure probability estimation), (iii) diagnosis and prognosis (HUMS) of dynamic, complex systems subject to degradation, (iv) uncertainty and sensitivity analyses, (v) structural reliability analyses.

Enhancing Lithium-Ion Battery State-of-Charge Estimation Across Battery Types via Unsupervised Domain Adaptation

ABSTRACT

Accurate estimation of the state-of-charge (SOC) in lithium-ion batteries (LIBs) is paramount for the safe operation of battery management systems. Despite the effectiveness of existing SOC estimation methods, their generalization across different battery chemistries and operating conditions remains challenging. Current data-driven approaches necessitate extensive data collection for each battery chemistry and operating condition, leading to a costly and time-consuming process. Hence, there is a critical need to enhance the generalization and adaptability of SOC estimators. In this paper, we propose a novel SOC estimation method based on Regression-based Unsupervised Domain Adaptation. We evaluate the performance of this method in cross-battery and cross-temperature SOC estimation scenarios. Additionally, we conduct a comparative analysis with a widely-used classification-based unsupervised domain adaptation approach. Our findings demonstrate the superiority of the regression-based unsupervised domain adaptation method in achieving accurate SOC estimation for batteries.

1. INTRODUCTION

Accurate real-time estimation of the state-of-charge (SOC) in batteries holds paramount importance across various domains, including electric vehicles and renewable energy storage systems. The SOC represents the percentage of remaining capacity, serving as a pivotal indicator of the battery's condition for facilitating effective operations.

Precise SOC estimation is imperative for optimizing energy utilization and mitigating premature degradation, consequently reducing maintenance costs and environmental impacts. However, SOC determination poses a formidable challenge due to its dependence on multiple interconnected variables such as voltage, current, resistance, and temperature, complicating precise estimation (Z. Wang, Feng, Zhen, Gu, & Ball, 2021). Thus, the development of robust and adaptable SOC estimation methods is essential to meet the escalating demand for sustainable energy solutions. Conventional SOC estimation approaches often falter in dynamic environments characterized by temperature variations, load fluctuations, and battery aging. Compounding this challenge is the diverse array of battery types with varying chemistries. Conventional methods necessitate significant investments in time and resources to acquire labeled data specific to each battery variant for accurate SOC estimation. Consequently, there arises a crucial need for innovative, adaptable SOC estimation methods capable of addressing these challenges while reducing reliance on expensive labeled data sources.

Numerous methodologies have been proposed for SOC estimation, employing diverse sensor data and modeling techniques. Traditional approaches, such as look-up table methods and direct-counting methods, often rely on simple algorithms but struggle with real-time estimation due to their requirement for stable discharge currents (Shen, Li, Meng, Zhu, & Shen, 2023). Conversely, model-based methods address this limitation but demand prior knowledge of battery characteristics, rendering them less suitable for dynamic and varied operational conditions. Recent advancements have introduced data-driven methods, which eschew reliance on domain knowledge and instead utilize battery parameters such as current, voltage, and temperature measurements to develop SOC estimators. Various data-driven techniques have been proposed for battery SOC estimation. (Li, Wang, & Gong, 2016; Hu et al., 2014; Tong, Lacap, & Park, 2016; Khumprom & Yodo, 2019; Chandra Shekar & Anwar, 2019). How et al. offer a comprehensive review of SOC estimation methods (How, Hannan, Lipu, & Ker, 2019). The primary drawback of data-driven approaches lies in their dependence on substantial training data, which can be expensive and time-intensive to acquire. In response to the challenge of limited data, transfer learning (TL) has emerged as a potent technique in machine

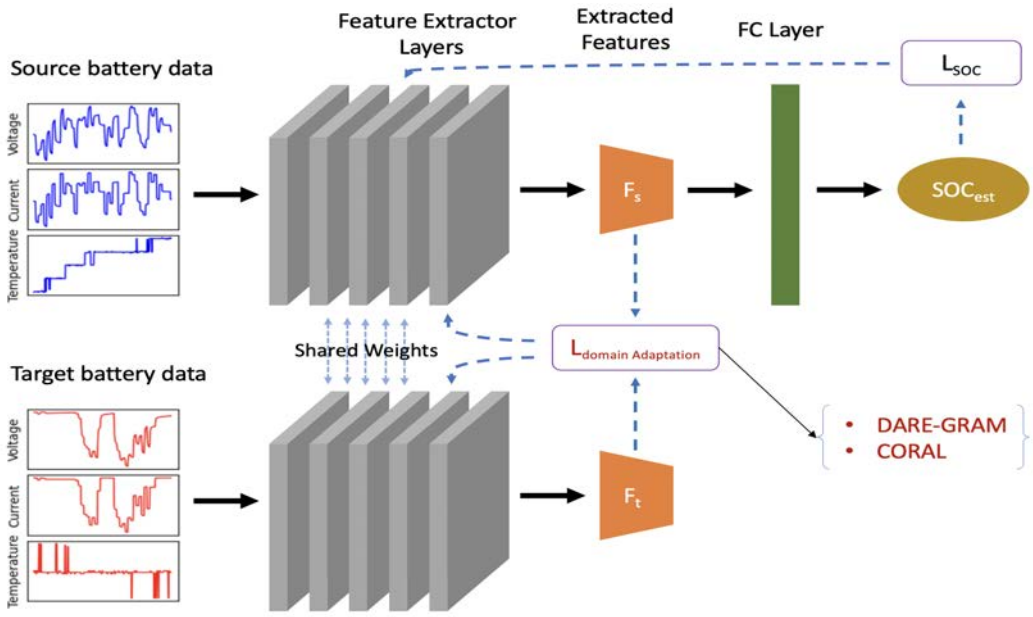

Figure 1. Structure of the Proposed Deep Neural Network Architecture for SOC Estimation using Domain Adaptation.

learning.

In the realm of battery SOC estimation, transfer learning holds promise by leveraging existing data from one domain (e.g., a specific battery type or environment), known as the source domain, to enhance SOC estimation performance in a different, less well-characterized domain, referred to as the target domain. Fine-tuning, the most popular TL approach, involves further training a pre-trained neural network model, originally trained on a large dataset for a different domain, using a smaller dataset specific to the target domain. Fine-tuning has recently been applied to battery SOC estimation to transfer knowledge between different ambient temperatures of the same battery type (Y.-X. Wang, Chen, & Zhang, 2022), or between different battery types (Bhattacharjee, Verma, Mishra, & Saha, 2021). However, fine-tuning necessitates access to labeled examples from the target domain, which may not always be readily available. In the case of lithium-ion batteries (LIBs), obtaining reliable labeled data under real-world conditions is particularly challenging.

To address the challenge of lacking labeled data for the target domain, machine learning researchers have introduced Unsupervised Domain Adaptation (UDA). Originating in the computer vision domain, UDA tackles the broader issue of transferring knowledge from a source domain to a target domain where labeled data is scarce (Long, Cao, Wang, & Jordan, 2015). This is particularly pertinent in scenarios where the characteristics of the target domain evolve over time, diverging from the source domain, and making traditional supervised learning approaches inadequate. Batteries are subjected to diverse environmental conditions, undergo degradation over time, and witness frequent introductions of new battery chemistries. A central strategy of UDA techniques is to generate domain-invariant feature representations by aligning feature distributions between domains (Wilson & Cook, 2020). This facilitates model adaptation to new and dynamically changing environments, enabling effective generalization without access to labeled data in the target domain.

A common approach for generating domain-invariant feature representations is to minimize a divergence measured as the distance between distributions. Maximum mean discrepancy (MMD) (Borgwardt et al., 2006), multi-kernel MMD (MK-MMD) (Gretton et al., 2012), and lastly, correlation alignment (CORAL) (Sun & Saenko, 2016) are among the popular divergence minimization techniques. Recently, there has been growing interest in applying UDA techniques to estimate battery SOC (Shen, Li, Liu, Zhu, & Shen, 2022; Bian, Yang, & Miao, 2020; Oyewole, Chehade, & Kim, 2022; Ni, Li, & Yang, 2023; Meng, Agyeman, & Wang, 2023). While these UDA techniques were initially developed for classification tasks, SOC estimation poses a regression task. A significant distinction between regression and classification problems is that regression problems are less robust to feature scaling, potentially impacting model robustness when aligning feature distributions with UDA methods (Chen, Wang, Wang, & Long, 2021).

To address this challenge, a specialized domain adaptation method for regression problems has emerged. DARE-GRAM (Nejjar, Wang, & Fink, 2023) is one such recent domain adaptation regression (DAR) technique motivated by the closed-form solution of ordinary least squares (OLS). Unlike pre-

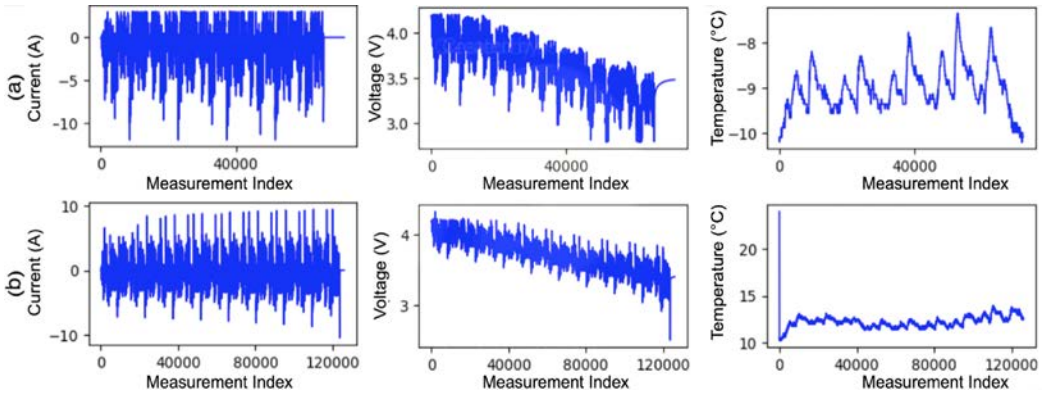

Figure 2. Measured Current, Voltage, and Battery Temperature During LA92 Drive Cycle. (a) Panasonic LiB and (b) LG LiB.

viously discussed classification-based methods that directly align features, DARE-GRAM aligns the inverse Gram matrix of the features. The authors demonstrated the capability and robustness of this method through experiments on three benchmark computer vision regression datasets.

In this paper, we explore the application of unsupervised domain adaptation (UDA) techniques within the framework of transfer learning (TL) to enhance the precision of battery State of Charge (SOC) estimation. We conduct a comparative study between a well-established classification-based domain adaptation method (CORAL) and DARE-GRAM, a regression-based method, marking the first application of a regression-based UDA method to battery management tasks, to the best of our knowledge. We examine their efficacy across a range of TL tasks and settings, aiming to provide comprehensive insights into their performance and suitability for addressing the complex challenges posed by evolving battery landscapes and diverse operational conditions.

The remainder of this paper is organized as follows. Section 2 presents the proposed methodology. Section 3 elucidates the LiB datasets and implementation details. Section 4 offers the experimental results and discussion. Finally, Section 5 concludes the paper.

2. METHODOLOGY

2.1. Problem Statement

We begin by defining the problem of cross-battery state-of-charge (SOC) estimation. The source domain D^s represents the battery type with labeled data $X^s = \{x_j^s, y_j^s\}_{j=1}^{n_s}$, where n_s denotes the number of source samples. Conversely, the target domain D^t represents the battery type with unlabeled data $X^t = \{x_j^t\}_{j=1}^{n_t}$, where n_t represents the number of target samples. x_j^s and x_j^t are the temporal measurements of voltage, current, and temperature for both source and target batteries until the current time-step, each with a length of l. Additionally, y_j^s represents the SOC at the current time-step for sample j. Specifically, each sample comprises previous voltage, current, and temperature measurements from time-step $k - l + 1$ to the current time-step k as input, with the SOC of the current time-step k as the label. This paper aims to establish an SOC estimation model to predict the SOC of the target battery y_j^t utilizing source data X^s and target data X^t, assuming the existence of a distribution discrepancy between the source and target data.

2.2. Deep Neural Network

Our approach leverages a deep neural network architecture to tackle the intricate task of state-of-charge (SOC) estimation. The architecture of our proposed network is depicted in Figure 1, comprising two main modules: a feature extractor and a predictor. The feature extractor plays a pivotal role in capturing the temporal dynamics and patterns inherent in the battery data, facilitating the extraction of informative features crucial for precise SOC estimation. This module may encompass convolutional layers in convolutional neural networks (CNNs), recurrent layers in recurrent neural networks (RNNs), or fully connected layers in feedforward neural networks. Each type of feature extractor possesses distinct strengths and weaknesses, and their performance can vary depending on the specific problem at hand. Subsequently, the extracted features are propagated through a fully-connected layer with a single output node, tasked with mapping these features to the SOC estimation.

2.3. Domain Adaptation

Unsupervised Domain Adaptation (UDA) techniques can be instrumental in mitigating the domain discrepancy between source and target domains. These methods facilitate the alignment of feature distributions across domains, thereby enabling the effective transfer of knowledge from the source domain to enhance state-of-charge (SOC) prediction in the target domain. Metric-based UDA methods aim to alleviate cross-domain distribution discrepancies by applying static criteria. In this study, we leverage a classification-based UDA method, CORAL, and a regression-based UDA method, DARE-GRAM.

Correlation Alignment (CORAL) (Sun & Saenko, 2016) stands as a potent domain adaptation technique designed to align the second-order statistics of both the source and target domains. Its primary objective is to diminish the distribution discrepancy between these domains by matching their covariances. This process involves whitening the source and target data to eliminate disparities in variances and subsequently re-coloring the source data to align with the color (covariance) of the target data. By aligning these statistical properties, CORAL effectively enhances the similarity between the source and target distributions, thereby bolstering the transferability of models from the source domain to the target domain. CORAL demonstrates particular efficacy in scenarios where distribution shifts predominantly stem from alterations in data covariances.

DARE-GRAM (Nejjar et al., 2023) harnesses the power of the inverse Gram matrix to align the feature space, taking into consideration the discriminative capability of the final linear layer. This approach prioritizes angle alignment and scale alignment to foster greater compatibility between the source and target domains. The underlying motivation is to identify a feature space conducive to facile learning by a shared linear regressor. Leveraging the ordinary least-squares (OLS) closed-form solution, the method estimates the parameters of the linear layer for regression purposes. By emphasizing the alignment of the angle and scale of the inverse Gram matrix, DARE-GRAM presents a more stable and robust approach compared to direct feature alignment. DARE-GRAM loss function is expressed as follows:

$$L_{DAREGRAM}(F_s, F_t) = \alpha L_{cos}(F_s, F_t) + \gamma L_{scale}(F_s, F_t) \quad (1)$$

where F_s and F_t are extracted features from the source and target domains, respectively. α and γ are hyper-parameters governing the influence of angle and scale alignment, respectively. $L_{cos}(F_s, F_t)$ corresponds to angle alignment, aiming to maximize the cosine similarity between the F_s and F_t. Meanwhile, $L_{scale}(F_s, F_t)$ represents the scaling alignment term, endeavoring to minimize the discrepancy between the k-principal eigenvalues, where k is selected using a specified threshold.

2.4. Training Process

During the training phase, we leverage both source and target data to cultivate domain-invariant representations. The network is guided by two distinct loss functions: the SOC prediction loss, aimed at minimizing the disparity between predicted and actual SOC values in the source domain, and the domain alignment loss, which mandates the resemblance of feature distributions between the source and target domains. The synergy of these loss functions ensures that the network acquires both precise SOC prediction capabilities and domain-invariant features, thereby augmenting SOC estimation accuracy in the target domain. The total loss of the deep network in an end-to-end training scenario is subsequently computed as follows:

$$L_{total} = L_{SOC} + L_{DomainAdaptation} \quad (2)$$

where L_{SOC} denotes the prediction loss, and $L_{DomainAdaptation}$ represents the domain adaptation loss. Since both L_{SOC} and $L_{DomainAdaptation}$ losses are equally critical to the success of the model, we set equal weights to both losses to prevent either loss from dominating. We employ two domain adaptation methods introduced in the previous section to calculate

the domain adaptation loss.

3. Experimental Setup

3.1. Dataset Description

In this study, the efficacy of the proposed method is evaluated using two publicly available LiB datasets: 1) the Panasonic 18650PF dataset (Kollmeyer, 2018) acquired from the University of Wisconsin–Madison, and 2) the LG 18650HG2 dataset (Naguib, Kollmeyer, & Skells, 2020) obtained from McMaster University in Hamilton, Ontario, Canada.

For the Panasonic 18650PF dataset, testing involved brand-new 2.9Ah Panasonic 18650PF cells in an 8 cu.ft. thermal chamber, utilizing a 25 amp, 18 volt Digatron Firing Circuits Universal Battery Tester channel. Similarly, for the LG 18650HG2 dataset, testing was conducted with brand-new 3Ah LG HG2 cells in an 8 cu.ft. thermal chamber, employing a 75 amp, 5 volt Digatron Firing Circuits Universal Battery Tester channel. Both datasets encompassed a series of drive cycles, including US06, HWFET, UDDS, and LA92, performed for each battery. Notably, the battery tests in both datasets were conducted at discrete ambient temperatures ranging from -20°C to 25°C. Figure 2 illustrates the voltage, current, and battery temperature measurements of the two batteries during the LA92 drive cycle.

3.2. Implementation Details

The Panasonic and LG batteries are designated as the "source" and "target" batteries, respectively. Specifically, each experiment involves one Panasonic battery type under a particular ambient temperature serving as the source domain, while LG battery type under a different ambient temperature acts as the target domain. The target data is evenly partitioned into training and testing sets, with the training set utilized for domain adaptation and the testing set employed for performance assessment. As our objective is to assess the efficacy of various unsupervised domain adaptation methods for near-real-time State of Charge (SOC) estimation, we restricted the input sensor data history to the ten most recent observations, ensuring a balanced evaluation across methods without sacrificing generality.

In the deep neural network architecture, we employ Bidirectional Gated Recurrent Unit (BiGRU) modules as feature extractors. GRUs are well-suited for tasks involving sequential information as they efficiently capture temporal dependencies while maintaining a simpler and more streamlined architecture compared to Long Short-Term Memory (LSTM) networks. Moreover, initial experiments conducted as part of our model development phase demonstrated that GRUs outperformed LSTMs in terms of both prediction accuracy and training efficiency. In addition, (Ye & Yu, 2021) demonstrated the efficiency of BiGRU for battery state-of-health

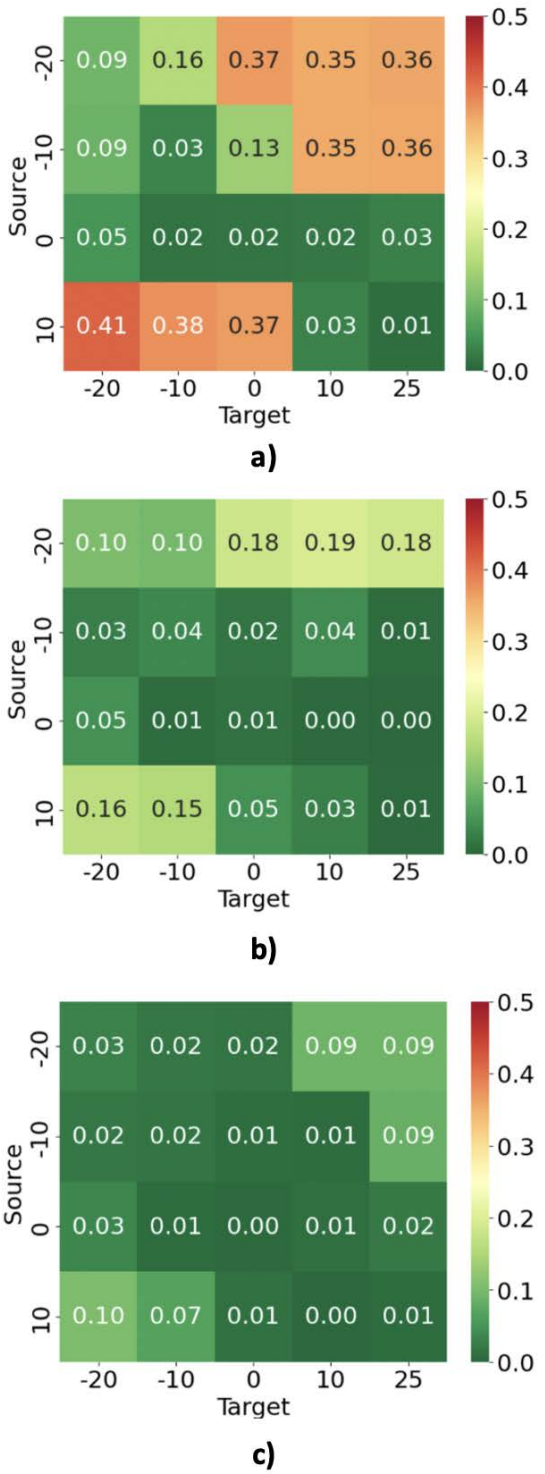

Figure 3. Heatmap of Target Mean Squared Error (MSE) for Different Domain Adaptation Methods under Different Source and Target Temperatures (°C). **a)** No TL, **b)** CORAL, and **c)** DARE-GRAM.

prediction. We run an initial set of experiments to determine the best hyper-parameters to be used in the deep learning

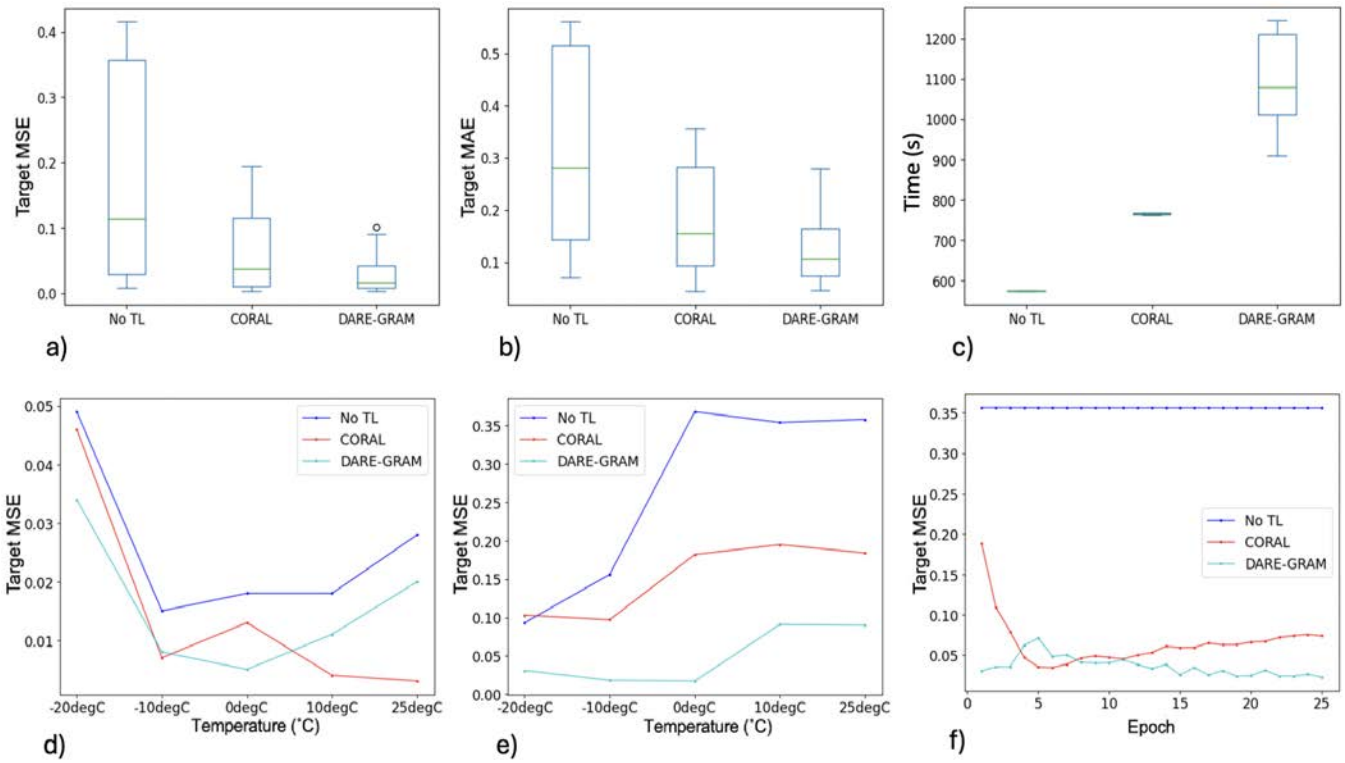

Figure 4. Comparison of Domain Adaptation Methods in State-of-Charge (SOC) Estimation. (a) Target MSE, (b) Target MAE, (c) Training Time (s), (d) Target MSE for Different Temperatures of the Target Battery when the Source Battery is Panasonic in 0°C, (e) Target MSE for Different Temperatures of the Target Battery when the Source Battery is Panasonic in -20°C , and (f) Target MSE Over Training Epochs.

model. The architecture of the feature extractors comprises five layers, each containing 200 hidden units, with a fully-connected (FC) layer consisting of 400 neurons. Additionally, L2 regularization and dropout techniques are applied to enhance the model's generalization and robustness. The number of training epochs is set to 25 for all experiments, with Mean Squared Error (MSE) serving as the loss function for the SOC prediction module.

In addition to utilizing the DARE-GRAM method, we also conduct experiments using the CORAL technique, a well-established classification-based domain adaptation approach, for performance comparison purposes. Furthermore, we perform experiments without any domain adaptation, denoted as the "No TL" model. In "No TL" model experiments, the training process excludes the utilization of target data, with the testing set of target data reserved solely for evaluating the performance of the trained model on the source data. This article utilizes mean-square error (MSE) and mean absolute error (MAE) as the performance evaluation metrics.

4. Results and Discussion

We conduct a thorough analysis of cross-battery state-of-charge (SOC) estimation, comparing the performance of regression-based and classification-based domain adaptation methods. We present the results of our experiments, focusing on the SOC estimation achieved by the BiGRU network with different domain adaptation methods.

Table 1 and Figure 3 summarize the SOC estimation outcomes. In each experiment, the Panasonic battery serves as the source domain, while the LG battery serves as the target domain. While no single domain adaptation method outperforms all others across every experiment, the DARE-GRAM method consistently demonstrates superior performance. Out of the 20 transfer learning tasks conducted, DARE-GRAM outperforms other methods in 15 tasks. Figures 4a,b illustrate box plots for the Mean Squared Error (MSE) and Mean Absolute Error (MAE) values across all tasks for different domain adaptation methods, further highlighting the superiority of the DARE-GRAM approach.

However, it is worth noting that despite its superior performance, the DARE-GRAM method demands more training time. As depicted in Figure 4c, the average training time of the model for DARE-GRAM method is approximately 40% longer compared to other methods. This disparity in computational costs can be attributed to the computation of the domain adaptation loss function. While DARE-GRAM yields

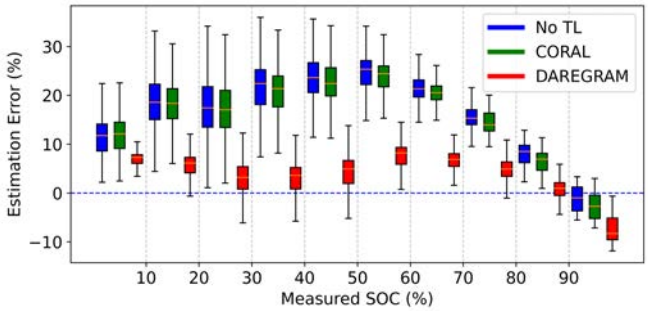

Figure 5. Comparison of Domain Adaptation Methods in SOC Estimation for Panasonic Battery at 10°C to LG Battery at 10°C Task.

impressive results, its computational overhead may pose practical considerations in certain contexts.

While the DARE-GRAM method demands a relatively longer training time over a fixed number of epochs, it exhibits a notably faster convergence, requiring significantly fewer training epochs to reach a stable state. Figure 4f shows the MSE of the target domain for different domain adaptation methods and the "No TL" model over the training epochs for one transfer task (Panasonic -10°C to LG -10°C). This plot shows that with only one epoch, SOC estimations of the target domain for the DARE-GRAM model are significantly more accurate than other methods.

Figure 4d,e shows the results of two different temperatures of the source battery. In each plot, the MSE values of different domain adaptation methods and the "No TL" model are depicted over different temperatures of the target battery. These two plots indicate that cross-battery SOC estimation using the measurements of the source battery under -20°C temperature is significantly more challenging than 0°C. Another important finding is that as the difference between the temperatures of the source and target domains increases, the transfer learning task becomes more rigorous.

Figure 5 illustrates the SOC estimation using different domain adaptation methods for a specific task (Panasonic 10°C to LG 10°C). While the performance of the CORAL method closely resembles that of the "No TL" model, the DARE-GRAM method yields more accurate SOC estimations. DARE-GRAM estimates are somewhat inferior to the other methods when the battery is at full SOC.

The results reveal that for certain transfer tasks, such as Panasonic at 0°C to LG -10°C, even the "No TL" model achieves satisfactory performance. This suggests that at under certain settings, the model trained solely on the source data can effectively estimate the state-of-charge (SOC) for the target data without the utilization of any domain adaptation or transfer learning methods in general.

5. Conclusion

In this work, we introduced a regression-based unsupervised domain adaptation method, DARE-GRAM, for SOC estimation. Through a series of experiments, we assessed the performance and effectiveness of DARE-GRAM in cross-battery SOC estimation, comparing its results with those obtained using the classification-based UDA method, CORAL. Our findings consistently demonstrate the superiority of the DARE-GRAM method in achieving accurate SOC estimation. DARE-GRAM consistently outperformed CORAL, showcasing its robustness and adaptability across various battery domains. Moreover, DARE-GRAM exhibited the ability to prevent negative transfer, ensuring that knowledge transfer did not compromise SOC estimation performance. Furthermore, our results underscored the influence of ambient temperature on model transferability. When the ambient temperatures of both the source and target batteries were similar or closely aligned, the transferability of the model was notably enhanced, leading to improved SOC estimation accuracy. Overall, our study highlights the effectiveness of DARE-GRAM as a powerful tool for enhancing SOC estimation in diverse battery management scenarios, offering valuable insights for future research in the field.

ABSTRACT

Predictive maintenance has become a highly favored application in Industry 4.0, particularly in complex systems with requirements for reliability, robustness, and performance. Aircraft engines are among these systems, and several studies have been conducted to try to estimate their remaining lifespan. The C-MAPSS dataset provided by NASA has greatly served the scientific community, and several works based on physical models and data-driven approaches have been proposed. However, several limitations related to data quality or data availability of failures persist, and integrating domain knowledge can help address these challenges. In this article, we are currently implementing a new approach based on knowledge coupled with qualitative spatial reasoning to study the propagation of faults within system components until complete shutdown. Region Connection Calculus (RCC8) formal model will be used to describe the component relationships, drawing inspiration from the C-MAPSS dataset.

1. INTRODUCTION

In Industry 4.0, predictive maintenance (PdM) allows for the detection of anomalies and the anticipation of upcoming breakdowns in equipment, machines, or components (Nunes, Santos, & Rocha, 2023). Through the continuous collection of multi-sensor data and system performance analysis, this maintenance strategy relies on machine learning (ML) algorithms capable of building models with the ability to detect early signs of impending failures or malfunctions. Early detection of anomalies allows for prevention, anticipation of corrective actions, and reduced downtime. In this context, PdM solutions rely on estimating the remaining useful life (RUL) before failure (Zio, 2022), which represents the remaining operating time before a component or machine failure. Several approaches are cited in the literature: model-based, data-driven, knowledge-based, or hybrid approaches combining the previous three (Cardoso & Ferreira, 2021). In the aeronotic context, Aircraft engines are among these systems, and several studies have been conducted to try to estimate their remaining lifespan (de Pater, Reijns, & Mitici, 2022). The C-MAPSS dataset provided by NASA [1] has greatly served the scientific community. The solutions proposed in the literature mainly address data-driven approaches (Kumar, 2021; Vollert & Theissler, 2021; Barry, Hafsi, & Mian Qaisar, 2023; Asif et al., 2022), but very few hybrid approaches (Dangut, Jennions, King, & Skaf, 2022) are proposed or tested and no approach attempting to integrate domain knowledge or expert knowledge exists (Barry & Hafsi, 2023; Mayadevi, Martis, Sathyan, & Cohen, 2022).

In this study, we aim to focus on the C-MAPSS dataset referenced in the domain literature and attempt to explore a new approach based on knowledge coupled with qualitative spatial reasoning to study the propagation of faults within system components until complete shutdown. RCC8 rules will be used to describe the component relationships, drawing inspiration from the C-MAPSS dataset (Saxena, Goebel, Simon, & Eklund, 2008), which corresponds to a dataset generated by simulating the operational functioning of aircraft engines, with the aim of evaluating the performance of RUL estimation models. The main objective concerns the modeling of a domain ontology or a semantic graph from the domain knowledge integrated into the C-MAPSS dataset. Spatial and topological representation of system components will be addressed by using RCC8 relations.

2. CONTEXT

Commercial Modular Aero-Propulsion System Simulation (C-MAPSS) developed by NASA, is a simulation tool for a realistic large commercial turbofan engine flights, used for the

PHM'2008 challenge to generate un large dataset called C-MAPSS dataset (Saxena et al., 2008). It consists of a simulated engine model in the $90,000lb$ thrust class. It also includes an atmospheric model that can simulate operations at various altitudes (sea level to $40,000ft$), Mach numbers (0 to 0.90), and sea-level temperatures (-60 to $103F$). The C-MAPSS dataset is commonly utilized in the field of PdM and engine health prognostic (Vollert & Theissler, 2021). These data are often employed for developing and assessing engine health diagnostic algorithms, failure prediction models, and PdM strategies. The dataset is segmented into different simulation units as demonstrated in Table 1, where each representing an individual engine, with varied failure profiles. Due to its complexity and diversity, C-MAPSS serves as a popular testbed for validating PdM techniques in the aerospace engineering field.

Researchers often leverage this dataset to benchmark their algorithms and methodologies, comparing the performance of different approaches in predicting engine failures and assessing the health status of engines. Moreover, C-MAPSS provides a valuable resource for studying the behavior of engines under various operating conditions and environmental factors (Vollert & Theissler, 2021).

3. Related work

3.1. Predictive Maintenance & PHM Background

In light of the evolving and knowledge-intensive nature of the manufacturing domain, there has been a growing interest in employing semantic technologies (Xia, Zheng, Li, Gao, & Wang, 2022), particularly ontology-based approaches, for PdM. Recent research has introduced various ontologies and rule-based extensions aimed at enhancing knowledge representation and reuse in PdM with several applications in Industry 4.0 (Dalzochio et al., 2020) like in Machinery: (mechanical machines) (Nuñez & Borsato, 2018), (bearings) (Cao, Giustozzi, Zanni-Merk, de Bertrand de Beuvron, & Reich, 2019), elevator running systems (Hou, Qiu, Xue, Wang, & Jiang, 2020), hydraulic systems (Yan et al., 2023), Cyber-Physical Systems (Cao et al., 2022a; Oladapo, Adedeji, Nzenwata, Quoc, & Dada, 2023) and industrial robots (X. Wang, Mingzhou, Liu, Lin, & Xi, 2023). This section provides a review of the most significant research efforts in this area. In

(Cao, Samet, Zanni-Merk, De Bertrand de Beuvron, & Reich, 2019), the authors argue that existing PdM approaches have been limited to predicting the timing of machinery failures, while lacking the capability to identify the criticality of the failures. This may lead to inappropriate maintenance plans and strategies. Authors introduce a novel ontology-based approach to facilitate PdM in industry, by combining fuzzy clustering with semantic technologies. Fuzzy clustering techniques are employed to determine the criticality of failures based on historical machine data, while semantic technologies utilize the results of fuzzy clustering to predict the timing and severity of these failures. In (Cao et al., 2022b), the authors address the problem of complexity arising from heterogeneous industrial data, which leads to a semantic gap among manufacturing systems. There is an increasing need for uniform knowledge representation and real-time reasoning in Cyber-Physical Systems (CPS) to automate decision-making processes. In response to this challenge, the authors propose a hybrid approach that combines statistical and symbolic AI. They introduce a system called Knowledge-based System for PdM in Industry 4.0 (KSPMI), which utilizes statistical techniques such as ML and chronicle mining, along with symbolic AI technologies like domain ontologies and logic rules. This hybrid method enables automatic detection of machinery anomalies and prediction of future events. The effectiveness of the approach is demonstrated through evaluation on both real-world and synthetic datasets. In (Chhetri et al., 2022), authors raise the need to improve hard drive failure prediction, given its critical role in computing systems. The

authors point out that existing studies mostly rely on either ML or semantic technology, but each approach has its limitations: ML lacks context-awareness, while semantic technology lacks predictive capabilities. To address these limitations, the authors propose a hybrid approach that combines the strengths of both ML and semantic technology to enhance hard drive failure prediction accuracy. In (Yan et al., 2023), authors are interested in the problems due to the knowledge-intensive and heterogeneous nature of the manufacturing domain, the data and information required for PdM are normally collected from ubiquitous sensing networks. This leads to the gap between massive heterogeneous data/information resources in hydraulic system components and the limited cognitive ability of system users. To address this limitation, the authors propose a virtual knowledge graph-based approach for digitally modeling and intelligently predicting maintenance tasks.

3.2. Knowledge Representation & Spational Reasoning

In the industrial domain, representing knowledge involves organizing and structuring information about processes, systems, and domains. This helps in better understanding and decision-making. With the advancement of technology in Industry 4.0, effective knowledge representation is crucial for optimizing operations and driving innovation. In (Smith et al., 2019), authors highlight the need for a comprehensive ontology to support digital manufacturing, particularly in terms of standardizing terminology across various branches of the advanced manufacturing industries. They propose to develop an upper ontology for the Industrial Ontologies Foundry (IOF), based on the Basic Formal Ontology (BFO), to serve as a foundation for creating a suite of ontologies tailored for digital manufacturing. In (Confalonieri & Guizzardi, 2023) authors discuss the Multiple Roles of Ontologies in Explainable AI. Knowledge-based approaches for RUL estimation have several advantages over other methods (Barry & Hafsi, 2023), including the ability to incorporate domain-specific knowledge and experience into the model, and the ability to handle complex systems where data-driven methods may not be effective. However, they also have limitations, such as being dependent on the availability of expert knowledge and the potential for subjective judgments to influence the model. From an Operations perspective, knowledge-based methods, including fuzzy systems, provide a direct and cost-effective means for RUL estimation by leveraging expert knowledge. These methods prioritize ease of implementation and inter rater reliability. However, their effectiveness is closely tied to the quality of expert input.

Qualitative spatial reasoning, a branch of artificial intelligence, plays a significant role in enhancing decision-making processes within the industrial domain (Fraske, 2022). This approach focuses on analyzing spatial relationships and configurations without precise numerical measurements, allowing for a more intuitive understanding of industrial environments and processes. In the context of Industry 4.0, where smart manufacturing systems heavily rely on interconnected and sensor-rich environments, qualitative spatial reasoning offers valuable insights for optimizing resource allocation, scheduling tasks, and ensuring efficient workflow management (Ladron-de Guevara-Munoz, Alonso-Garcia, de Cozar-Macias, & Blazquez-Parra, 2023).

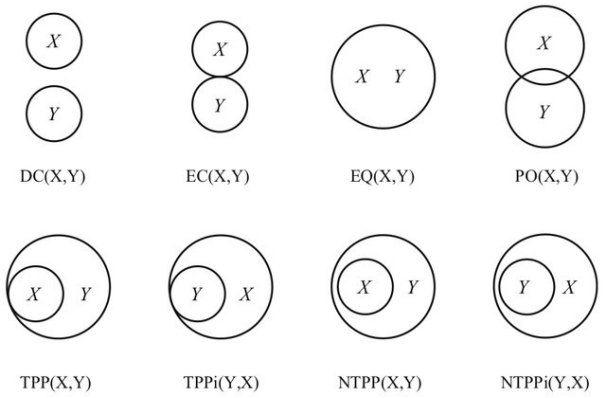

Figure 1. The 8 basic relations of RCC formalism.

RCC (Region Connection Calculus) is a logical formalism used in qualitative geometry intended for representing and reasoning about qualitative spatial relations among regions (Marc-Zwecker, De Bertrand de Beuvron, Zanni-Merk, & Le Ber, 2013). Based on the primitive connection relation $C(x, y)$, where x and y represent spatial regions consisting of a set of points in a plane, delimited by a continuous boundary. The RCC8 formalism defines eight basic relations between regions in space. These relations are exhaustive and mutually disjoint, allowing the definition of any relation between two spatial regions (Y. Wang, Mengling, Liu, & ye, 2018). The eight basic relations are DC (disconnected), EC (externally connected), PO (partially overlapping), EQ (equal), NTPP (non-tangential proper part), TPP (tangential proper part), NTPPi (the inverse of non-tangential proper part), and TPPi (the inverse of tangential proper part) as illustrated in Figure 1 (Lima, Costa, & Moreno, 2019).

4. Proposition

To develop a PdM method based on relationships between industrial components, we propose an approach with application to C-MAPSS aircraft engines as follows: (1) Domain study and advanced data characteristics analysis of aircraft engine components and sensors. (2) Formalization of knowledge in concepts and relationships with a focus on topological relationships between components. (3) Upgrading and describing topological relationships between components based on basic RCC8 relationships. (4) Configuration of a rule-base (based on assumptions) for error propagation across defined

relationships. (5) Determination of alert thresholds for each sensor and component to configure reasoning rules by using data-driven techniques. (6) Test the method and compare it with existing data-driven approaches.

This structured approach describes the steps involved in applying a knowledge-based PdM approach to aircraft engines, integrating domain knowledge with data-driven techniques for effective fault detection and planning main

4.1. Practical Insights into Knowledge Representation for C-MAPSS Scenario

To model and formalize domain knowledge, it is important to understand the functioning of the engine, its components, and the generated data. C-MAPSS consists of four datasets, with each dataset further divided into training and test subsets (Saxena et al., 2008). Each time series originates from a different engine of the same type. Three operational settings, which significantly affect engine performance, are included in the data. Furthermore, the data are contaminated with sensor noise. The engine operates normally at the beginning of each time series but begins to degrade at some point during the series. Multiple aircraft engines undergo varied usage throughout their operational history. A single engine unit may experience different flight conditions from one flight to another. Due to various factors, such as flight duration and environmental conditions, the extent and rate of damage accumulation will vary for each engine. Although the data is simulated, numerous phenomena and challenges have been incorporated to enhance the realism of the dataset. For instance, an initial wear is simulated reflecting typical manufacturing inefficiencies observed in real systems. The initial wear, manifested as minor alterations in pressure, temperature, airflow measurements, etc., is primarily intended to introduce a certain level of manufacturing variability into the data. Indeed, each engine is not identical upon leaving the factory due to manufacturing tolerances and differences in production processes, introducing variability right from the beginning of their use. Additionally, some non-ideal starting conditions or pre-existing degradations are simulated as initial wear due to manufacturing inefficiencies or storage conditions prior to use. Finally, noise is introduced at various stages of the simulation process, ultimately affecting the sensor measurements and mirroring real-world conditions (Saxena et al., 2008).

The engine consists of multiple components, as depicted in Figure 2 (Sánchez-Lasheras, Garcia Nieto, de Cos Juez, Bayón, & González, 2015) :

- **Fan:** The fan component draws in air, providing the initial thrust and airflow into the engine, crucial for combustion.
- **Combustor:** This section mixes fuel with the incoming air and ignites it, generating high-pressure and high-temperature gas for propulsion.

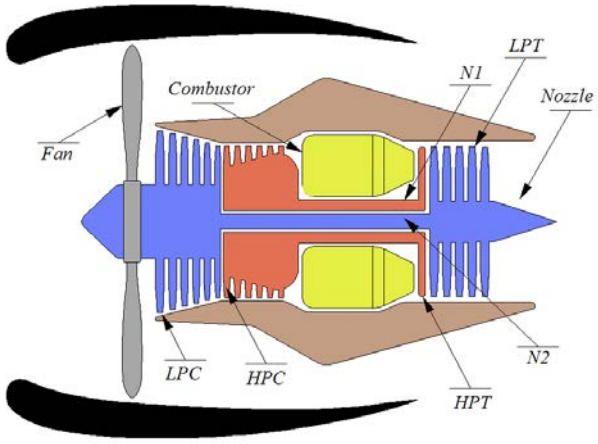

Figure 2. Schematic illustration of an aircraft engine model.

- **LPC (Low-Pressure Compressor):** It further compresses the air before it enters the combustion chamber, enhancing efficiency and power output.
- **HPC (High-Pressure Compressor):** This component significantly raises the pressure of the air, preparing it for combustion and ensuring optimal engine performance.
- **N2:** Represents the low-pressure shaft, connected to the LPC and fan, responsible for driving the fan and low-pressure compressor.
- **HPT (High-Pressure Turbine):** Extracts energy from the high-pressure gas flow to drive the HPC, maintaining compression efficiency.
- **LPT (Low-Pressure Turbine):** Utilizes remaining energy in the gas flow to drive the fan and LPC, contributing to overall engine power generation.
- **Nozzle:** This component accelerates the exhaust gases to produce thrust, directing the flow and converting thermal energy into kinetic energy.

The C-MAPSS dataset simulates engine operation data without providing a detailed description of the sensors utilized. In real-world engines, a diverse array of sensors is commonly employed to monitor various operational and performance parameters. These sensors may encompass:

- **Pressure sensors:** To measure pressure in different parts of the engine, such as combustion chambers, air inlets and outlets, and fuel lines.
- **Temperature sensors:** To monitor temperature in critical areas of the engine, such as combustion chambers, turbines, and exhaust sections.
- **Flow sensors:** To measure the flow rate of fuel, air, or coolant circulating through the engine.
- **Vibration sensors:** To detect abnormal vibrations or signs of imbalance in rotating components of the engine, such as turbine shafts and bearings.

Table 3. Description of the 21 C-MAPSS Sensors.

Sensor ID	Measurement	Unit
T2	Fan inlet temperature	°R
T24	LPC outlet temperature	°R

- **Speed sensors:** To monitor the rotational speed of engine components, such as turbines and compressors.
- **Position sensors:** To determine the position of valves, flaps, and other moving components of the engine.
- **Exhaust gas sensors:** To analyze exhaust gases and monitor emissions, including gas composition and pollutant levels.

These sensors play a crucial role in collecting engine operation data, which is then used to assess performance, diagnose issues, and predict potential failures as part of PdM and engine health monitoring. Table 3 provides an overview of the sensors included in C-MAPSS.

4.2. Conceptualization and Formalization of Knowledge Domain Ontology

A specialized methodology is used to conceptualize and develop the domain ontology. The Methontology methodology, developed by (Fernández-López, Gomez-Perez, & Juristo, 1997), provides a framework for constructing ontologies at the knowledge level. It includes the identification of the ontology development process and a lifecycle based on evolving prototypes, along with specific techniques for process description as depicted in Figure 3 (Blázquez, Fernández-López, García-Pinar, & Gomez-Perez, 1998).

Our ontology creation follows a systematic approach. The initial step involves the preparation of a formal document meticulously describing the domain to be represented according to the previous section. Subsequently, the conceptualization phase ensues, entailing the definition of concepts, properties, and relationships. For instance, an illustration of the main concepts related by three types of relations in two levels

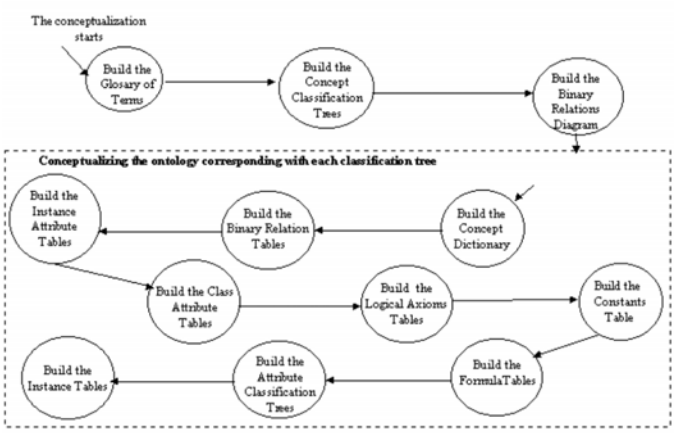

Figure 3. Development process ontology with the Methontology methodology.

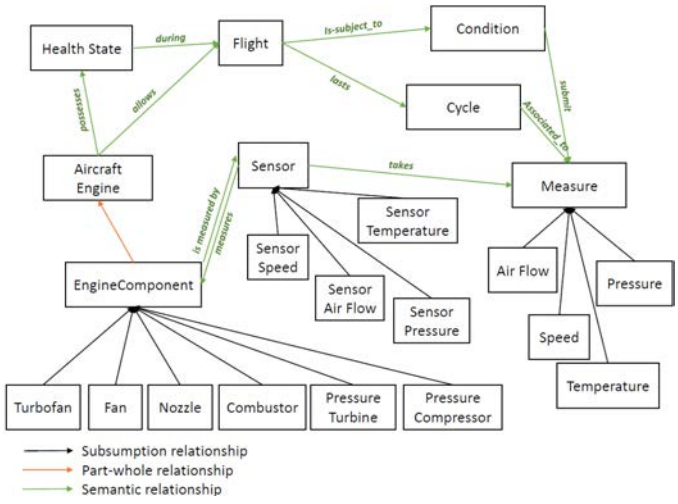

Figure 4. Diagram of ontology classes (concepts) in two main levels.

(subsumption relation/is-a, part-of/part-whole relation, and semantic relations) is provided in Figure 4. Following conceptualization, the third step focuses on formalizing the conceptual knowledge into a language understandable by computers. This modeling can be implemented in an ontology editing tool. In our case, we express the formal ontology in Description Logics (DL) language (Baader, Horrocks, & Sattler, 2005) and implement it using the OWL (Web Ontology Language) format (Taylor, 2009) within the open-source ontology editor Protégé 5.6 [2]. Once the ontology is created, it can be used to annotate and enrich the C-MAPSS dataset with semantic information about the components and their relationships, facilitating advanced analyses and data interoperability. In line with these principles, we establish a conceptual framework to represent pivotal elements and relationships within the C-MAPSS dataset domain. This domain in-

[2]Protégé editor: `https://protege.stanford.edu/`

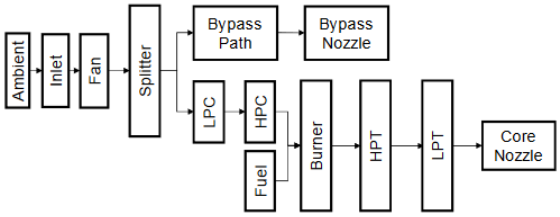

Figure 5. Diagram of modules and their connections in the aircraft engine model.

formation is captured as knowledge within a domain ontology named EngineFailureOntology. Within this ontology, we delineate various concepts, including: Aircraft engine, Engine component, Flight, Condition, Cycle, Measure, Sensor, Heath state, etc. The Definition in DL of Some Design Examples is Provided as Follows:

Engine $\equiv$ ComplexDevice $\wedge$ hasComponent some (Turbine $\sqcap$ Compressor $\sqcap$ Shaft)

Sensor $\equiv$ Device $\wedge$ measures some (Temperature $\sqcap$ Pressure $\sqcap$ Vibration)

TemperatureSensor $\equiv$ Sensor $\wedge$ measures only Temperature

OperationalSetting $\equiv$ Setting $\wedge$ includes some (EngineSpeed $\sqcap$ Load $\sqcap$ AmbientConditions)

4.3. Description of Topological Relationships Between Components

This step involves defining the topological relationships between components using the extension of RCC8 relations and drawing inspiration from diagram in Figure 5, which highlights the interconnections between components.

Some examples to illustrate how RCC8 relations can be used to describe spatial interactions among components of the C-MAPSS engine as follow:

Disjointness DC(Fan,Nozzle) : Fan and Nozzle components are mutually disjoint, as they occupy distinct spatial areas within the engine. This relationship can be expressed by:

$Fan \sqcap Nozzle \equiv \emptyset$

Others disjoitness relationships can be expressed as follows:
$Combustor \sqcap Nozzle \equiv \emptyset$

$Combustor \sqcap Fan \equiv \emptyset$

$LPC \sqcap LPT \equiv \emptyset$

External-Connected EC(HPC, Combustor): The Compressor (HPC) touches the Combustor because the compressed air from the compressor is then directed to the combustor for the combustion process. This relationship can be expressed as follows:

$HPC \sqcap Combustor \neq \emptyset$

Other components are externally connected to each other; these relations can be expressed as follows:

$HPC \sqcap LPC \neq \emptyset$

$LPC \sqcap N2 \neq \emptyset$

$N1 \sqcap Combustor \neq \emptyset$

$HPT \sqcap LPT \neq \emptyset$

$LPT \sqcap N2 \neq \emptyset$

$LPT \sqcap Nozzle \neq \emptyset$

The shaft or rotor (corresponding to the N2 component) is a tangential proper part of the turbine because it is physically attached to the turbine and rotates together with it. Additionally, some of its parts are covered by two other components: N1 and HPT. These relations can be expressed as follows:

$N2 \sqcap HPT \neq \emptyset$

$N2 \sqcap HPC \neq \emptyset$

Partially Overlapping PO(Fan , LPC): The fan overlap some part of the low pressure chamber and it overlap partially, as they share a common space within the engine. This relation can be expressed by:

$Fan \sqcap LPC \neq \emptyset$

The definition of topological relations based on the 2D diagram allows for connecting various components to facilitate the propagation of alerts if a malfunction is observed on a component. This enables the system to identify spatial interactions and dependencies between components, enhancing its capability to detect and propagate alerts effectively throughout the system.

4.4. Reasoning with SWRL rules

Several reasoning rules can be defined in collaboration with domain experts in aeronautics. In this study, we rely on extracting rules from our understanding of the data.

The first rule that can be defined pertains to subjecting a component to significant variations, which may cause fluctuations in sensor values, potentially leading to component fragility and resulting in localized and then generalized malfunction. The risk of impacting neighboring components directly may consequently increase. This rule will be formulated in the form of a SWRL (Semantic Web Rule Language) rule. After defining this rule, the next steps involve loading the time series data from the dataset, initiating the reasoning process, generating a new dataset, and studying the correlation of the new variables obtained through reasoning, in the form of new links or instance values in the knowledge base, with the RUL value. Although it is a logical rule, it is necessary to define

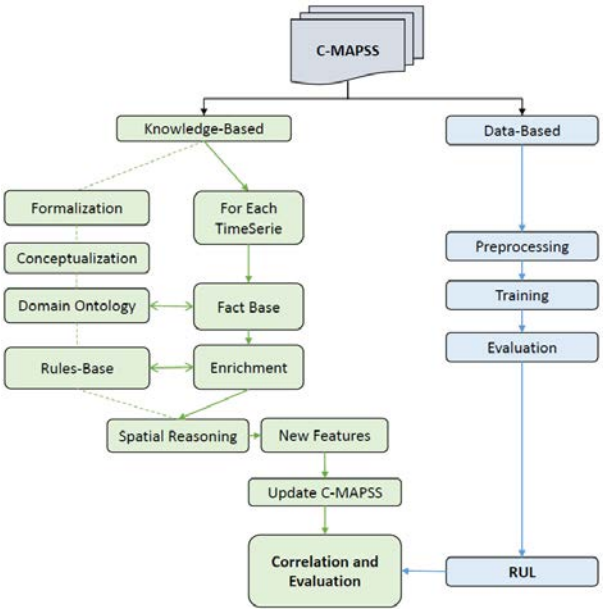

Figure 6. Main steps of the proposed approach involve treating each time series separately and creating features based on the proposed spatial reasoning.

alert thresholds for each sensor to weigh the estimated risk on each component. The definition of these thresholds can be initially done through advanced analysis of the C-MAPSS dataset using ML techniques. Subsequently, collaboration with aeronautical experts can further refine these thresholds.

Finally, we propose this validation technique because the dataset does not provide information on the types of failures and faulty components. Therefore, we will evaluate the validity and performance of our approach by assessing whether the learned knowledge has a positive or negative impact on the estimation of RUL through ML techniques.The process of the proposed approach is illustrated in Figure 6.

5. Discussion

The present study aimed to investigate a novel approach grounded in knowledge representation and spatial reasoning to predict failures by examining fault propagation and its repercussions across components, ultimately impacting the entire system. While similar methodologies have been explored in scientific literature for analogous yet distinct problems, the application of this approach remains novel within the context of our investigation. Despite the inherent complexity associated with its implementation, the potential contribution of this approach towards enhancing the explainability of machine learning (ML) models and elucidating degradation mechanisms holds substantial promise.

5.1. Consensus on the representation of domain and expert knowledge

The conceptualization, formalization, and formulation of rules within this study are predicated upon assumptions crafted within the confines of our research framework. However, it is imperative to acknowledge that such methodologies necessitate close collaboration with domain experts to ascertain the validity and relevance of the defined rules for effective reasoning. To further validate the efficacy of the approach delineated in this article, future endeavors will entail concerted efforts to engage domain experts in refining the formalization of knowledge and iteratively updating the associated reasoning rules. This iterative process of validation and refinement holds the potential to fortify the robustness and applicability of the proposed approach in real-world industrial settings.

5.2. Transition to RCC8 3D Formalism

Furthermore, it is essential to note that the rules of RCC8 pertain to regions in a 2D plane. In this study, we took into account the 2D diagram of components; however, transitioning to 3D objects could offer intriguing avenues for exploration in future research. By extending our analysis to encompass 3D objects, we can potentially enhance the fidelity and accuracy of our predictive models, thereby augmenting the applicability of our approach in diverse industrial scenarios.

5.3. Lack of data on failure types and their origins

Our study is based on the analysis of failure propagation among components, which assumes that a malfunction in one component can be detected or identified. However, the C-MAPSS dataset does not provide the necessary data to obtain this information. Preliminary work is required to estimate the health status of each component and define a threshold indicating failure at its level, as well as to study the propagation to other components. For this purpose, several SWRL reasoning rules can be specified to transition a component to a failure state when its condition is deemed critical. This also involves a detailed analysis of sensor data. For instance, sensors that detect abnormal fluctuations in the data of a component may indicate an impending failure.

6. Conclusion & Future Work

In the context of Industry 4.0 overall, and specifically in the estimation of aircraft engine lifespan, our objective in this article was to investigate the possibility and feasibility of a knowledge-based approach focusing on component degradation as a separate entity before overall system failure, by exploring the potential of qualitative spatial reasoning. The proposed method is currently under implementation, and its results have not yet been evaluated. However, the approach appears to offer tangible benefits, particularly in enhancing our understanding of internal functioning and incident prop-

agation among components. The next steps in this work involve finalizing the proof of concept and obtaining preliminary results. Subsequently, we plan to engage with domain experts to refine the established conceptualization and define reasoning rules that accurately reflect real-world scenarios. Depending on the outcomes, there is potential for applying the method to a cyber-physical system to enhance the explainability of machine learning models in place.

ABSTRACT

Track quality geometry measurements are crucial for the railways' timely maintenance. Regular measurements prevent train delays, passenger discomfort and incidents. However, current fault diagnosis or parameter deviation relies on simple threshold comparison of multiple laser scanners, linear variable differential transformer (LVDT) and camera measurements. Data threshold exceedances enact maintenance actions automatically. However, issues such as measurement error, and sensor failure can result in false positives. Broad localisation resolution prevents trending/ inferencing by comparison with healthy data baseline at the same position over periodic inspections.

False alarms can result in costly ineffective interventions, are hazardous and impact the network availability.

This paper proposes a novel methodology based on convolutional neural network (CNN) technique for detecting and classifying track geometry fault severity automatically. The proposed methodology comprises an automatic flow of data for quality assessment whereby outliers, missing values and misalignment are detected, restored and where appropriate curated. Improved, "clean" datasets were then analysed using a pretrained CNN model. The method was compared with a suite of machine learning algorithms for diagnosis including k-nearest neighbour, support vector machines (SVM), and random forest (RF).

The analysis results of a real track geometry dataset showed that track quality parameters including twist, cant, gauge, and alignment could be effectively diagnosed with an accuracy rate of 97.80% (CNN model). This result represents a remarkable improvement of 38% in comparison with the traditional threshold-based diagnosis. The benefits of this research are not only associated with maintenance intervention cost savings. It also helps prevent unnecessary train speed restrictions arising from misdiagnosis.

1. BACKGROUND

Rail transportation's convenience, punctuality and cost-effectiveness have made it the preferred mode for medium distance travelers and freight (Ghofrani et al., 2018; Wang et al., 2018) Train services as well as the total mileage of track is increasing, which poses a considerable challenge for the effective maintenance of railways infrastructure (Durazo-Cardenas et al., 2018). Degraded rail tracks can cause bumps and swaying when trains pass at high speed and can even cause derailments, putting at risk the safety of passengers. In the event of a failure, delays to the network can also cause significant economic losses (Sasidharan et al., 2020).

Wear and degradation are inevitable, and the railways have implemented safe, tolerance limits for track quality parameters (Railtrack PLC, 1998). Today, tracks are regularly inspected and repaired by dedicated infrastructure maintenance teams. This usually implies a combination of sophisticated track quality inspection trains and on-foot crews that validate and repair the defects flagged by the inspection trains. However, this requires experienced technicians working in hazardous environments, while reducing the availability of the network. Clearly, false alarms raised by the inspection trains contribute to further downtime and costs.

1.1. Measurements and data parameters

The New Measurement Train is an automatic inspection train that is currently the primary method of collecting track geometry data on the British Railways (*New Measurement Train (NMT)*, 2024) . It uses multiple laser scanners, linear variable differential transformer (LVDT), gyroscopes and

accelerometers and cameras Data from thirteen-time domain track parameters are acquired, plus additional imagery systems, accumulating terabytes of data. The NMT can measure track condition at 125mph and cover up to 115,000 miles in a year.

Cross-level, Gauge and Curvature are the essential features of a track alignment, transverse and vertical deviation. Cross-level is defined as the vertical height difference between the tops of the two tracks, while the distance between the two set of rails is known as the Gauge. Curvature is the radius of the arc of the rail, which describes the degree of curvature of the rail. For straight rails, the desired cross-level value approaches zero. while for curved rails, this closely matches the design value.

The *Twist* parameter combines deviations in vertical, and longitudinal dimensions and is typically measured at 3m intervals (Twist3m). The *Cant* parameter describes the difference between the track cross-level and the design cross-level value on curved track.

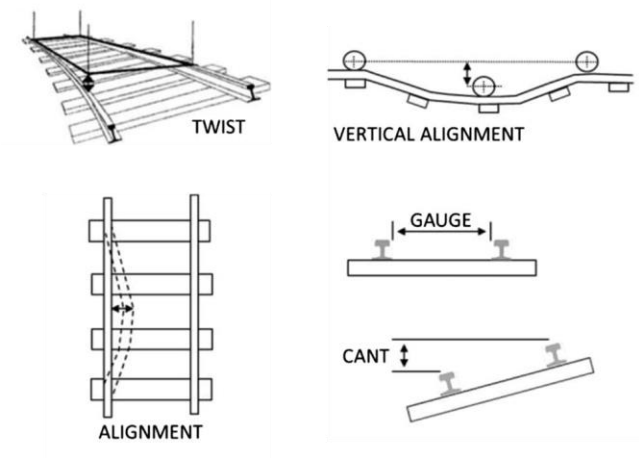

Figure 1 rail track quality parameters. Adapted from D'Angelo et al., (2018).

Top and *Alignment* (AL) account for the deviation between the actual track and the optimal planned path, where top is the vertical distance deviation of the top surface. AL refers to the horizontal distance deviation (Railtrack PLC, 1998). On the other hand, *Dip* is a measure of the depression of the track.

The standard deviation of the measured data parameters is compared to their threshold values for each 1/8 of mile. Exceedances are logged during the train inspection and corrective action notice are issued. Based on the severity of the faults detected and the nominal speed of the line, the health of the track section will be classified as Good, Satisfactory, Poor, Very Poor, and Super Red. Speed restrictions are then issued considering the parameter criticality, with 20 miles per hour being the lowest speed restriction, before track blockage. Network Rail standards(NR/L2/TRK/001/MOD11, 2015 also prescribe the actions to be taken upon threshold exceedances for each parameter, with these ranging from:

1. Block the Line
2. Correct before 36h.
3. Inspect in 72h and correct before 14 to 28 days.
4. Correct before 7 to 14 days.
5. Correct before 14 to 28 days.
6. Add it to the maintenance plan.

1.2. Dataset description

The data used in this this study comprises time series measurement data of the thirteen track parameters described above covering the Southampton-Waterloo line in both directions over a period of one year. This is considered a major line serving many commuter areas including southwestern suburbs of London and the conurbations based around Southampton. Datasets typically comprise CSV acquisition and PDF maintenance team activity logs, and track defect reports. Network Rail reports track quality assessments every 1/8 of mile, with up to 1000 measurements for each parameter acquired. Datasets typically exceed 2 GB.

1.3. Machine learning and related work

Machine learning is often used to analyze large amounts of data and identify connections, offering exceptional potential for anomaly detection analysis (Popov et al., 2022). Recent studies report on machine vision and SVM used to analyze images for track defect detection (Aydin et al., 2021). However, the settings could be significantly costly as it requires high specification tools (cameras, effective fast transmission systems, and efficient storage). Moreover, the large number of images generated bring real time processing challenges hence, affecting on time performance.

Based on time series data, reported accuracy of some traditional machine learning algorithms appears to be relatively low. Considering the disruption, cost and effort involved in railways repairs, higher accuracy is essential. For example, results of SVM algorithm used to detect combined track degradation from car body vibrations reported an accuracy of 80% (Tsunashima, 2019). Lasisi & Attoh-Okine, (2018),used Principal component analysis (PCA) to combine track geometry parameters into a lower-dimensional form and then used SVM, Linear discriminant analysis (LDA), and Random Forest (RF) to detect orbital faults with an accuracy of 92%. However, the true positive rate (precision) is only about 66%, potentially leading to many false alarms.

Several studies have compared the performance of machine learning methods. Sresakoolchai & Kaewunruen, (2019) used a range of supervised and unsupervised machine learning models to analyse track geometry data and sentence faults. The results showed that the non-linear models fitted significantly better, with deep neural network (DNN) having the highest accuracy at 94.3%, followed by convolution neural network (CNN) with 93.8%. The linear models all had

accuracy rates below 50%, with SVM being the poorest at 20%. The results showed that the relationship between features and labels is highly non-linear.

In this context, we propose and effective method to automatically detect and classify track defect using data driven approaches. The next section introduces the methodology.

2. METHODOLOGY

The five-step approach employed in this investigation is illustrated in **Error! Reference source not found.**. The initial data acquisition step is associated with the acquisition of data. Two different types of data were gathered for the analysis. The first datasets comprise of time series signals representing key track quality parameter measurements such as, the location, time, the CANT, the TOP, the gauge, the AL, the Cross-level and the Curvature. The second dataset represents a set of pdf files containing a threshold-based detection report and human based investigation maintenance logs. These files are useful to annotate the track fault observed in the time series data.

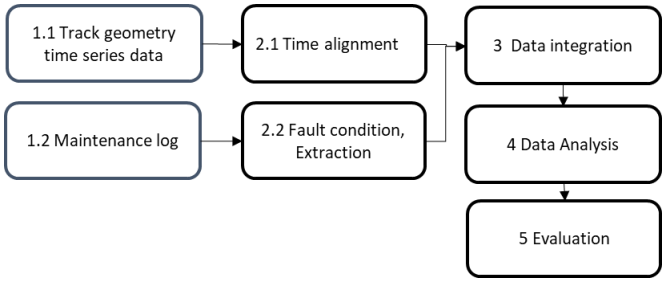

Figure 2 Flow chart of methodology steps.

Step two focuses on the enhancement of individual datasets quality. This was critical step given the issues often encountered with time series data. These datasets typically emanate from a variety of instrumentation sources and are prone to a myriad of consistency issues, including measurement discrepancies caused by instrument malfunctions or user errors. These issues manifest as missing data points, misaligned signals, and a significant presence of noise, each of which can distort the true signal and lead to inaccurate analyses if not properly addressed. To address the absence of data, a localized regression method is implemented. This approach leverages nearby data points to estimate and impute the missing values, assuming that these points observe a similar behavioral pattern. Such assumption is justified given that time series data often exhibits temporal correlation. The efficacy of the imputation process is vital, as it directly affects subsequent analyses. In addition to imputation, the dataset processing phase employs a combination of Dynamic Time Warping (DTW) and Cross Correlation techniques to detect and correct misalignments in the signals. DTW is an algorithm that allows for elastic transformation of time series, enabling the identification of similarities between data sequences that do not align perfectly in time. When used in conjunction with Cross Correlation, it becomes a powerful tool to detect shifts and distortions in the signal, thereby aligning them appropriately for further analysis. Further refining of the dataset includes processing of the maintenance log reports which undergo a procedure to extract and quantify salient features, such as fault type, spatial and temporal coordinates of the occurrences, severity of the detected faults, and the associated maintenance activities required. This information is crucial for understanding the context of the faults and planning preventive measures.

The third stage integrates the outputs of the previous stages, creating a consolidated dataset that is primed for machine learning analytics. This stage is pivotal as it synthesizes the cleaned and aligned time series data with the qualitative information extracted from the maintenance logs, setting the foundation for robust analytical models.

The fourth stage is the heart of the analysis, where two primary categories of machine learning techniques are employed: supervised and unsupervised learning methods. Unsupervised learning techniques, such as the Density-Based Spatial Clustering of Applications with Noise (DBSCAN), are adept at identifying novel fault types that may not have been previously recognized. DBSCAN is privileged for its proficiency in handling noise within the dataset, a common issue in large-scale industrial applications. However, while unsupervised methods excel at detection, they often falter in classification. To counter this, supervised learning methods are applied, harnessing the labelled data produced by unsupervised techniques to train models that can not only detect but also classify fault types. This dual approach ensures that newly occurring faults are not only detected but also categorized correctly. The supervised techniques selected for this stage include robust and widely used algorithms such as Convolutional Neural Networks (CNNs), which are particularly adept at spatial data recognition; k-Nearest Neighbors (kNN), which classifies data based on the proximity to known cases; Random Forests (RF), an ensemble method that improves prediction robustness; and SVMs, which are effective in high-dimensional spaces.

Finally, the last stage focuses on the evaluation of the model's performance, employing three key metrics: precision, recall, and the F1-score. Precision assesses the model's accuracy in predicting fault occurrences, mitigating the risk of false positives. Recall measures the model’s ability to identify all actual fault occurrences, thereby reducing false negatives. The F1-score harmonizes these two metrics, providing a single measure of the model’s accuracy in classification tasks, balancing the trade-off between precision and recall. This comprehensive and iterative process is essential for the identification and classification of faults in complex systems,

such as those encountered in Network Rail's infrastructure. By meticulously processing the data and employing a blend of machine learning techniques, the methodology aims to yield a high-performing model capable of detecting and classifying faults, thus enhancing the maintenance and reliability of the rail network.

3. Results and Discussion

3.1. Dataset analysis

The datasets used in this study come from Network Rail and pertains to track geometry data acquired between 2016 and 2017 during inspections run along the Southampton railway line. These datasets consist of 625 pdfs reports, 300 multivariate time series data which includes track geometry measurements, maintenance team activity logs, and track defect reports. The temporal scope extends over 33 days, with an average monthly coverage of three days. The location parameter, although not a track geometry feature, is a crucial piece of information in the dataset because it provides a baseline for comparing data from different measurement time at the same point. The positioning errors in the recording could reach 100 m. The instrument failure can also cause some positions to be recorded as missing points, resulting in various positions for the same serial number in the data sets. Missing data at a position t is imputed by using and interpolation of different data points observed at a location [t-w] and [t+w], where w (set to 5) helps including of neighbouring data points to enhance the imputation accuracy. For the alignment, the data points must first be aligned so that they are of the same length between data and that data points of the same ordinal number are in the same position. To perform the alignment, first DTW method was used to compute pairwise distance between the measurement, and close distance signal were used to compute a reference signal. Hence maximum value between the cross correlation and the reference signal were used to shift the measurement. **Error! Reference source not found.** and **Error! Reference source not found.** show an example before and after the alignment was performed using the Twist3m measurement.

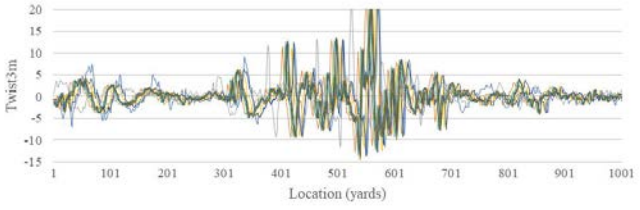

Figure 3 Twist3m measurement before alignment.

After the temporal data alignment, the maintenance log files (shown in **Error! Reference source not found.**) are processed to extract the track identifier (trackid), the mileage, the type of fault (shown in the column “channel”), the peak value observed and the corresponding threshold value. These data are used to locate the fault in the temporal data and hence annotate it. We segmented by file instead of by time series index as the initial experiment on time index split provided imbalanced issues.
The final annotated 300 multivariate time series datasets with about 20000 datapoints each are split into training (60%), validation (20%) and testing (20%).

3.2. Algorithms parameters

The parameters summarised in **Error! Reference source not found.** were empirically tested and configured for this analysis.

For Convolutional Neural Networks (CNN), the setup includes Conv2D, MaxPooling2D, and Dense layers with ReLU and Softmax activations, optimised using adaptive moment estimation (ADAM) with a learning rate of 0.001.

The RF is configured with 100 trees, no maximum depth to allow full growth, a minimum of 2 samples required to split a node and uses the Gini criterion for quality of splits. DBSCAN was set with an epsilon value of 0.5 for maximum neighbourhood distance, and a minimum of 5 samples for core points, while employing Euclidean distance for its metric. DBSCAN being an unsupervised method cannot map automatically with classes, hence we mapped manually the

cluster with a script that computes the cluster centre and the known fault centre.

The k-NN algorithm uses 5 neighbours, uniform weights, automatically selects the algorithm for computing, and utilizes the Minkowski metric. Lastly, the Support Vector Machine (SVM) is configured with an RBF kernel, regularization parameter C set to 1.0, 'scale' for gamma, and a polynomial degree of 3, optimizing for non-linear data separation. Each configuration reflects the algorithm's focus, from spatial clustering and decision forests to similarity-based learning and hyperplane optimization, illustrating the adaptability and specificity required for effective machine learning applications.

Table 1 Methods and parameter settings.

Method	Parameter Configuration Example
CNN	Layers: Conv2D, MaxPooling2D, Dense; Activation: ReLU, Softmax; Optimizer: Adam; Learning Rate: 0.001
RF	Number of Trees: 100; Max Depth: None; Min Samples Split: 2; Criterion: Gini
DBSCAN	Epsilon: 0.5; Min Samples: 5; Metric: Euclidean
kNN	Number of Neighbours: 5; Weights: Uniform; Algorithm: Auto; Metric: Minkowski
SVM	Kernel: RBF; C: 1.0; Gamma: Scale; Degree: 3

3.3. Analysis

The evaluation of the employed method on the testing datasets through precision, recall, and f1-score metrics offers a detailed perspective on their performance in predictive modelling tasks. With a multiclass classification problem, average performance results are computed. As highlighted in **Error! Reference source not found.**, CNN showcased a well-rounded performance with a precision of 97.8%, a recall of 97.69%, and an f1-score of 97.73%, indicating a high degree of accuracy and reliability in identifying relevant instances. RF also demonstrated a strong balance between precision (93.6%) and recall (95.21%), culminating in an f1-score of 94.4%, which underscores its effectiveness in handling various data scenarios. DBSCAN, with a precision of 100%, indicates a perfect identification of relevant instances within its clusters, though its lower recall (88.60%) suggests some relevant instances may not be captured within its clusters, reflected in an f1-score of 93.95%. kNN and SVM both achieved high precision rates (97.6% and 100%, respectively) but with slightly lower recall rates (90.37% and 87.95%, respectively), leading to f1-scores of 93.84% and 93.58%, highlighting their precision in classification but at the expense of some sensitivity.

Table 2 Method performance on the datasets.

Method	Precision **(%)**	**Recall (%)**	**f1-score (%)**
Threshold	59.8	53.80	56.64
CNN	97.8	97.69	97.73
RF	93.6	95.21	94.4
DBSCAN	100	88.60	93.95
kNN	97.6	90.37	93.84
SVM	100	87.95	93.58

Figure 6 CNN confusion matrix.

Focusing on CNN, **Error! Reference source not found.**7 provides a confusion matrix table displaying the performance of a classification model on a testing set, summarizing how well the model distinguishes between five fault classes: Gauge Fault, Twist Fault, AL Fault, Cant, and Top. The matrix shows actual class labels on the vertical axis (TARGET) and predicted labels on the horizontal axis (OUTPUT), with each cell containing the count and percentage of instances. Diagonal cells (in green) represent correctly classified instances, while off-diagonal cells (in red) indicate misclassifications. The overall performance is impressive, with the model correctly classifying 97.80% of the instances (2445 out of 2500) and misclassifying only 2.20% (55 out of 2500). Notably, "AL Fault" has the highest accuracy (99.00% correct), while "Top" has the highest

misclassification rate (4.00%), indicating a specific area for potential improvement. The table also includes sum totals for each class, providing a comprehensive overview of the model's classification capabilities. Figure 8 showing detailed performance tabulation was obtained by computing the relevant performance indicators from Figure 7.

Class Name	Precision	1-Precision	Recall	1-Recall	f1-score
Gauge Fault	0.98	0.02	0.98	0.02	0.98
Twist Fault	0.98	0.02	0.95	0.05	0.97
AL fault	0.99	0.01	0.98	0.02	0.98
Cant	0.98	0.02	0.99	0.01	0.99
Top	0.96	0.04	0.99	0.01	0.97
Accuracy	0.98				
Misclassification Rate	0.02				
Macro-F1	0.98				
Weighted-F1	0.98				

Figure 7 CNN detailed performance.

Discussion of these results illustrates the inherent trade-offs between precision and recall metrics across different algorithms. CNN and RF, with their balanced precision and recall, are suited for applications where both false positives and false negatives carry significant consequences, providing a robust option for complex classification tasks. The perfect precision of DBSCAN and SVM suggests their utility in scenarios where the cost of false positives is high, making them ideal for applications requiring high confidence in the prediction of positive instances. However, their lower recall rates indicate a potential shortfall in identifying all actual positive instances, which could limit their application in scenarios where missing any positive instance carries a higher risk. kNN, while slightly less precise than SVM or DBSCAN, offers a good compromise between precision and recall, making it a versatile choice for many practical applications. These results underscore the importance of choosing the right algorithm based on the specific requirements and constraints of the task at hand, considering the balance between identifying relevant instances accurately while minimising false identifications. Although these algorithms have various degree of success, they still overperform traditional thresholds technique which precision is 59.8%.

Comparing the machine learning model performance from the literature with the metrics provided reveals a notable advancement in precision, recall, and F1-score. While the literature highlights variances in SVM accuracy from 20% to 80% across applications, this implementation showcases a substantial leap approaching 100% precision for SVM, underscoring a highly effective application or different context. Similarly, The CNN and kNN models not only surpass some of the literature's DNN and CNN benchmarks with CNN achieving a near parity with the highest reported accuracy of 94.3% (Sresakoolchai & Kaewunruen, 2022) but with superior precision and recall. The inclusion of DBSCAN in this analysis, demonstrating a 100% precision, further highlights the potential of selecting and tuning models to suit specific data characteristics and problem contexts. This synthesis underscores the importance of advanced model fine-tuning, the choice of metrics for performance evaluation, and the adaptability of machine learning algorithms to achieve higher efficacy in complex, non-linear problem spaces, especially in critical applications like fault detection in railway systems. In terms of training time, Figure 6 shows the models average estimated time (in blue) and their standard deviation denoted as Std (orange). Random Forest (RF) and Convolutional Neural Network (CNN) methods demonstrate the shortest training times, approximately 1000 and 1200 seconds respectively, with minimal variability. These observations highlight that while SVM is computationally intensive, RF and CNN are more efficient, making them suitable choices when computational resources or time are limited.

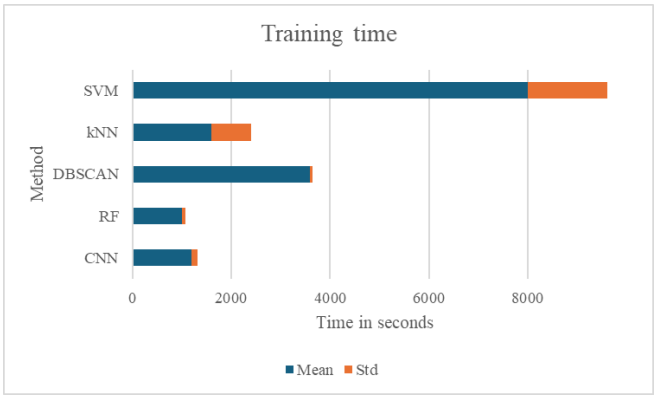

Figure 8 Average Model training time.

4. CONCLUSION

This paper presents a machine learning methodology that successfully improves false alarm rate of railway track quality inspections by 38%. While the datasets examined in this paper only pertain to one specific route, the methods presented here are applicable to all other railway lines across Britain, since the same NMT inspection vehicle is used.

In the railways, repair interventions are costly, typically requiring a manual confirmation of the fault severity, parts,

labour, travel, service disruptions (denial), and penalty fees, as well as being hazardous for the on-foot personnel involved. The ability to correctly diagnose faults also ensures unnecessary speed restrictions are removed, improving journey times and passenger comfort. Evidently, the proposed methodology can potentially have considerable financial impact.

Future work includes an analysis of the potential cost savings achieved using this methodology as well as the integration of context knowledge in the diagnostics.

ABSTRACT

This study proposes an approach to monitor multiple components in complex mechanical systems using a single, externally placed remote sensor. In automobiles and petrochemical plants, where numerous components (e.g., powertrain, bearing, and gear), sensor placement is often compromised by cost and installation environment constraints, resulting in sensing the components far from the regions of interest. To address this challenge, this paper proposes an Operational Transfer Path Analysis (OTPA)-based approach that derives the transfer functions between the vibration excitation source and the measurement point (i.e., receiver). The model for OTPA enables the reverse estimation of the excitation source's signal from the receiver. Subsequently, the estimated (i.e., synthesized) source signal is fed into a diagnostic model to identify system faults. The OTPA and diagnostic models are constructed using neural network architectures, enabling better adaptation to operational conditions and system-induced nonlinearities. The proposed approach is validated from case studies using hydraulic piston pumps in construction vehicles and next-generation electric vehicles.

1. INTRODUCTION

Rotating machine components inevitably produce vibrations during operation, which sensitively reflect the health condition of the rotating machines. Hence, vibration data is predominantly used for fault diagnosis. Such data is often complex and high-dimensional, making effective analysis challenging. Several years ago, deep learning-based approaches were proposed for fault diagnosis in rotating machines. For instance, Zhao, Yan, Chen, Mao, Wang, and Gao (2019) significantly improved the accuracy of motor fault diagnosis using Convolutional Neural Networks (CNN). Their research demonstrates that CNN can successfully classify complex vibration patterns and detect early signs of faults in motors. Additionally, Chen, Zhang, Cao, and Wang (2020) utilized one-dimensional Nonlinear Output Frequency Response Functions and Stacked Denoising Auto-Encoders (SDAE) for diagnosing faults in Permanent Magnet Synchronous Motors (PMSM). The superiority of the proposed method was validated using data from simulations of nonlinear systems such as PMSMs in passenger vehicles.

The existing methods discussed above input data captured from sensors attached to key rotating components such as motors and bearings into deep-learning models for fault diagnosis. Such approaches are effective when sensors can be installed at fault-sensitive points of the rotating machines. In the testbed of the rotating machines, multiple sensors can be attached at various points to diagnose rotating machines effectively using collected vibration data. However, in most operating rotating machines, vibrations arise from numerous rotating parts, and installing sensors at each potential vibration point is often impractical due to cost and environmental constraints. If it is possible to diagnose health conditions using a single sensor installed far from the vibration source, it could significantly reduce costs for data acquisition. Upon further literature review, several innovative studies were found. Choudhary, Mian, Fatima, and Panigrahi (2022) and Yao, Liu, Song, Zhang, and Jiang (2021) creatively proposed diagnosing rotating machines using non-invasive acoustic sensors. Even while acoustic sensors have the amazing benefit of being able to detect signals over long distances, their susceptibility to external

noise can make them inappropriate for use in particular machines such as passenger vehicles.

This paper proposes a novel approach to address two challenges: (1) difficulty in installing vibration sensors on various rotating components within rotating machines, and (2) reduced signal sensitivity and increased interference from external noise when using vibration signals measured at external points. Through Operational Transfer Path Analysis (OTPA), the vibration signal measured at an external point is converted into a vibration signal from the core vibration source, and faults are diagnosed using a denoising deep learning model.

The remainder of this paper is organized as follows: Section 2 describes the OTPA concept, which forms the theoretical background of this paper. Section 3 discusses the proposed approach. Section 4 presents two case studies using a hydraulic pump in a construction vehicle (CV) and a drivetrain of an electric vehicle to verify the proposed approach. Finally, Section 5 summarizes the content of this paper.

2. THEORETICAL BACKGROUND

OTPA is a technique that identifies and quantifies the paths through which vibration and noise are transferred from a source to a receiver (van der Seijs, de Klerk, and Rixen, 2016). Within rotating machines, the input excitation source and the output receiving point can be represented as shown in Figure 1. The relationship between the input excitation source and the output receiving point can be modeled by Frequency Response Function (FRF) as in Eq. (1). through which the response at the receiving point due to an input at the excitation source can be calculated.

$$\mathbf{X}(\omega)\mathbf{H}(\omega) = \mathbf{Y}(\omega) \tag{1}$$

The transfer function is formulated as:

$$\begin{bmatrix} x_1^{(1)} & \cdots & x_1^{(M)} \\ \vdots & \ddots & \vdots \\ x_r^{(1)} & \cdots & x_r^{(M)} \end{bmatrix} \begin{bmatrix} H_{11} & \cdots & H_{1N} \\ \vdots & \ddots & \vdots \\ H_{M1} & \cdots & H_{MN} \end{bmatrix} = \begin{bmatrix} y_1^{(1)} & \cdots & y_1^{(N)} \\ \vdots & \ddots & \vdots \\ y_r^{(1)} & \cdots & y_r^{(N)} \end{bmatrix} \tag{2}$$

where r represents the total count of data sets collected for each point during operation.

In the process of delineating the transfer function matrix, it is imperative to compute the inverse of the matrix X. However, typically, the matrix X is not a square matrix, its inverse matrix cannot be calculated. To overcome this limitation, the Singular Value Decomposition (SVD) technique is employed (Cheng, Zhu, Chen, Song, Zhang, Gao, Liu, Nie, Cao, and Yang, 2022). SVD enables the decomposition of the matrix X as shown in Eq. (3).

$$\mathbf{X} = \mathbf{U}\boldsymbol{\Sigma}\mathbf{V}^{\mathrm{T}} \tag{3}$$

where U signifies the unitary matrix; Σ denotes the diagonal matrix constituted by singular values; and $\mathbf{V}^{\mathrm{T}}$ represents the conjugate transpose of the unitary matrix V. Through Eq. (3), it is feasible to obtain the pseudo-inverse of matrix X, a process equivalently captured in Eq. (4).

$$\mathbf{X}^{+} = \mathbf{V}\boldsymbol{\Sigma}^{-1}\mathbf{U}^{\mathrm{T}} \tag{4}$$

Subsequently, the formulation of the transfer function is articulated as:

$$\tilde{\mathbf{H}} = \mathbf{X}^{+}\mathbf{Y} \tag{5}$$

3. METHODOLOGY

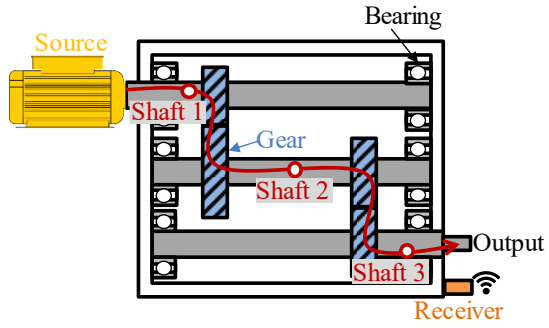
This section presents the proposed approach in this paper. Section 3.1 elaborates on the selection of critical points within rotating machines for vibration signal acquisition and the preprocessing of these signals for the OTPA model. Section 3.2 discusses the architecture of the OTPA model, which transforms measured vibration signals at the receiver into the source vibration signals, and the architecture of the fault diagnosis model that inputs the synthesized vibration

signals. Finally, Section 3.3 describes the training procedure of the models and the metrics employed for performance evaluation.

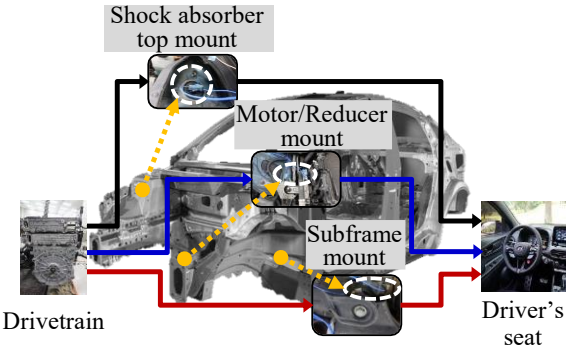
3.1. Data Acquisition and Signal Preprocessing

For the deployment of the OTPA model, initial steps involve the identification of crucial data acquisition points. For instance, in a standard gearbox scenario, sources can be designated as the motor, the receiver as the output case, and transition locations as shafts 1, 2, and 3, as depicted in Figure 2(a). Similarly, for electric vehicles (EVs), the source (excitation point) is determined as the motor, the receiver as the driver's seat, and transition points include the shock absorber mount, subframe mount, and motor/reducer mount, illustrated in Figure 2(b).

Subsequently, acquired vibration signals are converted into frequency spectra using the Fast Fourier Transform (FFT). To mitigate discontinuity issues stemming from finite signal length, a Hanning window is utilized. The overlap rate is 50 %.



(a)



(b)

Figure 2. Source, receiver, and transition locations: (a) CV gearbox, (b) EV chassis.

3.2. Model Building

The proposed model framework, as shown in Figure 3, is comprised of an OTPA deep learning model and a drivetrain fault diagnosis deep learning model. The OTPA deep learning model features two serially connected pairs of a feature extractor and a regressor. The initial OTPA module pair aims to model the transfer function relationship between the receiver signals and those of the transition locations. The subsequent pair focuses on modeling the transfer function relationship between the transition location signals and the excitation source signals.

Feature extractors are composed of 1D convolutional layers, with subsequent regressors mapping the extracted features to vibration signals at transition locations and the drivetrain. Signals measured at the receiver, upon traversing the first feature extractor and regressor combination, are transformed into vibration signals at transition locations; these are then converted into drivetrain vibration signals via the second combination. The final loss function, as represented in Eq. (6), summation of the L_1 losses at transition locations and the drivetrain.

$$L_{total} = L_{trans} + L_{source} \tag{6}$$

where L_{trans} represents the loss at transition locations; and L_{source} denotes the loss at the excitation source. The proposed deep learning model is trained to minimize the combined loss of transition and excitation source locations.

The difference between the proposed deep-learning-based OTPA and conventional OTPA methods lies in the feature extractor. Traditional OTPA methods calculate output signals for specific input signal frequency components using transfer functions, assuming linear independence among measurement directions and locations (de Klerk & Ossipov, 2010). However, such assumptions do not hold when nonlinear interactions within rotating machine components exist. Conversely, the proposed method integrates all frequency components as a singular input to the feature extractor for overall output calculation. Furthermore, the feature extractor leverages activation functions within each layer to learn the nonlinearities between measurement directions and locations. Significantly, 1D convolutional layers facilitate the learning of local band-specific features within the frequency domain, an advantage under variable speed conditions common in rotating machines.

The preprocessing stage involves augmenting the receiver vibration signals with Gaussian noise of varying intensities, creating a dataset with a broad range of signal-to-noise ratios for deep learning model training. While the input data for model training incorporate noise-enhanced signals, the output data utilize the original, unaltered vibration signals. The objective is to train the deep learning model on input data variability, thus ensuring signal transformation accuracy against external noise influences. This approach anticipates effective vibration signal conversion even in harsh operational conditions characterized by significant external noise.

The deep learning model for fault diagnosis employs a conventional Multi-layer Perceptron (MLP) architecture. Input data consist of triaxial (x, y, z) drivetrain frequency domain vibration signals. Parallel-configured MLPs for each channel extract data features, which after layer normalization, are concatenated. The combined features traverse another MLP layer, ultimately outputting indices pertaining to fault types.

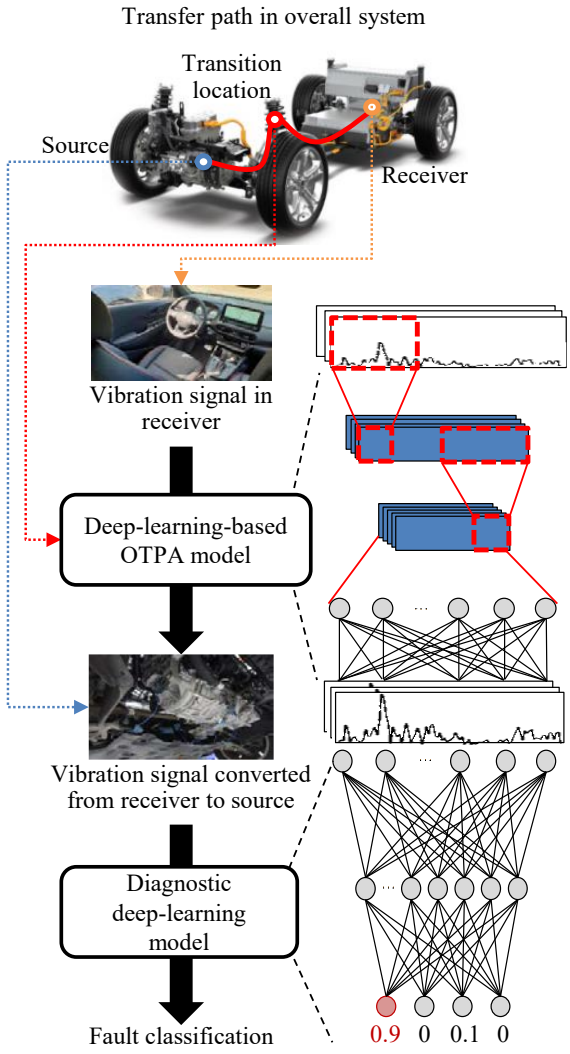


Figure 3. Model construction in the proposed approach.

3.3. Model Training and Performance Evaluation

The synthesized source vibration signals from the deep-learning-based OTPA model are inputted into a trained fault diagnosis deep learning model for assessing the rotating machines' condition. Activation functions across layers in both the OTPA and fault diagnosis models utilize the Rectified Linear Unit (ReLU), with loss functions employing L1 and cross-entropy functions, respectively. The optimizer of choice is Adam.

To objectively evaluate the deep learning models' performance, k-fold cross-validation is conducted. The Mean Absolute Error (MAE) metric assesses the regression fit of the OTPA model. Additionally, accurately realizing local band amplitude fluctuations in the synthesized vibration spectrum, akin to the measured spectrum, is crucial. This aspect can be assessed through variance, thus employing the correlation coefficient as an auxiliary performance metric.

4. EXPERIMENTS

4.1. Case I: Hydraulic Piston Pump

Hydraulic piston pumps are integral in various industries such as construction, maritime, and mining for energy conversion processes. Compared to electric vehicle systems, hydraulic piston pump systems usually have shorter distances between the excitation source and the receiver, resulting in less variance due to external noise. This study investigates the denoising efficacy of the proposed method by artificially introducing external noise to vibration signals obtained at the receiver.

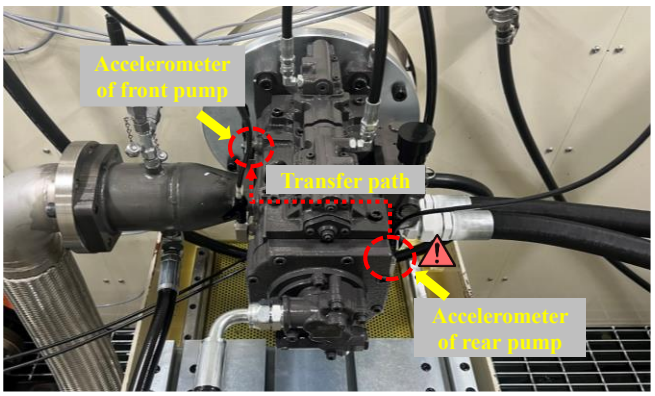

Figure 4. Hydraulic piston pump testbed, measurement points, and transfer path.

4.1.1. Overview

A hydraulic piston pump used in a 22-ton excavator was selected as the subject of our test bed, depicted in **Error! Reference source not found.**. The pump operates at 1800 rpm with a discharge pressure maintained at 350 bar. It is equipped with an axial piston pump at both the front and rear, forming a pair. Artificial defects were introduced into the rear pump piston.

The primary failure modes of axial piston pumps are known to be surface wear between the piston and slipper. Wear occurs due to the chemical degradation of internal lubricants, potentially leading to piston detachment from the slipper, ultimately damaging the piston pump. Based on an

understanding of these failure origins, mechanisms, and modes, piston surface defects were simulated by artificially altering the piston surface tolerances, thereby mimicking increased part tolerances. Tolerances ranging from 0 to 15 μm were classified as normal, 90 to 120 μm as partially-degraded, and 120 to 150 μm as severely-degraded.

Assuming the front pump as the receiver and the rear pump as the excitation source (i.e., the location of fault occurrence), it was hypothesized that utilizing the synthesized vibration signal from the front to the rear pump for diagnosis could achieve higher accuracy. This is because the front pump, physically distant from the actual fault-occurring rear pump, acquires vibration signals that are more susceptible to external noise and contain attenuated signals from the rear pump.

Table 1. Experimental setup for hydraulic piston pump testbed.

Operation condition	1800 rpm
Load condition	350 bar
Oil temperature	50 °C
Number of samples	3 EA
Fault condition (Clearance)	Normal (0~15 μm) Rear partially-degraded (90~120 μm) Rear severely-degraded (120~150 μm)
Sampling rate	10,240 Hz
Measurement points	6 channels (Rear, front x, y, z axis)
Acquisition time	900 sec

Table 2. Train and test dataset configuration for case I.

Training	Original, SNR 20, 10, 0 dB
Test	Original, SNR 20, 15, 10, 5, 0, -5, -10 dB

4.1.2. Data Acquisition and Signal Preprocessing

Vibration data were collected under the conditions detailed in **Error! Reference source not found.** using triaxial accelerometers mounted on the axial piston pump. As described in Section 3.1, the acquired signals were preprocessed and converted into frequency spectra using FFT. A Hanning window of 10,240 data points was used without overlap between consecutive windows. The frequency domain of the transformed vibration signals ranged from 0 Hz to 5,120 Hz. For data set efficiency, frequency domains from 0 Hz to 1,280 Hz were utilized.

To simulate environments with greater distances between vibration acquisition points and more susceptibility to external noise than the hydraulic piston pump samples used in this study, data was augmented by adding Gaussian noise to the assumed receiver signal (front signal), thereby decreasing the SNR as detailed in **Error! Reference source not found.**.

4.1.3. Model Construction and Training

The architecture of the OTPA deep learning model consists of 1D CNN and FC layers, incorporating feature extractors and regressors. Input data comprise frequency spectra of triaxial vibration signals measured at the front pump, while output data consist of the rear pump's triaxial vibration signal spectra. Hyperparameter optimization, conducted empirically, set training epochs at 150, batch size at 64, and learning rate at 0.0001.

For the fault diagnosis deep learning model, the inputs consist of three-channel excited source spectra with 1,280 data points. Outputs predict the fault vector. Hyperparameter optimization resulted in setting training epochs at 50, batch size at 64, and learning rate at 0.0001. This case study implemented a five-fold cross-validation.

4.1.4. Results

Vibration signal synthesizing results are presented in Figure 5. Using the conventional SVD-based OTPA method, MAE values of 0.0106 m/s² for the original test dataset and 0.0437 m/s² for the dataset with the lowest SNR of -10 dB were observed. In contrast, the proposed method yielded MAE values of 0.0057 m/s² for the original dataset and 0.0070 m/s² for the -10 dB SNR dataset, demonstrating superior performance across all SNR datasets compared to the existing method. Notably, despite all methods showing increasing error trends with higher noise levels, the proposed method exhibited significantly lowered error growth rates, indicating its robustness against noise. Correlation coefficient comparisons also affirmed the superior performance of the proposed method, highlighting the effectiveness of the proposed deep learning-based vibration signal synthesizing method.

Piston fault diagnosis outcomes, comparing front signals to synthesized rear pump signals, are illustrated in Figure 6. Diagnosis performance using front signals was evaluated based on models trained on identical front signals, whereas diagnosis with synthesized rear signals was based on models trained on actual rear signals. Up to SNR 20 dB, both front and synthesized rear signals demonstrated near-perfect diagnostic accuracy. However, as noise levels increased, the diagnostic accuracy based on front signals declined sharply, whereas the accuracy based on synthesized signals remained relatively stable. Notably, for datasets not included in the training process with SNR of -10 dB, front signals showed the diagnostic accuracy of 38.59%, while synthesized signals achieved a significant difference of up to 89.08%. This indicates that, in noisy environments, inputting synthesized

signals from the front to the rear pump enables better differentiation of piston defects, demonstrating the OTPA model's effectiveness in denoising.

4.2. Case II: Electric Vehicle Drivetrain

This case study sought to validate the efficacy of the proposed method by implementing it to EVs in the field, synthesizing vibration signals acquired from the driver's seat into drivetrain signals for fault diagnosis. This section consists of subsections including data acquisition and signal

preprocessing, model building, training, and performance evaluation, and results.

4.2.1. Data Acquisition and Signal Preprocessing

Vibration data from an electric vehicle, having completed approximately 300,000 km of operation, were collected. Experimental conditions are detailed in **Error! Reference source not found.**. Using a triaxial accelerometer (DYTRAN 3093M4) with the sampling rate of 25,600 Hz, data were acquired from key components within the EV chassis. The EV drivetrains, comprising motor and gearbox components, were prepared by installing faulty or healthy components to simulate different health condition combinations. Data collection covered various driving conditions, including constant speeds of 30, 50, 80, 100 km/h, and dynamic acceleration-deceleration cycles (Wide Open Throttle; WOT and Middle Tip In; MTI), as illustrated in **Error! Reference source not found.**.

Following the methodology outlined in Section 3.1, collected vibration signals underwent preprocessing before being transformed into frequency spectra using the Hanning window of 25,600 data points and the 50% overlap between consecutive windows. The frequency range of the transformed signals was from 0 to 12,800 Hz. The data from 0 to 4,000 Hz deemed most informative for the dataset.

4.2.2. Model Building, Training and Performance Evaluation

The input to the OTPA deep-learning model consisted of triaxial vibration spectrum data acquired from the driver's seat. These signals were processed through first feature extractor and regressor to convert them into transition locations vibration signals, which were then further converted (or synthesized) into drivetrain vibration signals via second feature extractor and regressor. After optimizing hyperparameters, the training epochs was 150; the batch size was 64; and the learning rate was 0.0001. Performance evaluation of the OTPA model was segmented into constant speeds, acceleration, deceleration, and overall conditions.

The drivetrain fault diagnostic deep-learning model followed the same approach as described in the previous case study. Inputs were the frequency spectra of the converted drivetrain signals, with outputs categorizing into four classes: "normal," "faulty motor," "faulty reducer," and "faulty motor and reducer." After optimizing hyperparameters for the drivetrain fault diagnosis model, the training epochs were 50; the batch size was 64; and the learning rate was 0.0001. The EV drivetrain fault diagnosis model's performance was evaluated under interpolation and extrapolation conditions. In the interpolation condition, models were trained using datasets encompassing all three driving profiles (constant speeds, WOT, MTI), then tested on the same driving conditions. For extrapolation, models were trained exclusively on WOT datasets and tested on constant speeds and MTI datasets not used during training. A three-fold cross-validation was conducted for this case study.

Table 4. Performance evaluation of OTPA models in case of EV.

Transfer path	Driving speed profile	Mean absolute error (dB)		Correlation coefficient	
		Proposed method	SVD	Proposed method	SVD
From driver's seat to transition locations	Constant speed	5.58	6.17	0.77	0.73
	WOT	5.84	6.22	0.67	0.66
	MTI	5.81	6.31	0.70	0.67
	Average (=A)	5.67	6.21	0.74	0.70
From transition locations to drivetrains	Constant speed	5.47	10.25	0.70	0.37
	WOT	6.60	9.16	0.63	0.39
	MTI	6.24	9.89	0.64	0.31
	Average (=B)	5.80	10.02	0.68	0.36
From driver's seat to drivetrains	Total (= A + B)	11.47	16.23	1.42	1.06

4.2.3. Results

The performance of the proposed models was presented in **Error! Reference source not found.**. The proposed model showed the MAE of 11.47 dB and the sum of correlation coefficients of 1.42. The conventional SVD model showed the MAE value of 16.23 dB, significantly higher by 41.4% compared to the proposed model. The sum of correlation coefficients was 25.4% lower at 1.06 than the proposed model. This underscores the superior performance of the proposed model in the operational transfer path analysis.

Subsequent fault diagnosis using the synthesized signals was performed. The performance of the drivetrain fault diagnostic deep-learning model was divided into interpolation and extrapolation conditions for evaluation. The drivetrain fault diagnostic results for each input signal are summarized in Table 5. Interpolation performance showed nearly 100% diagnostic accuracy for both actual driver's seat and

drivetrain signals, and similarly high accuracy for signals synthesized via the proposed methods. However, the conventional SVD approach showed a slight decline to 95.60% accuracy when performing OTPA under varying operational and condition settings (multiple SVDs), and a significant decrease to 34.83% when a single model approach (single SVD) was applied across all conditions.

For extrapolation, the driver's seat signals exhibited a diagnostic accuracy of 90.38%, and drivetrain signals showed 99.32% accuracy. This indicates that the diagnostic model distinguishes drivetrain fault modes more effectively when drivetrain signals are inputted under new driving conditions than when driver's seat signals are used. Additionally, synthesized drivetrain signals, excluding the conventional SVD method, also demonstrated nearly 100% accuracy, similar to actual drivetrain signals. This indicates that the synthesized signals accurately reflect the fault characteristics of actual drivetrain signals, suggesting the effectiveness of the proposed method in accurately diagnosing faults in electric vehicle drivetrains under various operational conditions.

Table 5. Fault diagnostic performance evaluation.

Input	Accuracy (%)	
	Interpolation	Extrapolation
Actual signal measured at driver's seat	99.96	90.38
Actual signal measured at drivetrain	99.98	99.32
Synthesized signal by Single SVD	34.38	33.65
Synthesized signal by multiple SVDs	95.60	93.60
Synthesized signal by proposed method	99.92	99.31

5. CONCLUSION

This paper presented an approach based on Operational Transfer Path Analysis (OTPA) deep-learning modeling for diagnosing faults in rotating machines. The proposed method aimed to address two primary challenges: (1) the absence of vibration sensors at the excited source and transition locations in rotating machines, and (2) the reduction in signal sensitivity due to external noise interference when utilizing vibration signals measured at the receiver. Initially, the transfer paths between the noise generation point (source), transition locations, and the sensor acquisition point (receiver) were defined. Subsequently, a denoising deep-learning model was proposed based on the OTPA concept to capture the nonlinear relationships between the frequency spectra of the excited source, transition locations, and the receiver. To validate the effectiveness of the proposed approach, two case studies were conducted. The case study involving a hydraulic piston pump in construction vehicles demonstrated that the OTPA deep-learning model could convert noise signals into target point vibration signals, significantly reducing noise. At the SNR of -10 dB, the signal conversion accuracy, based on MAE values, indicated that the proposed approach exhibited approximately six times lower error and 50% higher fault diagnosis accuracy than conventional methods. In the case study using an operational electric vehicle, the signal conversion accuracy improved by 59% under various operational conditions compared to the conventional SVD method, and the fault diagnosis accuracy of the proposed approach improved by about 10% under new operational conditions compared to existing seat signal-based diagnostics.

The contributions of this research can be summarized in three key points. First, we proposed an approach that allows for the diagnosis of excited sources and transition locations in rotating machines without installed vibration sensors, using OTPA deep-learning model. Second, the proposed deep-learning model for OTPA demonstrated its capability to address nonlinearities occurring under various operational and fault conditions. Lastly, we introduced a deep learning model that effectively reduces the impact of external noise infiltrating during machine operation and amplifies the excited source's vibration signal.

ABSTRACT

Autonomous vehicles (AVs) are undergoing level 4 technology development and should have a system that can be operated without driver's intervention, so that it must be possible to diagnose failures and predict life cycle themselves. In this study, we propose a technology to estimate signal changes and sensor faults through transfer learning-based domain generalization (TLDG) using limited actual vehicle test information from LiDAR for autonomous vehicles. Because autonomous vehicles operate in various climate/weather conditions over the world, their mechanical, electrical and electronic components must also have stable performance in all environmental conditions. However, an electronic device, especially laser diode (LD), which is one of core components of LiDAR, shows various degradation aspects depending on environmental conditions. We acquired multivariate LiDAR performance data under various environmental conditions through an actual vehicle test driving of about 2,000 km in summer and winter, and based on this, we create the LiDAR fault diagnosis and performance prediction model generalized to the domain under various environmental conditions. Fault prediction and estimation model created through summer and winter data in the environment domain will also adapt to other environmental conditions such as spring and fall. To develop highly accurate performance estimation models under various environmental conditions based on limited data, it is very important to extract correlations and characteristics between data, including environmental conditions. We employ the data augmentation techniques to solve the problem of lack of training data and apply bi-directional Bayesian transfer learning to generalize data and models under uncertainty. To prove the effectiveness of the present study, the data from actual vehicle tests conducted at different temperatures will be divided into train data and test data, and the validity of the generalized degradation performance estimation model will be statistically validated. The proposed domain generalization method, i.e., TLDG can be utilized to estimate signal changes and sensor faults in LiDAR under unexperienced environmental conditions such as weather changes, and even freezing and hot regions.

1. INTRODUCTION

With the advancement of automobile technology, such as autonomous driving, the need for technology to diagnose and predict automobile failures is emerging. For example, there are AI-based vehicle big data analysis, pre-failure diagnosis and remaining life prediction of parts and systems, and predictive maintenance technology, and these technologies ultimately aim to improve vehicle safety and availability. In level 4 autonomous driving, there is no driver intervention, so the system must independently diagnose and predict failures to ensure safety. Real-time fault diagnosis of autonomous systems is being studied in a variety of ways using data-driven approaches.

AV sensors are composed of composite materials and various electronic elements. As a result, the performance of the sensor may vary depending on the weather environment, and abnormal operation of the sensor may occur under severe conditions (Zhao et al., 2023). Abnormality diagnosis is possible by detecting and scoring abnormal information from changes in sensor performance. Real-time fault diagnosis of autonomous driving systems is being studied in a variety of ways, mainly using edge artificial intelligence (edge AI) and data-based approaches (Gültekin et al., 2022). Research on anomaly detection based on statistical and classification techniques has been active (Ahmed et al., 2016), and recently, research on AI technique-based methods such as adversarial learned denoising shrinkage autoencoder (ALDSAE) has also

been actively conducted in the field of autonomous vehicles (Fang et al., 2023).

Failure prediction and evaluation using transfer learning-based domain generalization presents an innovative approach to solving key problems in the automotive industry and robotics fields (Xu et al., 2019). Domain generalization techniques frequently provide solutions to rotating machinery fault diagnosis problems. The initial approach developed and verified the model under conditions where both training and test data were available. Recently, a method has been proposed to generalize learned knowledge to a new target domain without assuming the availability of test data (Li et al., 2020). Additionally, a new approach called cross-domain augmentation diagnosis, which enables robust defect detection even when the target domain is unknown, is also being studied (Li et al, 2023). However, previous research addresses domain generalization and domain expansion techniques for signals with repetitive operating patterns, such as rotating devices. This is difficult to apply in problems considering multiple stresses because only limited parameters are covered when performing domain generalization. Because automobiles are used all over the world, all systems must operate in a variety of temperature environments. Therefore, when developing safety improvement technologies such as failure prediction, they must be trained or verified considering the distribution of various climate environments. However, due to the considerable time and financial investments required for collecting data through sensor performance measurements across various temperature environments, there are inevitable limitations to the available training and test datasets. Moreover, since sensor components comprise various electronic elements and composite materials, they demonstrate different operating characteristics upon temperature fluctuations. Consequently, there is the potential for poor performance when diagnosing faults based only on limited training data. This problem can be solved through transfer learning-based domain generalization technology, and in this study, we aim to solve the fault detection problem of LiDAR sensors by applying this technology.

In this study, we review the failure modes of LiDAR sensors and select target parameters necessary for failure diagnosis and prediction. The main contributions of the study are as follows:

- Through FMEA analysis of LiDAR defects, we investigate the causal relationship of LiDAR failures that may occur in the vehicle environment, and this allows us to present a practical and versatile model as it deals with hardware level defects by selecting key parameters.
- To solve the problem of accuracy degradation due to outliers encountered in domain generalization problems, we propose an Archimedes spiral-based preprocessing method based on the relationship between input and output data.
- The proposed method provides considerable diversity and flexibility by allowing sensor faults to be predicted with minimal information under diversifying environmental conditions, and the same method can be easily applied for other failure modes.

The rest of the paper is organized as follows. Section 2 gives a failure mode analysis to select key parameters for this study. Section 3 presents preprocessing techniques for outlier data, and Section 4 describes the domain generalization method. The experimentally study is shown in Chapter 5 and finally we conclude in Chapter 6.

2. FAILURE MODE ANALYSIS

LiDAR uses a laser light source to measure distance and recognize the surrounding environment and obstacles. It consists of various components such as laser diodes, thermoelectric elements, signal processing modules, optical lenses, and galvano scanners. In the driving environment, stresses such as heat, vibration, and electrical noise continuously occur, which can causes breakdowns of LiDAR sensors (Chang et al, 2023). The potential failure modes of frequency modulated continuous wave (FMCW) LiDAR are shown in Table 1. Thermal management of FMCW lidar sensors is directly related to sensor performance. When

Table 1. Failure mode analysis of AV LiDAR sensor

Components	Potential failure mode	Potential effects of failure	Potential factors of failure
Laser device	Decrease light intensity	Loss of distance information	High temp/humid., Thermal fatigue
	Fail to detect a returned signal	Increase in false detection	High humid, Vibration
	Fail to keep managed temp.	Non-operation of the sensor	High/Low temperature
Control board	Open circuit	Non-operation of the sensor	Thermal fatigue, Vibration
	Short circuit	Unintended operation	Ingress of dust and moisture
Lens	Fail to focal length	Increase in missed/ false detection	Thermal fatigue, Vibration
	Surface contamination	Increase in missed/false detection	Ingress of dust and moisture
Galvano-meter	Poor responsiveness of actuator	Decrease in sampling rate of scanning	Low temperature, Vibration
	Optical axis misalignment	Increase in missed/false detection	Thermal fatigue, Vibration

analyzing design vulnerabilities through accelerated stress testing, a failure mode in which the laser output of the LiDAR sensor was suddenly cut off under high temperature conditions was identified. This failure mode occurs when the ambient temperature of the laser diode module rises above approximately 75°C. Considering the climate environment of hot weather regions and the sensor self-heating, it can be classified as a failure mode that requires management because it is a condition that can be sufficiently exposed. The laser diode module uses a Peltier-based thermoelectric cooler (TEC) and controls voltage and current to enable the laser diode to maintain a constant temperature. However, when the ambient temperature exceeds a certain range, TEC control ability is lost, and thermal runaway of the laser diode module occurs.

3. OUTLIER DETECTION

In this paper, a study is conducted using the data of the multivariate database acquired through actual vehicle driving test. In the case of actual vehicle driving test data, outliers occur due to uncertainty factors such as road environmental conditions, equipment defects, and frequency errors. To create a robust model, these outliers must be selected and processed in advance and used for training.

As a study on outlier detection, a study has been conducted to propose a fast diagnostic method for internal short circuit (ISC) through local-gravitation outlier detection (Yuan et al, 2023). There is also research on the performance improvement of mechanical failure diagnosis based on audio signal analysis (MFDA) based on outlier detection (Tang et al, 2022).

We would like to propose a signal processing method through Archimedes spiral as a new outlier detection method. Using the following method, Archimedes spiral can be used to create a deep learning model that is generalized to the domain without overfitting. When Archimedes Spiral is expressed using a polar coordinate system, it can be expressed as Equations (1) using the real constant a, b and the angle θ. Changing the parameter b controls the distance between loops. Since we want to check that the output value changes for the input variable, we just need to check how the distance of the spiral changes at a specific angle set as the input variable. Here, when input data is x_{input} and output data is y_{output}, it can be expressed as Equation (2). Next, to solve the problem that is not visually clear by setting the starting point as the origin when drawing the spiral, the data was normalized between 2π and 4π at the start of the second spiral, as shown in Equation (3) and (4). When the data is sorted through this, data including the uncertainty factor appears as an area, and data processing based on the confidence interval is possible according to the data area.

$$r = a + b \cdot \theta \tag{1}$$

$$(r, \theta) = (x_{input} \cdot y_{output}, x_{input}) \tag{2}$$

$$x_{normalized} = \frac{x_{raw} - x_{min}}{x_{max} - x_{min}} \tag{3}$$

$$\begin{aligned} x_{input} &= 2\pi \cdot x_{normalized} + 2\pi \\ y_{output} &= 2\pi \cdot y_{normalized} + 2\pi \end{aligned} \tag{4}$$

As illustrated in Figure 1, if you enter the temperature data of LiDAR in x and the current TEC current to be estimated in y, normal data and outlier data are distinguished. In addition, it is possible to statistically process the outlier of the data through the confidence interval. Ultimately, we want to create a regression deep learning model through the data classified as normal and generalize it to the domain.

4. Transfer Learning-Based Domain Generalization

In this paper, we propose a transfer learning-based domain generalization method to overcome the limitations of data acquisition under various environmental conditions, including extreme conditions. It is known that transfer learning can improve predictive performance in terms of interpolation or extrapolation of the model by utilizing only a small amount of data from the target domain based on the model generated using the source domain (Weiss et al, 2016). However, domain generalization differs in predicting physical phenomena in the unseen domain region using improved models. We intend to gradually transfer a small amount of data to the target domain, use it to predict data in the new unseen area, and use it again as target data for transfer learning to generalize the domain. As illustrated in Figure 2, First, we created a regression model based on deep natural network (DNN) that predicts TEC current using temperature, humidity, current, and voltage data for the underlying source domain. Next, after importing the feature extraction area of the underlying source domain model to be untrainable, transfer learning was performed by adding new layers for transfer learning.

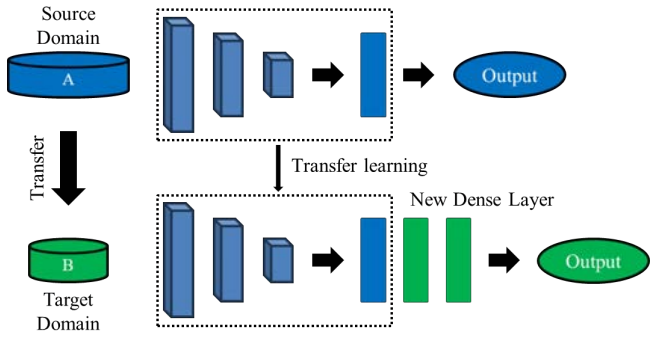

Figure 2. Architecture of transfer learning

5. Experimental Study

5.1. Datasets

In this paper, LiDAR data acquired through actual vehicle driving data in summer were used. Temperature, humidity, current, and voltage data were measured including TEC current of the Laser diode, and actual vehicle driving test data of more than 1000 km including city, country, and highway were acquired. The sensor used was the FMCW 4D LiDAR G-Series from Infoworks, and the internal and external temperatures of the sensor were measured using the SHT45-AD1B temperature sensor from Sensirion. Actual vehicle test data was obtained by installing the LiDAR on a Hyundai Azera and collecting TEC current and temperature data under actual driving conditions. Through this, 283,706 data points were acquired every 0.25 seconds. As illustrated in Figure 3, The left axis represents temperature, and the right axis represents TEC current. The environmental temperature is 28.96°C to 45.65°C, and in the case of TEC current, it may be confirmed that outlier exists. Among them, 268,402 data in which outliers were removed were selected through outlier detection based on Archimedes spiral. In addition, the ratio of training, validation, and test data was divided into 0.6, 0.2 and 0.2, and normalization was performed and used for training and model evaluation. For training, the temperature range of the training data and the temperature range of the test data were set by setting the scenarios of interpolation and extrapolation, respectively. And for transfer learning, 0.5% of the test data was arbitrarily extracted and set as data from the target domain.

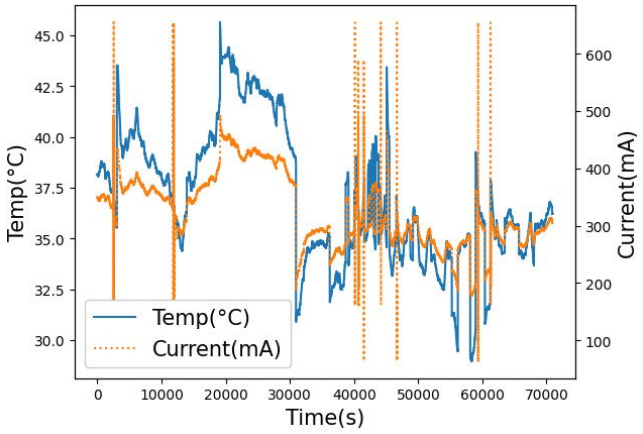

Figure 3. Actual driving test data for temperature (°C) and TEC current (mA)

5.2. Results

This paper proposes a method for predicting data based on outlier detection and transfer learning using actual driving data. All data were utilized in a state where outlier detection was conducted by Archimedes spiral. This method shows superior performance compared to other preprocessing techniques. Specifically, when comparing accuracy using methods interquartile range (IQR) and Hampel filter, the outlier detection performance was 3.23% for method IQR and 83.26% for method Hampel filter, while our proposed method demonstrated a performance of 100%. Before represents the result before performing transfer learning, and after represents the performance after transfer learning. First, looking at interpolation case 1, data from 35°C to 40°C were used as test data, and other data were used as training data. Although the error improved from 0.01 to 0.0009 based on mean absolute error (MAE), the r-squared of the DNN model was so good that the interpolation problem did not require transfer learning. This was also shown in the case of interpolation case 2. However, in the case of extrapolation, the performance error of the model before transfer learning is relatively large. However, if improvement is made through transfer learning, in case 3, it improved from 0.81 to 0.96 based on r-squared, and MAE also improved from 0.027 to

Table 2. Comparison table of transfer learning results

Scenarios	Case	Train data (°C)	Test data (°C)		R-squared	MAE
Interpolation	Case 1	28.96 ~ 35.00, 40.00 ~ 45.65	35.00 ~ 40.00	Before	0.98	0.010
				After	0.98	0.009
	Case 2	28.96 ~ 33.00, 43.00 ~ 45.65	33.00 ~ 43.00	Before	0.97	0.021
				After	0.99	0.011
Extrapolation	Case 3	28.96 ~ 40.00	40.00 ~ 45.65	Before	0.81	0.027
				After	0.96	0.010
	Case 4	28.96 ~ 35.00	35.00 ~ 45.65	Before	0.77	0.066
				After	0.99	0.014

0.010. Finally, in the case of case 4, which used only data up to 35°C as training data, it improved from 0.77 to 0.99 based on r-squared, and MAE also improved from 0.066 to 0.014. The results of case 4 are expressed visually through Figure 4. The prediction accuracy gradually decreases in the case of test data far from the area of the train data. However, after transfer learning, prediction accuracy has improved even in areas away from training data.

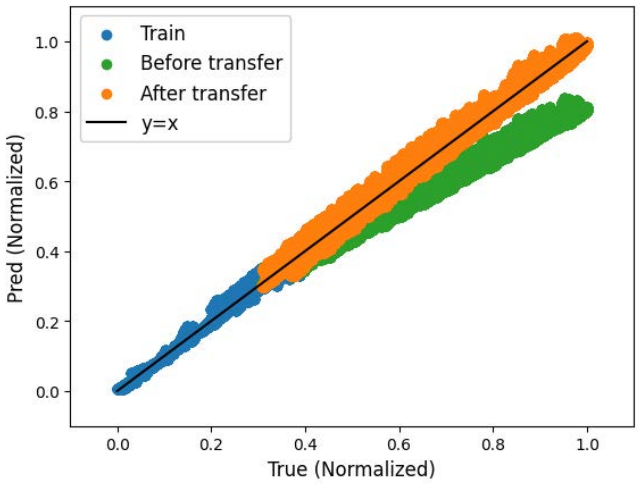

Figure 4. Extrapolation result for Case 4 in Table 2

6. Conclusion

In this paper, we propose a transfer learning-based domain generalization model for FMCW LiDAR signals that change with external temperature changes. This introduces a new approach to predicting LiDAR sensor errors by allowing sensor behavior to be predicted in unseen regions. LiDAR failure mode analysis justifies the selection of TEC current as a predictor and experimentally demonstrates the nature and validity of this signal. Real-world driving data often contains outliers due to various errors, and using Archimedes Spiral-based data preprocessing improves the prediction accuracy of the model. In the generalization task, temperature, humidity, current, and voltage data from the source domain were used, and transfer learning was performed using a DNN-based regression model and a new Dense Layer. The generalized model showed high accuracy and proved to be effective for extrapolation. Extensive training data covering a variety of climate conditions can further improve the accuracy of this model. The existing model was developed using only summer data, but future iterations will incorporate winter data to develop a domain generalized model that takes low-temperature environments into account. Through interpolation methods, it may be possible to predict sensor failure under all climatic conditions in Korea. Our goal is failure prediction under severe weather conditions. This is an extrapolation technique, and we plan to develop a domain-generalized model that can predict failures in hot areas like Phoenix or even in extreme cold areas like Minneapolis. This research could have important implications for diagnosing and predicting electronic component failures at the vehicle level and could be widely applied to other components as well.

BIOGRAPHIES

Sanghoon Lee received his B.S. and M.S. degrees in Automotive Engineering from Kookmin University, Seoul, South Korea, in 2008 and 2009, respectively. From 2009 to 2011, he worked as a research engineer at the Korea Institute of Science and Technology (KIST), Seoul, South Korea. Since 2011, he has worked at the Reliability and Certification Research Laboratory of the Korea Automotive Technology Institute (KATECH), Cheonan, South Korea, where he is currently a principal researcher. He is currently pursuing a Ph.D. in mechanical engineering from Yonsei University, Seoul, South Korea. His research interests include failure-based lifetime prediction and the health management of automotive systems.

Jaewook Lee received his B.S. degree in Mechanical Engineering from the Yonsei University, Seoul, South Korea in 2021. He is currently pursuing an Integrated M.S. and Ph.D. student in Mechanical Engineering at Yonsei University, Seoul, South Korea. His research interests are on the field of prognostics and health management (PHM), signal processing, deep learning-based data augmentation and knowledge transfer learning.

Jongsoo Lee received B.S. and M.S. in Mechanical Engineering at Yonsei University, Seoul, Korea in 1988 and 1990, respectively and Ph.D. in Mechanical Engineering at Rensselaer Polytechnic Institute, Troy, NY in 1996. After a research associate at Rensselaer Rotorcraft Technology Center, he has been a professor of Mechanical Engineering at Yonsei University since 1997. His research interests include multi-physics design optimization (MDO), reliability-based robust optimization, virtual product design and development, model-based system engineering (MBSE), prognostics and health management (PHM), and industrial artificial intelligence of data augmentation, transfer learning, domain adaptation, domain generalization and domain randomization with applications to structures, fatigue/durability, lifetime prediction, noise and vibration problems.

From Prediction to Prescription: Large Language Model Agent for Context-Aware Maintenance Decision Support

ABSTRACT

Predictive analytics with machine learning approaches has widely penetrated and shown great success in system health management over the decade. However, how to convert the prediction to an actionable plan for maintenance is still far from mature. This study investigates how to narrow the gap between predictive outcomes and prescriptive descriptions for system maintenance using an agentic approach based on the large language model (LLM). Additionally, with the retrieval-augmented generation (RAG) technique and tool usage capability, the LLM can be context-aware when making decisions in maintenance strategy proposals considering predictions from machine learning. In this way, the proposed method can push forward the boundary of current machine-learning methods from a predictor to an advisor for decision-making workload offload. For verification, a case study on linear actuator fault diagnosis is conducted with the GPT-4 model. The result demonstrates that the proposed method can perform fault detection without extra training or fine-tuning with comparable performance to baseline methods and deliver more informatic diagnosis analysis and suggestions. This research can shed light on the application of large language models in the construction of versatile and flexible artificial intelligence agents for maintenance tasks.

1. INTRODUCTION

Predictive analytics for product health management has attracted increasing attention from the industry with the rise of machine learning in the last decade. With the advent of advanced data processing and statistics methods, features and patterns of the system's running state can be captured from historical logs and sensor data. By doing this, potential system failure can be forecasted and allow people to outline the plan for maintenance or adjustment in advance of system deterioration. This can not only prolong the lifespan of the system but also lead to lower costs of periodic checking and overhauls in traditional preventive and reactive maintenance (Zonta et al., 2020).

Since the 2010s, deep learning that builds upon artificial neural networks (ANNs) played an essential role in predictive analytics and performed state-of-the-art results in many situations. Without tedious and complex feature engineering, deep learning can be effectively and efficiently applied to different data formats and draw relatively accurate predictions in an end-to-end way compared to other methods.

Even though the exciting breakthrough brought by deep learning for predictive maintenance, most of the research on this topic mainly focuses on boosting prediction metrics of the proposed methods such as precision or recalling rate, which provide limited information to the maintenance plan outlining (Roy et al., 2016). A higher prediction accuracy may indicate a more stable and reliable alarm in practical applications but does not necessarily suggest helpful decision support. It is practical and meaningful to know how to address an issue rather than merely anticipate it, especially in dealing with a complicated system containing numerous variables. Under this circumstance, predictions may only be treated as notifications and consequently ignored by human operators due to restricted proactive guidance. Thus, there is a strong call for extending machine learning beyond predictor to a more engaged advisor for action recommendation and insightful analysis (Matyas et al., 2017).

The mentioned main issue cannot be overcome by pure data-driven approaches based on statistics and algorithms since data collected from sensors only represent low-level signal patterns that are hard to analyze by human beings. Thus, it is difficult to form useful and helpful advice or guidance for decision-making (Sapna et al., 2019). To address this challenge, knowledge of contextual information is required to elaborate the prediction results into high-level representations such as natural language or graph-structured data so that human beings can view them straightforwardly. Hence, the industry calls for a more advanced agent system that can generate human-understandable descriptions for reviewing and validation based on detected faults.

The critical gap lies in the missing link between sources on the low-level data side and the high-level knowledge side.

In the last five years, there has been dramatic progress in the natural language process (NLP) because of the occurrence of large language models (LLMs). By pretraining a very deep neural network with billions of parameters on an extensive textual corpus, the LLMs can be multi-task learners with impressive performances on a wide range of tasks including article summarization, multilingual translation, and text generation. More importantly, recent research indicates the emergent capability of the LLMs for multi-step reasoning to accomplish more complex tasks without much human supervision and hardcore programming (Bommasani et al., 2021).

This exciting phenomenon indicates a solution to the mentioned challenge that the link can be regarded as a step-by-step transformation workflow starting from data to knowledge using LLMs with proper prompts. A basic idea is to allow LLMs to be aware of the fault in the system at first, and then parse relevant search queries related to the predicted fault for knowledge retrieval in the database. The obtained search results can then be combined and summarized as a document for action recommendation. In this way, the LLM is an information fusion unit to elaborate predictions with information from different databases for decision support.

According to this motivation, in this research, GPT-4, a popular large language model released by OpenAI (OpenAI et al., 2023), is applied to implement the above idea. The agent is built upon a fault classification model and external knowledge databases for the retrieval-augmented generation of the system maintenance support documentation. In addition, a use case on linear actuator fault diagnosis will be conducted for proof-of-concept verification. In summary, the contribution of the paper can be summarized as:

Develop an agent for linking prediction results with the knowledge base to generate descriptions for maintenance decision-support based on the large language model.

The remaining of the paper is organized in the following structure. In section two, some related work of this research will be presented for a preliminary introduction to the critical concept used in the proposed method. In section three, the system diagram and the framework will be illustrated in detail including the principles and workflow of the method. Then, there is a use case for linear actuator fault diagnosis will be conducted and experiments will be carried out to first show the effectiveness of methods for fault detection without extra training and fine-tuning. After that, another experiment will show how the LLMs can output a more context-related conclusion for a more satisfactory decision support delivery based on predictions.

2. RELATED WORK

2.1. Random Convolution Kernel Transformation (ROCKET) for Time Series Classification

For system state monitoring, multiple sensors will be installed on an asset to record a series of time-ordered data points during the system running. The collected time series will vary when the equipment works under different conditions, conversely, the time sequence data can represent in what situation the system is working and suggest what potential fault will probably be. To build the relationship between the time sequence with the corresponding system state, a classifier is the most effective way to implement, and this task is called Time Series Classification (TSC). It is one of the basic and essential time series mining that aims to assign unseen samples with labels in the training data by pattern exploitation. With TSC, a real-time collected time series can be categorized into states for a quick diagnosis. Therefore, the TSC is vital and commonly blind tightly to the industrial Internet of Things (IoT) for automatic system fault detection.

However, it is a challenge to apply conventional statistical or machine learning methods for the TSC. The main reason is the continuity property of the sequence of observable data points along time. Unlike textual data, which can be discretized by a set of sub-words (tokens) for processing, it is difficult to figure out the proper segmentation and transformation of the given time series for dimensionality reduction. This will cause an issue called the ‘curse of dimensionality’ and the model will be hard to recognize and capture discriminative features in the data for categorization.

There are fruitful results in TSC (Faouzi, n.d., 2022). Baseline methods such as K-nearest neighbors (KNN) classification with dynamic time warping (DTW), the bag-of-pattern method (BoP), and the remarkable ensemble classifier HIVE-COTE are proposed for this purpose, but they suffer from heavy computation and memory usage. Approaches based on deep learning such as recurrent neural network (RNN), InceptionTime (Fawaz et al., 2019), and relatively new Transformer-based models (Nie et al., 2022) are becoming popular. Although these methods boosted the accuracy and are able to generalize to different datasets compared to traditional machine learning, the model has to be trained to optimize parameters for inference which are either time-consuming or resource-intensive. Even worse, all the deep learning methods require retraining when samples are out of training data leading to a low extendibility in industrial applications.

To address these challenges, random convolution kernel transformation, short for ROCKET, was proposed to transform the time series into a vector representation using a random convolution kernel for classification (Dempster et al., 2019). Unlike conventional convolutional neural networks (CNN), parameters in the ROCKET are generated randomly and require no optimization or fine-tuning during the data transformation. Without an iterative learning process, the

ROCKET is efficient in computation and can adapt to different time sequences. Also, the ROCKET combined with traditional classification models such as the 1-NN classifier, support vector machine (SVM), and ridge classifier can achieve or even exceed state-of-the-art TSC algorithms with lightweight computation in an endurable timespan.

Therefore, considering the computational efficiency, extendibility, and performance, the ROCKET will be applied as the method for time series processing in this project. Using ROCKET as an encoder for the time series classification, the vectorization result will be processed and recognized by the LLMs to outline the prescription.

2.2. Retrieval-Augmented Generation (RAG)

Research on the application of LLMs in various workflow automation is conducted to unleash the power of LLM's human-like logical reasoning and inference capability. However, one of the main challenges comes in the *hallucination issue* of the LLMs. It means that the fake or incorrect information will be generated by LLMs. This can cause failure in task performance and may hurt the trustworthy between humans and the LLMs when they are in cooperation (Huang et al., 2023).

An effective approach for alleviating the hallucinating issue is to enable the LLMs to generate their responses based on some factual evidence from other existing sources such as the internet or knowledge databases. According to the retrieved information, the LLMs can follow the requirements and instructions given in the prompt to compile information that is rooted in ground truth and users' demands. It combines the searching techniques and the generation ability of LLMs to offer reliable and user-friendly information to people. This concept is defined as retrieval-augmented generation (RAG). The RAG has successfully been used in text, image, and multimodality searching and generation, but the application in the time series analysis on industrial sensor networks is yet fully explored. This piece of research is an initial exploration of applying the same idea for time series classification and allowing the LLM can generate the document based on the prediction to mitigate the hallucinations. In this research, the RAG will be the main methodology for retrieving historical time series samples to label the newly arrived data as a prediction outcome. The fault analysis can then be generated based on the retrieved result by the LLM.

2.3. Prompting Engineering, Chaining, and LLMs Agent

To obtain desirable outcomes from the LLMs, it is crucial to craft proper instructions for model commanding, and this concept is referred to as prompt engineering. Depending on the emergent capability, the LLMs can generate responses following descriptions in the prompts, and this is an effective way to alleviate the hallucination issue. Despite the usefulness, it is also cumbersome to tune the proper prompt to get satisfactory outcomes in a trial-and-error way.

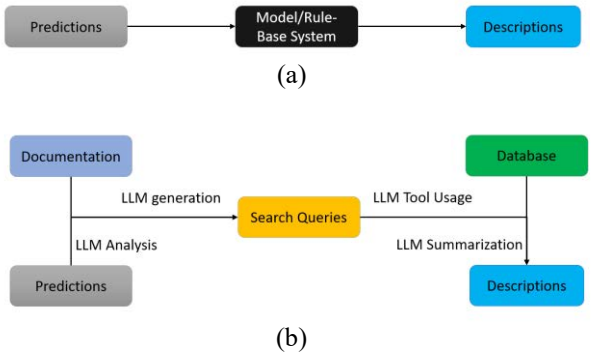

Figure 1. Different methods to convert predictions to descriptions (a). End-to-end generation (b). Multi-step transformation with the LLM

Instead of composing zero-shot prompts fully manually for LLMs to arrive at solutions immediately, (Wei et al., 2022) proposed chain-of-thought prompting that breaks down complex tasks into sequential sub-tasks and encourages the LLMs to figure out answers to each problem. By doing this, the LLMs can enhance their ability to successfully carry out intricate tasks such as math reasoning and arithmetic computations. In addition, (Yao et al., 2022) developed the ReAct prompting to enable LLMs to incorporate external tools usage and observation results obtained after tools leverage into their reasoning activity. The experiment indicated an apparent improvement in performance for LLMs on interactive text-based games and online shopping tasks as compared to traditional imitation learning or reinforcement learning approaches.

Furthermore, multiple prompts for different purposes can be serialized into a chain for workflow automation. Building on this advantage, the concept of the LLM agent, or AI agent, emerges to facilitate more functional applications of LLMs across diverse domains. The fundamental principle is to treat the LLMs as a connector or a controller among toolsets including databases, calculators, and web browsers to produce a series of actions based on their logical reasoning. In each step, LLMs can yield more reliable intermediary results and merge findings from prior stages to aggregate a more solid outcome in the final. Moreover, users can monitor the problem-solving process and understand the rationale provided by the agent, offering an opportunity for human intervention via a natural language interaction. Preliminary successful implementations of the LLMs agent in various fields are illustrated in (Xi et al., 2023).

3. Design of the Context-Awareness Agent

3.1. Initial Analysis

To compile a report of fault diagnosis with fault type, fault description, and potential recovery or maintenance strategies,

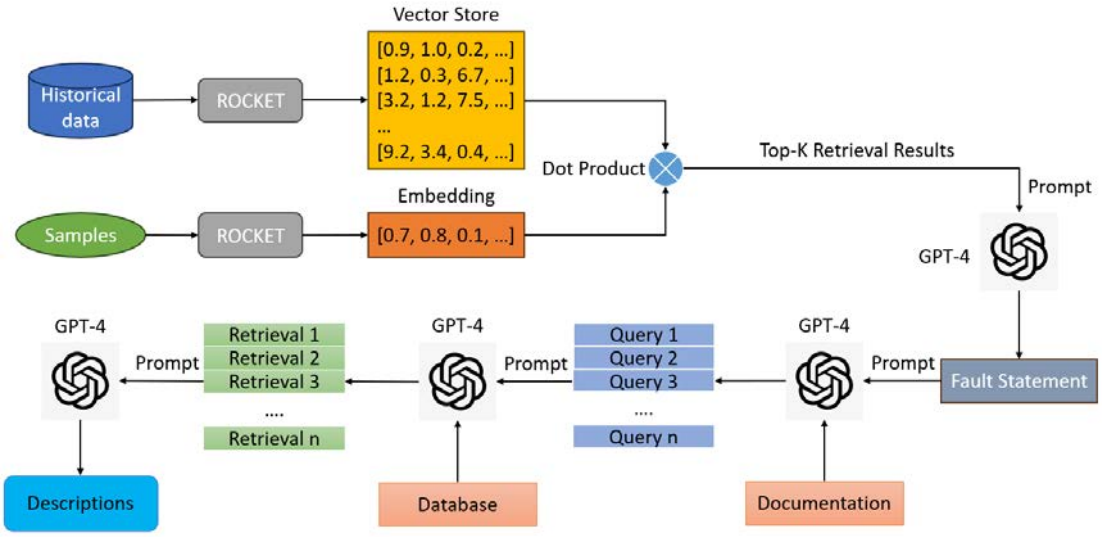

Figure 2. The diagram of the agent system

a direct way, as shown in Figure 1. (a), is to define a rule-based system that allows the prediction to go through and route to a corresponding solution. Or to craft a dataset of prediction-solution pairs to train a model for transformation. However, defining rules and collecting datasets manually are human-labor intensive and time-consuming. Also, the predefined rule-based system or model is hard to update and extend to unseen situations. From this perspective, end-to-end generation may be friendly in the development stage but may be challenging to maintain when the model or the system has been deployed in the production environment in industrial environments due to low adaptability to a dynamically evolving situation.

Another way to consider this problem is to divide the transformation into a series of steps with the LLM, external database, and tools (usually a bunch of calling Application Programming Interface), as shown in Figure 1. (b). After receiving the prediction from the data processing step, LLM will be asked to recognize the fault based on the prediction result and try to reason about what problem should be solved based on providing the contextual background described in the documentation. The generated search queries will then be thrown to a database by LLM's tools calling capabilities to retrieve relevant information on repairing suggestions. Finally, the LLM can be instructed to summarize all information into a report for human beings to review.

In this way, the workflow can be independent of a fixed set of rules and ensure contextual information is involved in the final description generation. In each step, human operators can track and offer comments or feedback to inject their expertise into the agent by providing prompting to get a more comprehensive result. The essential idea of the proposed method is *the multi-step generations based on factual evidence*, which is the core idea of the RAG. In the following section, the details of the agent system will be illustrated.

3.2. Overview of the Agent System

The diagram of the agent system is illustrated in Figure 2. A set of historical data will be transformed into a set of vectors and stored in memory for comparison. The method for sample vectorization is the ROCKET as introduced in the above section. In detail, several randomly generated convolution operators will slide the input time series to conduct dot product computation. In mathematics, according to the paper (Dempster et al., 2019), the outcome from implementing a kernel, w, with dilution, d, and bias b, on a specific set of time series X from position i in X_i is presented as follows:

$$X_i * w = \left(\sum_{j=0}^{l_{kernel}-1} X_{i+(j\times d)} \times w_j\right) + b \quad (1)$$

A feature map M will be obtained from the kernel computation, and two real values will be extracted as features for each kernel including the *maximum values* and the *proportion of positive values* (*ppv*) in the M by the following formula:

$$ppv(M) = \frac{1}{n}\sum_{0}^{n-1}[m_i > 0] \quad (2)$$

Where m_i is the numerical value in the feature map. Therefore, there will be two features produced per kernel operation, and for an effective time series representation, 10000 kernels are used to transform the data leading to 20000 features to represent each time series. The ROCKET algorithm is applied to all samples in the historical database which will be stored for retrieval. Since there is no parameter optimization and fine-tuning during the data processing, the computational efficiency can be extremely fast compared to

deep learning or other statistical methodologies. Therefore, the requirement on hardware configuration is much lower enabling a constant vectorization of new samples as experience accumulation.
